THE PHYSICAL REVIEW

ATMOSPHERIC IONIZATION BY COSMIC RADIATION*

By E. O. HULBURT

NAVAL RESEARCH LABORATORY

(Received November 22, 1930)

ABSTRACT

From Millikan's measurements of the intensity and the absorption coefficients of cosmic radiation the ionization in the atmosphere is calculated from sea level to 60 km. The electron density is negligibly small in this region. The ion density increases with the height to 3.5×10^3 ion pairs cm^{-3} at about 50 km and is roughly constant above this to 60 or 70 km where the solar ultraviolet light ionization sets in. The 50 km ion bank refracts appreciably radio waves longer than 12 km and being unchanged with the day and night accounts for the propagation of waves longer than 12 km, which are known to show no marked diurnal variations. The agreement with the facts of long radio waves indicates that there exists in the high atmosphere but little cosmic radiation of less penetration than Millikan has already detected.

By considering the effect of the earth's magnetic field on high speed electrons the "run away" electron hypothesis of C. T. R. Wilson to account for cosmic radiation is shown to lead to a distribution most intense at low latitudes and feeble at high latitudes, thereby being in disagreement with Millikan's observation of the constancy of the cosmic radiation with latitude.

1. It is pretty generally accepted, as a result of the work of Hess, Bauer, Swann, Mauchly, Millikan and others,¹ that the ionization in the lower atmosphere is caused primarily by a penetrating radiation of cosmic origin. Over the land in the levels of the atmosphere below about 2 km the radiation from radio-active materials in the earth may cause an appreciable part, as much as a half or more, of the ionization. But from levels above 2 km over the land, and from about sea level upward over the sea, up to the limit of direct observation² at about 15 km, the measurements support the view that the ionization is caused by a cosmic radiation coming in from all directions and absorbed exponentially in its passage through the atmosphere.^{2,3} In the present paper the ionization due to cosmic radiation is calculated from sea level to about 70 km, where the Kennelly-Heaviside layer begins, and is

found to agree with certain facts of the propagation of long wireless waves. A calculation of the ionization by cosmic radiation was made by Benndorf.⁴ The more recent observations of cosmic radiation were of course not available to him and he did not consider such actions as the attachment of electrons to oxygen molecules, etc.; the present calculation which includes these factors is thought to be more nearly correct. In section 6 it is shown that the "run away" electron hypothesis of C. T. R. Wilson is inadequate to account for the observed facts of cosmic radiation.

2. THE RATE OF PRODUCTIONS OF IONS IN THE ATMOSPHERE BY COSMIC RADIATION

The second column of Table I gives the values of n , the total number of molecules and atoms cm^{-3} , assuming no hydrogen in the atmosphere, for various heights z above sea level. The values of n are from Maris' tables⁵ for winter day conditions in temperate latitudes. From $z=0$ to 100 km n is given, within an approximation sufficiently good for the present calculations, by

$$n = n_0 e^{-pz}, \quad (1)$$

where n_0 is the value of n at sea level and $p = 1.38 \times 10^{-6}$ for z in cm. Since the curve of $\log n$ against z is not exactly a straight line p varies a little with z ; for z from 100 to 300 km the average value of p is 1.21×10^{-6} , a value used in a former paper.⁶ For summer night conditions n is much the same as the values of Table I, for summer day and winter night conditions n is slightly different. We are content, however, to use the winter day values to represent a rough average condition of the atmosphere.

TABLE I.

1 z	2 n	3 q'	4 q	5 I	6 Temp.	7 α	8 y

Millikan, Bowen, Otis and Cameron^{2,3}, by sending up apparatus in balloons, made direct observations of the ionization due to cosmic radiation up to a height of about 15 km. They calculated² the absorption coefficient μ and the values of q' from sea level to 20 km and at the "top" of the at-

⁴ Benndorf, Phys. Zeits. 27, 686 (1926), see also Pederson, "The Propagation of Radio Waves," page 62 (1927).

⁵ Maris, Terr. Mag. and Atmos. Elec. 33, 233 (1928); 34, 45 (1929).

⁶ Hulburt, Phys. Rev. 31, 1018 (1928).

mosphere, using the Gold⁷ tables for the case of radiation entering the atmosphere equally distributed in all directions above the horizontal plane. They found that the radiation became softer, i.e., less penetrating, as z increased, the average absorption coefficient μ per meter of water from $z=0$ to 0.9 km being 0.23 and for z greater than 0.9 km being 0.25. q' is the number $\text{cm}^{-3} \text{sec}^{-1}$ of ion pairs which would be produced by the cosmic radiation in 1 cm^3 of air at sea level pressure placed at various heights in the atmosphere. The values of q' given in column 3, Table I, are taken from their Table IV, ref. 2.

In dealing with the atmosphere it is more convenient to use q instead of q' , where q is the number of ion pairs $\text{cm}^{-3} \text{sec}^{-1}$ produced in the atmosphere by the cosmic radiation. Then

$$q = q'n/n_0. \quad (2)$$

The values of q calculated from q' for $z=0$ to 20 km are given in column 4, Table I. With $\mu=0.25$ per meter of water the molecular absorption coefficient β of atmospheric molecules, taken to be four parts nitrogen to one part oxygen, is 1.20×10^{-25} , on the assumption that β is proportional to the mass of the absorbing layer. β is defined in the usual way by

$$dI = -I\beta ndz, \quad (3)$$

where dI is the reduction in the intensity of radiation $I \text{ erg cm}^{-2} \text{sec}^{-1}$ in passing through a thickness $dz \text{ cm}$ of n atmospheric molecules cm^{-3} . Assuming that all of the absorbed energy goes into producing ions,

$$q = I\beta n/w, \quad (4)$$

where w is the work of ionization of the atmospheric particles. For oxygen and nitrogen atoms w is 2.15×10^{-11} and $2.32 \times 10^{-11} \text{ erg}$, corresponding to ionization potentials 13.48 and 14.56 volts, respectively, and a little more for the molecules. With (4) I was calculated directly from the known values of q for $z=0, 10$ and 20 km and was continued into the higher levels by means of the Gold table.⁷ The values of I are in column 5, Table I. From I and (4) q was calculated for the levels above 20 km , column 4, Table I. The extrapolation into the high levels assumed that β was constant throughout the region from $z=20$ to 60 km , i.e., that there exists no cosmic radiation of μ greater than 0.25. The evidence from wireless waves, section 5, indicates that this assumption is probably not much in error.

The total rate of production of electrons and positive ions by cosmic radiation in a 1 cm^2 column of the atmosphere from 60 km to interplanetary space is $\int_{60}^{\infty} q dz = 1.54 \times 10^{-2} / 1.21 \times 10^{-6} = 1.28 \times 10^4$. This is much less than the production of ionization by the ultraviolet light of the sun, which amounts to 2×10^8 electrons and positive ions sec^{-1} in a 1 cm^2 vertical column above 180 km and many more below this level.^{6,8} It is concluded that the

⁷ Gold, Proc. Roy. Soc. **82**, 43 (1909).

⁸ Hulburt, Phys. Rev. **34**, 1167 (1929).

ionization caused by cosmic radiation in levels above 60 km is inappreciable compared to that produced by solar ultraviolet light in all latitudes at all hours of the day and night.

3. THE IONS AND ELECTRONS IN THE ATMOSPHERE CAUSED BY COSMIC RADIATION

It is assumed that the cosmic radiation ionizes the air molecules and atoms to produce electrons and positive ions. The electron density y_e , assuming the loss of electrons arises only from recombination with positive ions and attachment to neutral oxygen molecules, is given by the steady state equation

$$q = \alpha_e n y_e^2 + b n' y_e, \quad (5)$$

where α_e is the J. J. Thomson⁹ recombination coefficient for electrons and positive ions and b is the coefficient of attachment of electrons to oxygen molecules.⁶ n' is the density of oxygen molecules. For $z=0$ $\alpha_e = 0.52 \times 10^{-23}$, $b = 8.3 \times 10^{-14}$ and putting $q = 1.4$ into (5) gives $y_e = 3 \times 10^{-6}$. y_e increases with z , but even at $z = 60$ km y_e is only of order 10^{-3} . Therefore the electron density in these levels due to the ionizing action of cosmic rays is very small, being much less than 1 electron cm^{-3} . Further, the loss of electrons by attachment to oxygen molecules exceeds by several orders of magnitude the loss by recombination with positive ions. For example at $z=0$ $b n' y_e = 1.4$ and $\alpha_e n y_e^2 = 1.3 \times 10^{-15}$, and at 60 km are equal to 1.5×10^{-2} and 10^{-13} , respectively. Therefore the electrons do not remain free very long but become attached to oxygen molecules almost as fast as they are formed. We may then take the values of q of column 4, Table I, to be the rates of production of ion pairs and calculate the ion densities which exist in a steady state.

For this case y , the number of ion pairs cm^{-3} , is given by

$$q = \alpha n y^2, \quad (6)$$

where α is the recombination coefficient of positive and negative ions.⁹ α is a function of the temperature and the molecular density n for n greater than 10^{18} ; the values of the winter day temperatures and of α are given in columns 6 and 7, Table I. The values of y calculated from (6) are given in column 8, Table I, and are plotted as abscissas against z as ordinate in Fig. 1. The values of y for winter night and for summer day and night are the same as those of Fig. 1 within 40%. The ion curve of Fig. 1 was obtained omitting diffusion. This is justifiable, for from Eq. (5), ref. 6, the rate of increase of ions due to diffusion is small compared to q for levels below 80 km. Winds would not be expected to disturb the curve very much. With the values of q of column (4), Table I, it takes roughly 10, 34 and 196 minutes to build up the steady state values of y at $z=0$, 30 and 40 km, respectively. Therefore the air must move upwards or downwards with velocities of the order of kilometers per minute in order to change the ion curve. Such movements seem improbable under ordinary circumstances.

⁹ Thomson, Phil. Mag. 47, 337 (1924); see also ref. 6 and 8 for a discussion of these coefficients.

4. AGREEMENT WITH OBSERVATION

The value 825 ion pairs at sea level of Table I agrees with observation during fine weather, although, to be sure, we can not regard the present calculation, which omits such well-known effects in the lower atmosphere as water vapor, dust, ion clustering, ionization due to the splashing of waves, etc., as being a very complete statement of sea level conditions.

The ion layer of Fig. 1 will not cause appreciable absorption of wireless waves, even for those as long as 100 km. It will, however, refract long waves. The shortest wave, denoted by λ_s , ref. 6, which will be turned back to the earth is 11 km in length, and this only when incident on the layer at as near grazing incidence as possible, in which case the rays leave the earth tangentially (Eq. (26), ref. 6). Waves shorter than 11 km will pierce through the cosmic ion layer at 50 km to be refracted in the higher lying ionization

Fig. 1. Density γ of ions pairs in the atmosphere caused by cosmic radiation.

above 70 km caused by the solar ultraviolet light. As the wave-length increases beyond 11 km the wave is refracted downward at decreasing angles of incidence on the 50 km layer, until a 90 km wave is returned at normal incidence. All waves longer than this will be returned at all angles of incidence. Thus we should expect low angled rays of wave-length greater than, say, 12 km to be refracted downward by the cosmic ion layer and that the long distance propagation of these wave-lengths should be governed by the layer. Since the cosmic rays are fairly uniformly distributed in direction, their ionization is constant throughout the day and night and therefore communication with waves longer than 12 km should experience no diurnal or seasonal changes. This conclusion is in good accord with observation, it being well known that wireless waves 10 km and less in length exhibit diurnal and seasonal variations and that those of length 15 km and greater show no such variations.

The foregoing agreement with the facts of long wireless waves sets an upper limit to the amount of cosmic radiation of absorption coefficient somewhat greater than $\mu = 0.25$ which can be entering the earth's atmosphere. Roughly one may say that the intensity of such radiation can not be as great as $1 \times 10^{-4} \text{ cm}^{-2} \text{ sec}^{-1}$. For example, suppose that a less penetrating radiation existed for which $I = 10^{-4} \text{ erg cm}^{-2} \text{ sec}^{-1}$ outside of the atmosphere and $\mu = 2.5$ per meter of water or $\beta = 1.2 \times 10^{-24}$. Its ionization in levels below 10 km would be too small to detect, but in levels above 40 km it, together with the ionization of Table I, would give $y = 1.2 \times 10^4$. λ_s would be 7 km instead of 12 km, which would be contrary to the observation that λ_s is between 10 and 15 km.

Finally, Hollingsworth¹⁰ interpreted his experiments on interference effects of 15 km radio waves to indicate that the waves reached an effective height of 70 km, although Eckersley¹⁰ thought that the experiments accorded better with a height of about 50 km in agreement with some results of his own.¹¹ These heights would agree with the curve of Fig. 1 which gives a real height of 40 to 50 km and an effective height of 50 to 70 km, the exact value depending upon the angle of incidence of the wireless ray.

5. THE NATURE OF COSMIC RADIATION

The measurements of Millikan in California, Bolivia, Canada, etc., covering magnetic latitudes from about 0 to 78°, showed that the intensity of the cosmic radiation was the same in all these places within 1%, so that at the present time the conclusion is that the intensity is constant over the earth.* Recently Epstein¹² calculated that high speed electrons from an external source impinging on the earth would be diverted by the earth's magnetic field into high latitudes; electrons of 10^9 volt energy could not hit the earth at magnetic latitudes below 58°, and of 2×10^9 volt energy below 50°. He concluded that in order to satisfy Millikan's observation of the uniform intensity of the cosmic rays over the earth the rays might be, (a) electromagnetic rays of cosmic origin, (b) corpuscular rays of higher energy than 10^9 volt, at least 6×10^{10} volt, of cosmic origin, (c) corpuscular rays of terrestrial origin. In later paragraphs we show that (c) is improbable.

We may add a remark about Epstein's conclusions. If the earth were the target of hypothetical high speed electrons of external origin, the earth would accumulate a negative charge. A charge of 7.1×10^5 coulombs would keep 10^9 volt electrons from reaching the earth; if some manner of escape of negative electricity from the earth were postulated the accumulated charge would be less. A negative charge on the earth does not disturb Epstein's analysis. To a fair approximation the electric field due to the charge would merely retard the incoming electrons, so that the 10^9 volt

¹⁰ Hollingsworth, Jr. *Inst. Elec. Eng.* **64**, 579 (1926).

¹² Epstein, *Proc. Nat. Acad.* **16**, 658 (1930).

electrons instead of hitting the earth in latitudes above 58° would be restricted to a region of still higher latitude.

According to C. T. R. Wilson,¹³ in his experiments and theory of the electric field in thunder clouds, differences of potential of 10^9 volt may exist between the upper and lower portions of a thundercloud, the electric field in the cloud being downward. For a cloud 1 km thick this meant a field of 10^4 volt cm^{-1} . Since the sparking potential of dry air is around 2×10^4 volt cm^{-1} , and since thunder clouds greater than 3 km in thickness are not frequent, it is probable that the total potential difference in thunder clouds would rarely exceed 5×10^9 volt. Electrons accelerated in such a field might soon move so fast that they would experience no collisions and might finally acquire nearly the full energy of the field. They would be "run away" electrons, as he called them, and would constitute a penetrating radiation. Wilson¹⁴ recently has suggested that run away electrons sprayed upward would describe helical paths of large radius around the lines of magnetic force and would enter the lower atmosphere at widely separated parts of the earth. This is case (c) of an earlier paragraph.

In order to examine Wilson's suggestion we use the same equations which Epstein¹⁵ employed in his calculation. The radius of curvature ρ of the path of an electron moving normally to a uniform magnetic field of strength H is

$$\rho = mv/He(1 - v^2/c^2)^{1/2}, \quad (7)$$

where m , e and v are the rest-mass, charge and velocity of the electron, respectively, and c is the velocity of light. All quantities are in c.g.s. electromagnetic units. The energy¹⁵ acquired by the electron in falling through a potential V is

$$Ve = mc^2(1/(1 - v^2/c^2)^{1/2} - 1). \quad (8)$$

Since v is nearly equal to c in the present problem $1/(1 - v^2/c^2)^{1/2}$ is very large compared to unity and -1 may be neglected in (8). With this approximation we have from (7) and (8)

$$\rho = V/He. \quad (9)$$

These equations are strictly valid only for slowly varying velocities. However, it may be stated without giving the calculation that the classical radiation term makes a negligible correction and may be omitted.

With $V = 5 \times 10^9$ volts, probably a maximum value, $v = c(1 - 5.2 \times 10^{-9})$, and with $H = 0.5$ gauss, as at 50° magnetic latitude, ρ is 333 km. At the equator $H = 0.3$ gauss, ρ is 520 km and the electron moves westward in approximately a circle of radius 520 km. Thus, keeping in mind the fact that $1/H$ and hence ρ is proportional to r^2 , where r is the distance to the center of the earth, in tropical latitudes below $\pm 20^\circ$ where H is approximately horizontal the 5×10^9 volt field, mainly vertical, of the thunder cloud sprays

¹³ Wilson, see Glazebrook, "Dict. of Applied Physics" 3, 84 (1923).

¹⁵ See Born, "Mechanics of the Atom" (1927).

the run away electrons over a region not greater than about 1000 km square to the westward.

For thunderclouds in high latitudes the electron spray is more spread out. It is difficult to calculate the distribution of the spray exactly, but an approximate idea of the distribution may be obtained. In general a thundercloud in the northern hemisphere can not spray its electrons northward, or one in the southern hemisphere southward. A northern thundercloud can, however, project its electrons southward. The magnetic line of force which touches the earth at magnetic latitude 50° rises to a maximum height of 9100 km above sea level at the magnetic equator. At this height the maximum value of ρ for the 5×10^9 volt electron is about 13,000 km, and by following out the warped helical path of the electron it is found that the electron descends to the earth in latitudes below 50° , swinging always to the westward. Therefore thunder clouds in latitude 50° spray their electrons into areas between the 50° magnetic parallels north and south, those in latitude 40° between the 40° parallels, etc., and the nearer the cloud is to the equator the more local is its run away electron spray.

Electrons ejected by 5×10^9 volt thunder clouds in higher latitudes than 50° start out approximately along the line of magnetic force and, since ρ becomes greater than r , leave the earth never to return; or at least they do so until sufficient positive charge has accumulated on the earth, 3.56×10^6 coulombs, to prevent the escape of any more electrons. After this has happened the high altitude electrons return to the earth mainly in high latitudes but it is difficult to say exactly where they will strike. However, there are relatively few thunderstorms above 50° compared to the number in lower latitudes,¹⁶ and their electron spray will be relatively unimportant. Therefore it is concluded that the run away electron hypothesis would lead to a penetrating radiation which is most intense at low latitudes and which becomes feeble in the high latitudes. This disagrees with Millikan's observations of the constancy of the cosmic radiation with latitude. It would seem that of the various suggestions as to the nature of the cosmic rays only two are left, the rays are electromagnetic rays of cosmic origin or are very high speed electrons of cosmic origin. If the second possibility is considered the question of the charge which would accumulate on the earth must be faced.

X-RAY DIFFRACTION IN WATER: THE NATURE
OF MOLECULAR ASSOCIATION

BY G. W. STEWART

DEPARTMENT OF PHYSICS, UNIVERSITY OF IOWA

(Received November 24, 1930)

ABSTRACT

The x-ray diffraction intensity-angle distribution for water and its variation for a temperature of 2° to 98° C, are given. Two important periodicities of 3.24 and 2.11 Å and a third of 1.13 Å at 21°C are established in satisfactory agreement with Meyer. The first one *decreases* with increasing temperature and the second *increases*.

It is shown that the conception of molecular complexes explains neither the existence of these periodicities nor their change with temperature. In fact, the description of "association" that involves complexes of two or three or more molecules, should be abandoned in favor of the molecular group conception, (cybotactic condition) emphasized by the author. These groups of molecules containing hundreds and perhaps thousands of molecules in each, have a temporary existence as individuals, have ill-defined boundaries, possess an optimum size and an internal regularity determined by the temperature and molecular forces, and expand anisotropically. The experimental facts are in agreement with this view. A detailed description of the molecular arrangement in water from x-ray data is not at present possible yet it simulates the crystal arrangement in ice. A mathematical treatment of the forces within and between the molecules in such groups can probably be studied with much profit only from the quantum viewpoint.

THE nature of water has received a great deal of attention, not merely because it is the most important liquid, but because its physical properties are unusual. The present paper is not an attempt to discuss the various theories¹ concerning the constitution of water. Its purpose is to give the results of x-ray diffraction studies and to emphasize the conclusions directly toward which these studies, as well as those of other liquids, seem to point.

The examination of crystals by x-rays has shed distinctly new light upon the structure of the solid state. Its method of examination is simple and direct, being based upon both classical and quantum theories, and there seems no doubt but that the space periodicities of concentration obtained by the applications of Braggs' law is correct. During the past few years many liquids have been examined by x-ray diffraction and the conclusion is becoming increasingly strengthened that here, too, the space periodicities may be determined.² Indeed, these periodicities, which are clearly made evident by the diffraction experiments, seem to be caused by an approximately orderly space array of molecules in small groups having ill-defined boundaries and temporary individual existence. These groups are not sparsely distributed, but occupy the greater portion of the volume, as can be shown

¹ For a resumé see H. M. Chadwell, Chemical Reviews 4, 375 (1927).

² See Stewart, Phys. Rev. 35, 726 (1930).

by a comparison of intensity in the liquid and powdered crystal state.³ Their magnitude appears to be of the order of hundreds or thousands of molecules, but no exact measurement has been made. The closest approach to such a measurement at present is contained in the experiments of McFarlan⁴ which show that an electric field will produce increased orientation of molecules of nitrobenzene to an extent that is far greater than would be expected from the orientation of independent molecules. The effect is so small that computations should perhaps await further data.

EXPERIMENTAL RESULTS

A full description of the apparatus and precautions may be found⁵ in an earlier article. The $\text{MoK}\alpha$ doublet radiation was used, being partially isolated by the use of a zirconium oxide filter. In Fig. 1 is shown an x-ray diffraction intensity-angle curve for powdered crystals of triphenylmethane. This shows, because of the comparative isolation of the line at 9° , the small amount of

Fig. 1. X-ray diffraction curves for equal masses per unit area of triphenylmethane in liquid and powdered crystal forms.

general $\text{MoK}\alpha$ radiation present. The general radiation is in evidence in the general elevation of the crystal curve. The maximum in the general radiation is about 6° , but the errors caused thereby, as indicated by Fig. 1 are small. A higher voltage would probably increase the general radiation to an undesirable extent. It is also to be borne in mind that the thickness of the specimen of water used was less than 1 cm or less than the optimum thickness. By this second precaution any accentuation of the general radiation by differential absorption is avoided.

³ For example, see Fig. 1 wherein the same mass of material is used. The integral intensity in the liquid case is comparable to that of the solid.

⁴ R. L. McFarlan, *Phys. Rev.* **35**, 12 (1930).

⁵ Stewart and Morrow, *Phys. Rev.* **30**, 232 (1927).

Fig. 2 shows the uncorrected results of Meyer⁶ by the broken line and those of the author by a continuous line. Meyer used a strictly monochromatic radiation obtained by crystal reflection. When the corrections of Meyer are made the alterations occur chiefly at the larger angles. Meyer's method was that of photography while that of the author was the ionization effect. Meyer used a stream of water and the author a thin walled glass tube as a receptacle. His monochromatic radiation gives his curve the greater quantitative weight.

Earlier diffraction experiments with water give the results presented in a foot note.⁷ But none had found more than one peak until the careful work of Meyer just cited.⁸

Fig. 2. Diffraction intensity of water, giving comparison of Meyer's uncorrected monochromatic curve with that of the author's. Temperatures 20° and 21°C respectively.

Fig. 3 presents the results for the change in temperature from 2° to 98°C. The tube was heated by hot (and cold) air blasts in such a manner as to prevent the introduction of any scattering material in the path of the x-rays. The temperature as given is correct to within 1.5°C throughout the entire range.

An additional experimental result must be mentioned, though it is not presented in detail because used only as a check experiment on known data. Diffraction curves were obtained with powdered ice, produced by plunging

⁶ H. H. Meyer, *Ann. d. Physik* 5, 701 (1930).

⁷ Sogani, *Ind. J. Physics* I, IV, 357 (1927), has one value, 3.27Å; Krishnamurti, *Ind. J. Phys.* II, IV, 491 (1928) has one value, 3.26Å; Keesom in *Physica*, p. 118 (1922) and Keesom and de Smedt, *Proc. Royal Soc. Amsterdam*, 25, 118 (1922) and 26, 112 (1923) give the values 3.05Å in the first two references and 3.04Å in the last. *Prins Zeits. f. Physik* 56, 617 (1929) gives one value, 3.1Å. He raised the temperature to 80°C with no noticeable alteration.

⁸ The author's experimental work preceded the publication of that of Meyer. The former was presented at the April, 1930 meeting of the American Physical Society and described by abstract only in the June 1, 1930 number of the *Physical Review*. Probably Meyer's article appeared in print a little later, the number of the *Annalen* reaching the author on July 29th, 1930, but Meyer's work was described in full at that time.

the glass tube receptacle in liquid air. The diffraction curves for two samples were in fair agreement and showed relatively prominent lines at approximately 10.5° , 11.7° , 18° and 19.5° . Dennison⁹ used a Mo target and zirconium filter and found the most prominent lines to be at (1) 11.16° , (2) 19.86° , (3) 11.88° and 30.2° , (4) 15.3° and 27.16° , (5) 10.44° and 18.12° and 21.38° , the relative values being 10, 5, 2, 1.5, and 1, respectively. It will now be seen that the liquid peaks at 12.5° , 19° and 31° in Fig. 3 correspond approximately with the most intense lines found by Dennison in an extended in-

Fig. 3. Displaced diffraction intensity curves of water at different temperatures.

vestigation, and by the author in the brief tests described, in the same apparatus as was used for water. In this approximate correspondence of liquid to solid state H_2O does not differ from other compounds.¹⁰ For example, see the liquid and crystal curves compared in Fig. 1. In case of no substance yet tried do the peaks of a liquid exactly correspond with the lines of the solid, and the difference is not a temperature one. It is evident that such periodicities as are found in the liquid state have strong quantitative similarity to the most important of those in the solid state.

CONCLUSIONS

There are several conclusions to be made directly from Fig. 3 and the foregoing assuming that Bragg's diffraction law gives the distances of separation in the periodicities represented by the peaks. Further, it is simplest to assume that these distances, 3.24, 2.11 and 1.13A, corresponding respectively to angles 12.5° , 18.8° and 31.0° of Fig. 2, or, at least the first two, correspond to molecular separations. This assumption is in accord with experiments with other liquids and with the similarity of liquid to solid state. H. H. Meyer gives as his results at $20^\circ C$, 3.13, 2.11 and 1.34A. With the assumptions cited, the conclusions are as follows:

⁹ Dennison, Phys. Rev. 17, 20 (1921).

¹⁰ See list of eight liquids given by Krishnamurti, Ind. J. Phys. III, II, 225 (1928). The present author has tested three additional ones.

1. The distance between molecules (scattering centers) represented by the most prominent peak decreases with temperature, whereas the distance corresponding to the next most important peak seems to increase. H. H. Meyer gives a decrease for the former of 0.0018Å per °C, whereas our results show 0.0014Å. He obtains a constant position for the second peak.

2. The second peak disappears with increasing temperature. H. H. Meyer showed at 40°C a reduction to two-thirds the value at 3°C.

3. The breadth of the large peak increases with increase in temperature.

4. There is a quantitative similarity between the periodicities found in the liquid and the three most prominent periodicities found in powdered ice.

A few years ago the reader might have concluded at once from Fig. 3 that therein is additional evidence of the complexity of the molecules and of the disappearance of one or more complexes with increasing temperature. But the evidence of to-day would indicate at once the incorrectness of this position. For x-ray diffraction experiments indicate that when two liquids are completely miscible in the proportions used, the marked periodicity found in the solution is not that of either constituent alone, but distinctly of the solution. This has been shown by Krishnamurti¹¹ with glycerine, ethyl alcohol and lactic acid in an aqueous solution. Meyer¹² used solutions of n-ethyl alcohol and methyl cyclohexane, n-butyl alcohol and orthodimethyl cyclohexane, quinoline and phenol, cyclohexane and tetranitromethane and phenol and water. As an illustration of results, each of the first four mixtures used by Meyer showed but a single periodicity and this was intermediate between the periodicities of the liquids examined separately. These mixtures were totally miscible. The phenol-water mixture showed the same effect when not an emulsion. As an emulsion the two peaks of the constituents were found. The evidence shows that, without exception, two liquids, totally miscible, in solution will show a grouping of molecules (a periodicity) that is not that of either one. It is, therefore, highly probable that, if there were two "complexes" in the water in our present experiment, they would be totally miscible and would not show their individual periodicities. Hence, we may safely conclude that the two peaks in the water diffraction curve correspond to periodicities of *one kind of molecular grouping and one kind only*. The complex molecule interpretation suggested at the beginning of this paragraph is not, therefore, tenable. Moreover, it cannot be claimed that the diffraction peaks with ice indicate several complexes. They correspond to the periodicities in one molecular grouping, one crystal structure. Yet the liquid peaks have a striking similarity that is not explained by the introduction of several complexes but rather, as in ice, by periodicities in one grouping.

Langmuir¹³ pointed out a number of years ago that liquids are very much more nearly like solids than like gases. Consider density, compressibility, temperature expansion, specific heats, refractive indices, other

optical properties, etc. The only essential difference between liquids and solids is that of fluidity. This one difference has had much to do with the hasty conclusion, held for many years, that the arrangements of molecules in a liquid are as irregular as in a gas. Now we learn from x-ray diffraction experiments that the liquid does have a crude regularity in multitudinous groups, an irregularity of orientation of these groups, and an irregularity of molecules between these temporary groups. With this view it would appear that the simple explanation of molecular association is the association in groups of a relatively large number of molecules and not in complexes consisting of two, three, etc., molecules. The number of molecules in a cybotactic group has not been determined, but one would expect it to be from several hundred to several thousand. Fig. 1 shows that these groups give as much scattering as powdered crystals of the same mass. The groups must therefore be practically everywhere present.

The physical chemist introduced the conception of complexes to account indirectly for the data of vapor pressure, boiling point, latent heat, viscosity, surface tension, etc.¹⁴ But the study of crystals points very clearly to a similarity of crystal forces and internal molecular forces, and gives ample reason to expect that liquid molecules in groups as described must act differently than molecules that are more nearly free as in a gas. Consequently, what formerly has been attributed to forces between molecules in a complex are now seen to be the forces within the groups causing the regularity of arrangement.

Arrangement of molecules in the groups. In order to make the description of "association" more definite, a brief discussion will be given of the present status of the group arrangements.

The arrangement of polarized molecules is not, for example, as suggested illustratively by Debye,¹⁵ the minimum potential configuration of two spheres (molecules) with idealized doublets of infinitesimal length at the centers, thus forming a double molecule with axes of the two doublets in line joining the centers of the spheres. Neither is the arrangement determined solely by the electrical effect of the doublets. With reference to the first point, the experiments in n-alcohols,¹⁶ isomers of n-alcohols,¹⁷ and normal saturated fatty acids,¹⁸ show that when the OH or OOH group is at the end of the chain two groups are adjacent in two molecules having their chain lengths lying in the same straight line. That is, the molecules are arranged head to head (the polarized group) and tail to tail in parallel lines continuing over a group of molecules. The doublets appear at the heads and not centered in the molecule. Moreover, the head to head junction is arranged in an orderly manner with other such junctions in the adjacent parallel lines, so

that their location forms a definite longitudinal periodicity recognized by x-ray diffraction. The planes associated with these junctions are not normal to the chain lengths. When the polarized OH group is attached not at the end of a chain but removed therefrom by at least one carbon atom,¹⁹ then the double arrangement disappears and the longitudinal periodicity referred to now occurs at a distance corresponding to the length of one molecule and the associated planes are normal to the chain lengths. At the same time the periodicity caused by parallel arrangement of molecules remains. It is to be noticed in the above pictures, we do not have double molecules and the association is that in a group, indeed, similar to the situation in a crystal. The original papers should be consulted for the evidence of the longitudinal grouping and the interpretation of it. So far the grouping (or association) may appear to be regarded as caused primarily by the electrical forces of the doublets. But this is not correct, for it does not account in general for the parallelism of chain molecules. A direct experiment is with n-paraffins.²⁰ Here the molecules lie parallel and yet they are unpolarized.²¹ We are dealing with other intermolecular forces than those due to doublets. In geometric language the "shape" determines the grouping to no small extent. With the paraffins there is no periodicity in the longitudinal direction as with the n-alcohols, etc., and it is evident that this periodicity of the last named may be regarded as caused by the presence of the doublets.

The detailed arrangement of molecules in other than long chain liquid compounds is not ascertained readily by x-ray diffraction, for the lack of approximately perfect regularity in the groups makes the detectable number of periodicities too small. Thus, in the case of water no further conclusion as to detail can be made than already stated. The periodicities are evidently quantitatively similar to the most prominent ones in ice, but this does not, of course, mean like arrangement.

The above discussion states that what was formerly regarded as the peculiar association of two, three or four molecules, as the case may be, now loses its identity in the orderly group formation of molecules. If this be correct, then, since the values formerly computed for the average number of associated molecules change with temperature, there should be evidence for the alteration of the groups with temperature. This proves to be true. Skinner²² found with a group of liquids that there were changes in the dimension of the periodicity that could not be accounted for by expansion. Similarly, in Fig. 3, it is shown that one such distance increases with temperature while the other decreases. Since neither isotropic nor anisotropic *expansion* accounts for the effect, it may be assumed that there doubtless may occur temperature changes in the molecular forces caused by alterations in molecular "shape," or essentially in the precise arrangement of atomic centers in the molecule. Skinner also showed that in certain cases the in-

tensity of the x-ray halo *increased* with increasing temperature. This also suggests alteration in grouping.

The x-ray study is not the only experimental evidence of such internal alteration. We know, for example, that when there are changes in magnetic moment as occurs, for example, in para-azoxyanisole, there must be internal changes in the molecule.

The group conception, as given above, seems to be in harmony with all the facts. On the other hand, there are good reasons for the abandonment of the theory of complexes. Reference to a recent contribution of G. G. Longinescu,²³ who has been an active contributor in this field, will satisfy the reader upon this point. The most important reason for turning from the older conception is that it has proved unprofitable and does not longer serve any useful purpose in stimulating new contributions. Its extended use has increased the inconsistent results and it has ceased to be even empirically satisfactory.

The new conception here proposed seems to be helpful in several respects. First, it suggests that experiments based upon the theory of complexes will not prove profitable and recommends their abandonment. Second, it states that the secret of association lies in an understanding of those forces, call them chemical or physical as one will, which bind atoms together in a molecule and which cause stable configuration in crystals and unstable arrangement in liquids. If, as at present appears, such an "understanding" will only be had through the development of quantum theory, these forces being studied by the energy levels obtained in radiation and absorption spectra of constituent atoms and molecules, then a physical description of the origin of these forces appears improbable. They will appear to exist only because of atomic and molecular energy levels,²⁴ and the resulting energy changes. They cannot be understood by distributions of electricity and the application of electrical laws. That has proved unsatisfactory even for the simplest atoms. In any event, the cybotactic group conception of association removes the difficulties inherent in molecular complexes and will prove helpful in a study of the nature of the liquid state.

I desire to express appreciation for the experimental skill of Mr. H. A. Zahl, research assistant, who is responsible for the observations involved in this report, and thanks for a supply of conductivity water to Professor J. N. Pearce of this University.

ON THE TRANSFORMATION OF LIGHT
INTO HEAT IN SOLIDS. I¹

BY J. FRENKEL

DEPARTMENT OF PHYSICS, UNIVERSITY OF MINNESOTA

(Received November 25, 1930)

ABSTRACT

Starting from the analogy between a crystal and molecule, it is shown that the electronic excitation, forming the first step in the process of light absorption, is not confined to a particular atom, but is diluted between all of them in the form of "excitation waves," similar to sound waves which are used to describe the heat motion in the same crystal. Owing to the interaction between the atoms the excitation state is split up into substates whose number is equal to the number of atoms n (excitation multiplet). By superposing several excitation waves "excitation packets" can be constructed representing the travelling of the excitation state from one atom to another. To each excitation sub-state there corresponds a definite crystal structure (lattice constant, vibration frequencies) slightly different from that of the normal, and giving rise to slightly different vibrational states. This influence of the excitation on the vibrational states provides an indirect coupling between them, which allows the excitation energy to be shared between a few hundred heat-oscillators with practically no direct coupling nor anharmonicity in a radiationless transition which forms the second state of the process of light absorption.

1. INTRODUCTION

IN A monatomic gas the transformation of the light energy absorbed by an individual atom into heat, that is into the kinetic energy of the translatory motion, is effected, on the quantum theory, through a *collision of the second kind* of the excited atom with some other (usually unexcited) one. If we now look for the corresponding process in a monatomic solid body, where the heat motion is represented by the vibration of a set of "elastic oscillators" (Debye's waves), we at once meet a grave difficulty. This difficulty consists in the apparent inability of the elastic or heat oscillators, so far as they are assumed to be harmonic and uncoupled with each other, to take up the big quantum of energy stored by the excited atom. This quantum is in fact about 100 times larger than the largest energy quantum of the heat oscillators, corresponding to the ratio between the frequency of the absorbed light and the highest frequency of the heat vibrations. In a radiationless discharge of the excitation energy the latter must therefore be either shared between a great many oscillators, which is impossible if they are uncoupled, or be absorbed by a single oscillator jumping at one time over at least 100 energy levels, which is also impossible if the oscillator is harmonic.

The solution of this difficulty seems at first sight to consist simply in taking account of the actually existing coupling between the different oscil-

¹ This paper is an extension of two previous ones on the absorption of light in gases: see J. Frenkel, *Zeits. f. Physik* 58, 798 (1929) and 59, 198 (1930).

lators and their nonharmonic character. It must, however, be rejected for it leads to extremely small probabilities for transitions of the type considered. In fact in order to get a non-vanishing probability for a transition involving N elementary jumps, either by N oscillators making each an elementary jump, or by a single oscillator making an N -fold jump, one must carry out the expansion of the potential energy of the oscillators as a function of their coordinates (or of the displacements of the atoms from their equilibrium positions) up to terms of the N -th order at least.² The terms one would get for $N \cong 100$, even if this was practicable, would be hardly large enough to account for the effect we are considering.

There seems to be a less trivial and more successful solution of the above difficulty, which is suggested by the analogy between a crystal (representing a solid body) and a molecule. The usual selection rule for the vibrational quantum number of a molecule (a diatomic molecule, say), restricting its change to unity, holds for such transitions only, for which the electronic state of the molecule remains unaltered. In case however of a combined transition, for instance of a spontaneous transition from an excited state to the normal one with emission of light, the vibrational quantum number can change by any amount (integral, of course) whatever. It may be noted that this "breach" of the selection rule has nothing to do with the possible presence of nonharmonicity, but depends upon the fact that the character of the vibrations in the normal and excited molecule is quite different.

In applying this consideration to a crystal we have only to develop the analogy between an excited crystal and an excited molecule. At the outset we have pictured an excited crystal as differing from the normal one by the presence of one *definite* excited atom. Now in case of a molecule consisting of two identical atoms the excitation cannot be traced to one of them, but has to be considered as a characteristic of the molecule as a whole. The same must be true with respect to a crystal consisting of any number of identical atoms. We thus see that we must first of all revise our conception of an excited crystal by allowing for the identity of all the atoms, and thereafter investigate the influence of the "electronic state" of a crystal on its vibrational states.

2. EXCITED STATES OF A CRYSTAL; "EXCITATION-WAVES"

We shall assume that the coupling between different—even neighboring—atoms is small compared with the forces holding the electrons within the separate atoms (thus excluding the case of metallic bodies). We shall further suppose that the atoms—or rather the nuclei—are fixed, that is, we shall neglect their vibratory motion, and shall consider only their inner state, characterized by a function of the coordinates of the electrons with respect to the nucleus. Lastly we shall leave out of account the possibility of interchanging the electrons between different atoms and shall consequently assign to a definite atom a definite group of electrons whose coordinates (relative

² See below, Section 4.

Taking into account the orthogonality and normality conditions for the functions ψ_I and ψ_{II} ,

$$\int \psi_I(\alpha) \psi_{II}^*(\alpha) d\tau_\alpha = 0, \quad \int \psi_I(\alpha) \psi_I^*(\alpha) d\tau_\alpha = \int \psi_{II}(\alpha) \psi_{II}^*(\alpha) d\tau_\alpha = 1,$$

we easily obtain from (3) if $k \neq l$:

$$U_{kl} = \int \cdots \int U \phi_k^* \phi_l d\tau_1 \cdots d\tau_n = V_{kl} \quad (4)$$

where V_{kl} is a function of the distance R_{kl} alone given by

$$V_{kl} = \int \int U(k, l; R_{kl}) \psi_{II}^*(k) \psi_I(k) \psi_I^*(l) \psi_{II}(l) d\tau_k d\tau_l \quad (4a)$$

It may be remarked that it is in general complex and therefore different from $V_{lk} = V_{kl}^*$.

For $k=l$ we get

$$U_{kk} \equiv V_{kk} = \sum_{l \neq k} \bar{V}_{kl} \quad (5)$$

where

$$\bar{V}_{kl} = \iint U(k, l; R_{kl}) |\psi_{II}(k)|^2 |\psi_I(l)|^2 d\tau_k d\tau_l \quad (5a)$$

may be defined as the average value of the mutual energy of the atoms k and l when one of them is in the normal and the other in the excited state. This is also of course a function of the distance R_{kl} only; it is moreover symmetrical with respect to k and l .

The equations (2) are very similar to those which determine the normal modes of vibration of a system of coupled classical oscillators with one degree of freedom each; in fact we have but to consider the coefficients c_k as the amplitudes of these oscillators and to replace the energies W' by the square of the classical frequencies (multiplied by a properly chosen proportionality factor). The matrix elements $U_{kl} (k \neq l)$ can be then interpreted as the coupling coefficients (since they actually depend upon the distance of the

the functions (1) by the following ones which are antisymmetrical with respect to all the electrons.

$$\phi_1 = \frac{1}{n^{1/2}} \begin{vmatrix} \psi_{II}(1, 1), & \psi_{II}(1, 2), & \cdots & \psi_{II}(1, n) \\ \psi_I(2, 1), & \psi_I(2, 2), & \cdots & \psi_I(2, n) \\ \cdots & \cdots & \cdots & \cdots \\ \psi_I(n, 1), & \psi_I(n, 2) & \cdots & \psi_I(n, n) \end{vmatrix}, \quad \phi_2 = \frac{1}{n^{1/2}} \begin{vmatrix} \psi_I(1, 1), & \psi_I(1, 2) & \cdots & \psi_I(1, n) \\ \psi_{II}(2, 1), & \psi_{II}(2, 2) & \cdots & \psi_{II}(2, n) \\ \cdots & \cdots & \cdots & \cdots \\ \psi_{II}(n, 1), & \psi_{II}(n, 2) & \cdots & \psi_{II}(n, n) \end{vmatrix}$$

etc. where $\psi_I(k, l)$ and $\psi_{II}(k, l)$ denote the wave functions of the atom formed by the association of the l -th electron to the k -th nucleus, in the normal and excited state respectively. Similar, though somewhat more complicated, results are obtained in the general case of several electrons per atom.

The case of two electrons with all the atoms being in the normal state has been recently treated by E. Hylleraas, Zeits. f. Physik 63, 771 (1930) in connection with the theory of the cohesive forces in a (non-excited) crystal of sodium hydride.

respective oscillators only), and the U_{kk} as the coefficients of the quasi-elastic forces for the uncoupled oscillators.

Until now the positions of the atoms have remained unspecified. We shall now assume that the nuclei are fixed at the lattice points of the crystal, neglecting the displacements due to the vibratory motion. We shall further assume that the crystal has a rectangular form (or the form of a parallelepiped whose edges are parallel to the crystalline axes). The normal modes of vibration for this case are well known. They do not depend upon the shape of the functions $V_{kl}(R_{kl})$ nor upon the value of the constant $V_0 = V_{kk}$, thus coinciding with respect to the position of the nodal planes with the acoustic or elastic vibrations (for which $V_0 = 0$). These vibrations can be described as *standing waves* with the wave-number components⁶

$$g_1 = \pm r_1/2a_1, \quad g_2 = \pm r_2/2a_2, \quad g_3 = \pm r_3/2a_3 \quad (6)$$

where a_1, a_2, a_3 are the edges of the crystal and r_1, r_2, r_3 numbers specifying the mode of normal vibrations and taking all integral values between 0 and $n_1 - 1, n_2 - 1, n_3 - 1$, respectively, n_i being the number of atoms along the i -th edged ($n = n_1 n_2 n_3$).

The triplet $(r_1 r_2 r_3)$ replaces the number r which was introduced to specify the various solutions of the equations (2). The single numbers k and l must be replaced accordingly by triplets $(k_1 k_2 k_3), (l_1 l_2 l_3)$ which may be associated with definite "oscillators," that is definite atoms of the lattice. It may be remarked that the coefficient c_k in (2) refers to that function ϕ_k in (1) which ascribes the excited state to the atom k . The solutions of the equations (2) can now be put in the form

$$c_{r_1, r_2, r_3; k_1, k_2, k_3} = A_{r_1 r_2 r_3} \cos \frac{\pi \delta}{a_1} k_1 r_1 \cos \frac{\pi \delta}{a_2} k_2 r_2 \cos \frac{\pi \delta}{a_3} k_3 r_3 \quad (7)$$

where δ is the lattice constant (for the sake of simplicity the lattice will be pictured as cubical), and $k_1 \delta = x_1, k_2 \delta = x_2, k_3 \delta = x_3$ the rectangular coordinates of the atom to which the excited state is assigned by the function $\phi_{k_1 k_2 k_3}$. $A_{r_1 r_2 r_3}$ is a normalization coefficient determined by the condition that the integral of the square of the function

$$\chi_{r_1 r_2 r_3}(1, 2, \dots, n) = \sum_{k_1 k_2 k_3} c_{r_1, r_2, r_3; k_1, k_2, k_3} \phi_{k_1 k_2 k_3}(1, 2, \dots, n) \quad (7a)$$

representing the r -th stationary state of the excited crystal (the r_1, r_2, r_3 component of the "excitation multiplet") over the configuration space of all the electrons should be equal to 1.

The energies $W'_{r_1 r_2 r_3}$ of the different states (with respect to the unperturbed energy $W_{II} + (n-1)W_I$) are given directly by substituting in the equations (2) the values (7) of the coefficients c . Since the matrix elements U_{kl} depend only upon the differences $k_1 - l_1, k_2 - l_2, k_3 - l_3$ one can put $k_1 = k_2 = k_3 = 0$ which gives

$$A_r W'_r = \sum_l U_{0l} c_{rl}$$

⁶ The wave number is the reciprocal of the wave-length; it is a vector parallel to the direction of the propagation of the waves.

or more fully written

$$W'_{r_1 r_2 r_3} = \sum_{l_1} \sum_{l_2} \sum_{l_3} U_{000, l_1 l_2 l_3} \cos \frac{\pi \delta}{a_1} l_1 r_1 \cos \frac{\pi \delta}{a_2} l_2 r_2 \cos \frac{\pi \delta}{a_3} l_3 r_3 \quad (8)$$

With increasing values of $l_1 l_2 l_3$, that is with increasing distance $R_{0l} = \delta(l_1^2 + l_2^2 + l_3^2)^{1/2}$, the values of $H'_{000, l_1 l_2 l_3}$ must in general decrease very rapidly. The summation in (8) can be therefore extended practically over all values of the l_i from $-\infty$ to $+\infty$. If the mutual action of neighboring atoms only (with smallest distance apart $R = \delta$) is taken into account, (8) reduces to

$$W'_{r_1 r_2 r_3} = V_0 + 2V_1 \left(\cos \frac{\pi \delta}{a_1} r_1 + \cos \frac{\pi \delta}{a_2} r_2 + \cos \frac{\pi \delta}{a_3} r_3 \right) \quad (8a)$$

where V_1 is the value of (4a) for neighboring atoms and V_0 six times the value of (5a) for the same atoms. The latter value is the average of the mutual potential energy between an excited and an unexcited atom, whereas V_1 has the character of an "exchange energy" which has no classical analogue.

Each stationary state of an excited crystal can be described as a "standing excitation wave" defined by (7) or by

$$c(x_1 x_2 x_3) = A \cos 2\pi g_1 x_1 \cos 2\pi g_2 x_2 \cos 2\pi g_3 x_3 e^{-2\pi i \nu' t}$$

where $\nu' = W'/h$, $x_i = \delta l_i$. Such a standing wave can be obtained by superposing eight "progressive excitation waves" of the type

$$(A/8) e^{2\pi i (g_1 x_1 + g_2 x_2 + g_3 x_3 - \nu' t)}$$

which represent the propagation of the probability for finding the excitation localized in a certain plane of the crystal. By superposing a number of such waves with slightly different values of g_1, g_2, g_3 (that is with slightly different directions of propagation and frequencies $\nu' = w'/h$) it is always possible to construct a wave-packet which will represent the excitation being concentrated in a definite atom or its neighborhood (according to the usual picture). The group velocity of such an "excitation-packet" may be determined by the relations

$$v_i = \partial \nu' / \partial g_i \quad (i = 1, 2, 3). \quad (9)$$

Putting

$$h\nu' = V_0 + 2V_1(\cos 2\pi g_1 \delta + \cos 2\pi g_2 \delta + \cos 2\pi g_3 \delta)$$

according to (8a) and (6), we get

$$v_i = - \frac{4\pi \delta V_1}{h} \sin 2\pi g_i \delta. \quad (9a)$$

For small values of g_i that is for long "excitation waves" this expression reduces to

$$v = - \frac{8\pi^2 \delta^2 V_1}{h} g \quad (9b)$$

that is the group velocity is approximately proportional to the wave number. It has in general the same direction so long as the "exchange energy" V_1 is negative. It reaches its maximum value $v \cong 4\pi\delta |V_1|/h$ for wave-lengths equal approximately to four times the interatomic distance δ . For $\lambda \cong 2\delta$ it falls down to zero and for still shorter wave-lengths becomes opposite to the direction of the wave propagation.⁷

To get a better understanding of the nature of the "excitation waves" it will be well to consider the process corresponding to them in the older quantum theory and in the classical theory. According to the former the excitation energy of an atom can and in fact must be transmitted to one of the other atoms of the same sort either by emission and (resonance) reabsorption, of light or directly in a non-radiative process. The closer the atoms are together, the larger must be the probability of such a non-radiative transmission, that is, the larger the velocity with which the "excited state" will travel from one place to the other. This is expressed by the fact that the group velocity, according to (9a), is proportional to the exchange energy V_1 . The ratio δ/v_{\max} which is of the order of magnitude of h/V_1 can be considered as the shortest time that the excitation remains confined to one definite atom.⁸

From the point of view of the classical theory an atom has to be considered as a harmonic oscillator, whose normal state is that of rest. The energy of the free oscillations, replacing the excitation energy, instead of being concentrated in one single atom (or a small number of them in the general case) has to be distributed here in a more or less uniform manner over all the atoms, each of them possessing accordingly but a very small energy. The excitation waves can be represented in this case by the familiar waves of the electric polarization with exactly the same wave-numbers as has been actually done above in the discussion of the equation (2).⁹ It should be noticed however that in the classical theory of the propagation of such waves the interaction between the atoms is considered to be a radiative one, that is proportional to their dipole moment and inversely proportional to the distance, whereas in the wave mechanical theory we are developing this interaction considered as a much more powerful non-radiative (electrostatic) one.¹⁰

⁷ These results are wholly analogous to those implied in Bloch's theory of the electrical conductivity of metals and discussed by R. Peierls.

⁸ In case of two atoms h/V_1 is just equal to the time in which the excited state oscillates from one atom to the other.

⁹ The situation becomes more complicated if instead of one excited atom we consider the case of two or more excited atoms. cf. J. Frenkel, *Zeits. f. Physik* 59, 198 (1930) in particular footnote on p. 203.

¹⁰ Cf. G. Breit and E. O. Salant, *Phys. Rev.* 36, 871 (1930). This paper dealing with the propagation of light in solids contains some results of the present section.

3. THE INFLUENCE OF EXCITATION ON THE GEOMETRIC AND ELASTIC PROPERTIES OF A CRYSTAL AND ITS VIBRATORY MOTION

We can now turn to the examination of the influence which an excited state of a crystal (that is a definite component of an excitation multiplet) exerts upon the heretofore neglected vibratory motion of the atoms. The exact way to deal with this question would be to consider simultaneously the "inner" and the "outer" (that is, vibratory) motion of the atoms. But this way is hardly practicable even in the simplest case of a diatomic molecule, and we shall therefore use an approximate method of the same sort which is applied in Debye's theory of specific heats to the determination of the normal vibrations corresponding to the unexcited state.

A normal vibration is described here by a system of standing sound waves of just the same geometrical type as that used in the preceding paragraph to describe the excitation states. It can be thus characterized by specifying the components of the wave-number according to the equations (6) which we shall rewrite in the form

$$g_1' = \pm r_1'/2a_1, \quad g_2' = \pm r_2'/2a_2, \quad g_3' = \pm r_3'/2a_3 \quad (10)$$

the primes serving to distinguish the sound waves from the excitation waves.¹¹

The frequency of the vibrations ν' can be determined from the equation

$$\nu' = g'u \quad (11)$$

where u denotes the *velocity of sound*, which is considered as independent of g' . The velocity of sound can be calculated by means of the formula

$$u = (\kappa/\rho)^{1/2}$$

where ρ is the density of the crystal, and κ its elastic modulus, which has different values for the longitudinal and the transverse vibrations.

Now in order to determine κ from atomic data we must consider the vibrationless state of the crystal and compare its energy in the equilibrium state with the energy corresponding to a slightly compressed (or expanded) state in the case of κ_{long} or to a slightly distorted state in the case of κ_{trans} .

Denoting the volume of the crystal with v and its energy—that is the mutual potential energy of all its atoms—in the normal (non-excited) state with W_0 we have, expanding W_0 in a power series with respect to the increment of volume $v - v^0$ ($v^0 = v$ in the equilibrium state)

$$W_0 = W_0^0 + \frac{1}{2} \left(\frac{\partial^2 W_0}{\partial v^2} \right)^0 (v - v^0)^2.$$

The second term represents the elastic energy

$$\frac{1}{2} \kappa_0 (v - v^0)^2 \cdot v^0$$

¹¹ We shall drop the primes later on when there will be no danger of confusing the sound waves with the excitation waves.

whence it follows

$$\kappa_0 = v_0^0 \left(\frac{\partial^2 W_0}{\partial v^2} \right)$$

or putting $v = n\delta^3$

$$\kappa_0 = \frac{\delta_0^2}{9} \frac{1}{v_0^0} \left(\frac{\partial^2 W_0}{\partial \delta^2} \right)^0 = \frac{1}{9n\delta_0} \left(\frac{\partial^2 W_0}{\partial \delta^2} \right)^0. \quad (13)$$

This formula determines the modulus of compressibility for the normal (unexcited) state of the crystal—as denoted by the subscript zero—and hence according to (12) and (11)¹² the frequency of the vibrations associated with this state. It may be remarked that the corresponding equilibrium value of $\delta = \delta_0^0 = \delta_0$ is given by the equation $(\partial W_0 / \partial v)^0 = 0$ or

$$(\partial W_0 / \partial \delta)^0 = 0 \quad (13a)$$

and that δ_0 is related to the density $\rho = \rho_0$ by means of

$$\rho_0 = m / \delta_0^3 \quad (13b)$$

m being the mass of an atom.

The above method can now obviously be applied to the determination of the vibrations associated with an excited state of the crystal. To do this we have but to replace in the preceding formulae the energy W_0 by the energy $W_r = W_0 + W'_r$, of one of the components of the excitation multiplet. In this way we shall get for the lattice constant of the crystal δ_r , its density ρ_r , and its elastic modulus κ_r values depending upon the character of the excitation substate and slightly different from those corresponding to the normal one.

Since the difference $\delta_r - \delta_0 = \Delta\delta_r$ is very small, we have to a first approximation

$$\left(\frac{\partial W_r}{\partial \delta_r} \right)^0 = \left(\frac{\partial W_0}{\partial \delta} \right)_{\delta=\delta_0} + \left(\frac{\partial^2 W_0}{\partial \delta^2} \right)_{\delta=\delta_0} \Delta\delta_r + \left(\frac{\partial W'_r}{\partial \delta} \right)_{\delta=\delta_0} = 0,$$

whence since the first term vanishes (according to 13a)

$$\Delta\delta_r = - \frac{\partial W'_r / \partial \delta}{\partial^2 W_0 / \partial \delta^2} (\delta = \delta_0) \quad (14)$$

The energy W_0 is proportional to the number of atoms n , whereas W'_r , according to (8) or (8a) depends upon it in a practically unimportant way. Putting in (8a)

$$a_1 = n_1\delta, \quad a_2 = n_2\delta, \quad a_3 = n_3\delta$$

(where $n_1 n_2 n_3 = n$) we have

$$W'_r = V_0 + 2V_1 \left(\cos \frac{\pi r_1}{n_1} + \cos \frac{\pi r_2}{n_2} + \cos \frac{\pi r_3}{n_3} \right) \quad (15)$$

and consequently

$$\Delta\delta_r = - \frac{\partial V_0}{\partial \delta} \bigg/ \frac{\partial^2 W_0}{\partial \delta^2} - 2 \left(\cos \frac{\pi r_1}{n_1} + \cos \frac{\pi r_2}{n_2} + \cos \frac{\pi r_3}{n_3} \right) \frac{\partial V_1}{\partial \delta} \bigg/ \frac{\partial^2 W_0}{\partial \delta^2} \quad (15a)$$

which is of the order of magnitude of $1/n$, since V_1 does not depend upon n .

¹² In the case of longitudinal vibrations.

In the same way we get from (13)

$$\Delta\kappa_r = \kappa_r - \kappa_0 = \frac{2}{9\delta n} \left[\frac{\partial^2 V_0}{\partial \delta^2} + 2 \left(\cos \frac{\pi r_1}{n_1} + \cos \frac{\pi r_2}{n_2} + \cos \frac{\pi r_3}{n_3} \right) \right] \frac{\partial^2 V_1}{\partial \delta^2}. \quad (15b)$$

The relative change of $\Delta\kappa_r$ being again of the order of magnitude of $1/n$.

These results seem very natural indeed. We should expect that the change of the geometric and dynamic properties of the crystal lattice, due to the excitation of a few atoms n' depends upon their *relative* number, that is upon the ratio n'/n , which in our case is equal to $1/n$. So long as n' is small compared with n the effects due to the excitation of the separate atoms must obviously behave additively (which would no longer be the case if n' were comparable with n), so that to get the total change of δ or κ we would have but to add the expressions (15a) or (15b) for all the n' excited atoms. It seems however that even with the largest values of n' that can be obtained by illuminating the crystal with intense light of the resonance frequency, the change in the elastic properties will be too minute to be detected by direct measurement.

This change must however manifest itself in an indirect manner by making possible the radiationless transitions of the crystal from an excited state into the normal one with conversion of the excitation energy into that of the vibrational motion, and also of course transitions of the inverse direction, leading to "thermal excitation" of the crystal and corresponding to "inelastic collisions of the first kind" or "activating collisions" in the case of a gas.

4. THE RELATION BETWEEN THE VARIABLES AND FUNCTIONS DESCRIBING THE HEAT OSCILLATORS IN THE NORMAL AND THE EXCITED CRYSTAL

In order to determine the probability of such transitions we must introduce first of all the "normal coordinates" characterizing the individual heat oscillators, which represent the different modes of vibration (standing elastic waves) of the crystal. Let these coordinates for the unexcited state be denoted by $\xi_1, \xi_2, \dots, \xi_n \dots \xi_{3n}$ (their number being equal to the number of degrees of freedom); we shall think of the first n as referring to the longitudinal vibrations and the rest to transverse ones.

We have to introduce in the second place the relations between these coordinates and the normal coordinates $\xi_{r1}, \xi_{r2}, \dots$ which correspond to the r -th excited state. These relations must be derived from the condition that the equilibrium positions of the atoms in the excited state are specified by zero values of the new coordinates ($\xi_{rs} = 0$) on the one hand and by definite non-vanishing values $\xi_s = \xi_s^r$ of the old ones on the other.

For the sake of simplicity we shall limit ourselves to the consideration of a *unidimensional* case, that is of a set of n atoms situated on a straight line and capable of moving along this line (that is to perform longitudinal oscillations). Such a set can be conveniently treated as a "bar." In order to allow for the change of length $L = \delta n$ of the bar, due to the excitation of one of its

atoms we shall imagine one of its ends to be fixed and the other free.¹³ The normal modes of vibration of such a bar correspond to wave-lengths $\lambda = \lambda_l$, determined by the equation

$$L = \frac{2l+1}{4} \lambda_l = n\delta \quad (16)$$

where $l=0, 1, 2, \dots, n-1$. The displacement Δx_k of an atom whose equilibrium distance from the fixed end is $x_k = k\delta$ can be represented by the sum

$$\Delta x_k = \sum_{l=0}^{n-1} c_{kl} \xi_l \quad (17)$$

where

$$c_{kl} = \gamma \sin \frac{2\pi x_k}{\lambda_l} = \gamma \sin \frac{\pi}{n} \left(l + \frac{1}{2} \right) k \quad (17a)$$

γ being determined by the "normality condition"

$$\sum_{k=0}^{n-1} c_{kl}^2 = 1 \quad (17b)$$

and ξ_l denoting the normal coordinate, which characterizes the l -th mode of vibration.

Using the formula

$$\sum_{k=0}^{n-1} e^{i\alpha k} = \sum_{k=0}^{n-1} \cos \alpha k + i \sum_{k=0}^{n-1} \sin \alpha k = \frac{1 - e^{i\alpha n}}{1 - e^{i\alpha}}$$

which is equivalent to

$$\begin{aligned} \sum_{k=0}^{n-1} \cos \alpha k &= \frac{1 + \cos \alpha(n-1) - \cos \alpha n - \cos \alpha}{2(1 - \cos \alpha)} = \frac{1}{2}(1 - \cos \alpha n) + \frac{\sin \alpha n \sin \alpha}{2(1 - \cos \alpha)} \\ \sum_{k=0}^{n-1} \sin \alpha k &= \frac{\sin \alpha(n-1) - \sin \alpha n + \sin \alpha}{2(1 - \cos \alpha)} = -\frac{1}{2} \sin \alpha n + \frac{\sin \alpha(1 - \cos \alpha n)}{2(1 - \cos \alpha)}, \end{aligned}$$

we get with the abbreviations $(l + \frac{1}{2})\pi/n = \beta$, $(l' + \frac{1}{2})\pi/n = \beta'$

$$\begin{aligned} \sum_{k=0}^{n-1} c_{kl} c_{k l'} &= \gamma^2 \sum_{k=0}^{n-1} \sin \beta k \sin \beta' k = \frac{1}{2} \gamma^2 \left[\sum_{k=0}^{n-1} \cos (\beta - \beta') k - \sum_{k=0}^{n-1} \cos (\beta + \beta') k \right] \\ &= n - 1 \text{ if } l' = l \text{ and } (-1)^{l \pm l' + 1} \text{ if } l' \neq l. \end{aligned}$$

We thus see that

$$\gamma = (n - 1)^{-1/2}$$

and moreover that the coordinates ξ_l are *not exactly* orthogonal as they would be in the limiting case $n \rightarrow \infty$, $n\delta = L = \text{const.}$

¹³ Similar results would be obtained by fixing the middle point of the bar and leaving both ends free and in the opposite phase.

Squaring (17) and summing up with respect to k we have in fact:

$$\sum_{k=0}^{n-1} (\Delta x_k)^2 = \sum_{l=0}^{n-1} \xi_l^2 - \frac{2}{n-1} \sum_{l < l'} (-1)^{l'-l} \xi_l \xi_{l'}.$$

The mutual potential energy of the atoms which in the simplest case is represented by the sum

$$\sum_{k=0}^{n-2} (\Delta x_{k+1} - \Delta x_k)^2$$

also will not be reduced exactly to a sum of squares of the type

$$2\pi^2 \sum_{l=0}^{n-1} \nu_l^2 \cdot \xi_l^2$$

ν_l being the vibration frequencies, but will contain cross terms vanishing in the limiting case of a continuous bar. The problem of finding the exact normal coordinates that is the exact transformation coefficients c_{kl} in the equations (17) for a given finite value of n is rather complicated and we shall therefore use the "nearly-normal" coordinates defined above.

Since the coefficients c_{kl} do not depend upon the equilibrium spacing between the atoms δ , the same formulae (17) could be used both for the "normal" and for the "excited" bar; it should be remembered however that Δx_k has in both cases a different meaning, the equilibrium position of the k -th atom in the excited state being displaced by $\Delta \delta_r k$ with respect to that corresponding to the normal state. The same position of the atoms which in the normal state is specified by the displacements (17) will be specified from the point of view of the excited state r by the displacements

$$\Delta x_{rk} = \Delta x_k - k \Delta \delta_r = \sum c_{kl} \xi_{rl}$$

whence

$$\sum_{l=0}^{n-1} c_{kl} (\xi_{rl} - \xi_l) = -k \Delta \delta_r.$$

If c_{kl} were the correct transformation coefficients then these equations would be immediately solved by

$$\xi_{rl} - \xi_l = \Delta \xi_{rl} = - \sum_{k=0}^{n-1} c_{kl} k \Delta \delta_r.$$

Introducing here the approximate values

$$c_{kl} = \frac{1}{(n-1)^{1/2}} \sin \frac{\pi}{n} \left(l + \frac{1}{2} \right) k$$

we have

$$\Delta \xi_{rl} = - \frac{\Delta \delta_r}{(n-1)^{1/2}} \sum_{k=0}^{n-1} k \sin \alpha k$$

or

$$\Delta \xi_{rl} \cong \frac{\Delta \delta_r}{n^{1/2}} \left(\frac{\partial}{\partial \alpha} \sum_{k=0}^{n-1} \cos \alpha k \right)_{\alpha=\pi/n(l+1/2)}$$

that is according to the summation formula given above, with $\cos \alpha n = 0$, $\sin \alpha n = (-1)^l$,

$$\Delta \xi_{rl} = (-1)^l \frac{\Delta \delta_r}{2n^{1/2}} \left[n - \frac{1}{1 - \cos \alpha} \right].$$

The second term in the brackets represents probably the error due to the fact that we have been using inexact values for the coefficients c_{kl} . It would have an important influence only in the case of very small values of α corresponding to very long waves.¹⁴

Dropping it we get finally

$$\Delta \xi_{rl} = (-1)^l \frac{1}{2} \Delta \delta_r n^{1/2} = (-1)^l \frac{1}{2} \frac{\Delta L_r}{n^{1/2}} \quad (18)$$

where $\Delta L_r = n \Delta \delta_r$ denotes the change of length of the whole bar in the r excited state. Since this change is actually due to the presence of one single excited atom, it must be practically independent of the total number of atoms, whence it follows that $\Delta \delta_r$ must be inversely proportional to n , a result which we have derived above from somewhat different considerations for the case of the real three-dimensional crystal. The preceding formula which we can safely extend to this case¹⁵ thus means that the change of the normal coordinates, produced by the excitation of one atom out of n is inversely proportional to the *square root* of n . The coefficient of proportionality $\frac{1}{2} \Delta \delta_r n$ is determined by (15a) and can be shown to be of the order of magnitude of atomic dimensions.

Having established the relation between the normal coordinates of the nonexcited and those of the excited crystal we must now turn to the consideration of the Schrödinger wave functions of the corresponding "heat oscillators." These functions will be denoted by $f_{s,N_s}^0(\xi_s)$ for the N_s quantum state of the s -th oscillator in the case of the unexcited crystal and by $f_{s,N_s}^r(\xi_{rs})$ in the case of a crystal in the r -th state of an excitation multiplet. The general form of the functions $f_N(\xi)$ is given by the formula

$$f_N(\xi) = [2^N N! (\pi \alpha)^{1/2}]^{-1/2} H_N(\alpha^{1/2} \xi) e^{-1/2 \alpha \xi^2} = f_N^*(\xi) \quad (19)$$

where H_N is Hermite's polynomial of the N -th degree and α is a constant proportional to the natural frequency of the oscillator ν . If the coordinate ξ is normalized in such a way that the energy of the oscillator is represented by

$$\frac{m}{2} \left[\left(\frac{d\xi}{dt} \right)^2 + 4\pi^2 \nu^2 \xi^2 \right]$$

¹⁴ In this case we should have

$$1 - \cos \alpha \cong \frac{1}{2} \alpha^2 = (l + \frac{1}{2})^2 \pi / 2m^2$$

and

$$c_{kl} \cong (-1)^l \frac{\Delta \delta_r}{n^{1/2}} \frac{n^2}{\pi^2 (l + \frac{1}{2})^2}$$

¹⁵ Replacing l by the sum $l_1 + l_2 + l_3$.

then¹⁶

$$\alpha = 4\pi^2 m\nu / h. \quad (19a)$$

The absolute value of α does not play any role since we can always replace the coordinate ξ by $\eta = \alpha^{1/2}\xi$. If however we have to compare the behavior of the same oscillator for two different values of the frequency parameter $\nu = \nu_0$ and $\nu = \nu_r$, then we must take into account the relative value of α which gives us two different wave functions of the form

$$f_N^0(\xi_1) = f_N(\xi_1) \text{ and } f_N^{(r)}(\xi_r) = f_N\left[\left(\frac{\nu_{rs}}{\nu_{0s}}\right)^{1/2} \xi_{rs}\right]. \quad (20)$$

The function $f_N(\xi)$ can be defined here and in the sequel by formula (5) with $\alpha = 1$.

5. DETERMINATION OF THE PROBABILITY OF THE INDIVIDUAL TRANSITIONS OF A CRYSTAL FROM THE EXCITED TO THE NORMAL STATE (or *vice versa*).

The stationary states of the crystal, including the vibratory motion of the atoms can be described to a first approximation by a wave function Ψ equal to the product of an electronic function $\chi(1, 2 \cdots n)$ specifying the inner states of the atoms and of the functions (20) for all the $3n$ oscillators. We thus get for the r -th excited substate

$$\Psi_r = \chi_r(1, 2, \cdots n) \prod_{s=1}^{3n} f_{N_{rs}}\left[\left(\frac{\nu_{rs}}{\nu_{0s}}\right)^{1/2} \xi_{rs}\right] \quad (21)$$

and for the normal state

$$\Psi_0 = \chi_0(1, 2, \cdots n) \prod f_{N_{0s}}(\xi_s) \quad (22)$$

with

$$\chi_0 = \psi_1(1)\psi_1(2) \cdots \psi_1(n) \quad (22a)$$

which is obviously the same approximation to the electronic function of a number of atoms in the same state, as the functions χ_r defined by (8), are for the case when one of them is excited.

It must be remarked that whereas the factorization of the oscillator functions corresponds to the assumed absence of any direct coupling between them, the multiplication of these functions with the electronic function χ does not mean that there is no coupling between the vibratory and inner motion of the atoms, this coupling being in fact expressed (in an approximate manner of course) by the dependence of the vibration frequencies ν_{rs} upon the electronic state. Through this interaction of the electronic (inner) and the vibratory (outer) motion the different oscillators are actually coupled with each other—in a rather indirect way—and it is just this indirect coupling that enables the simultaneous transition of any number of oscillators

¹⁶ Cf. A. Sommerfeld, *Wellenmechanisches Ergänzungsband*, p. 18. This normalization corresponds to the condition $\sum \xi_s^2 = \sum (\Delta\chi)^2$ or $\sum |c_k|^2 = 1$ used above.

from one state, specified by the quantum numbers $N_{01}, N_{02} \dots N_{03n}$ to another $N_{r1}, N_{r2} \dots N_{r3n}$, if this transition is combined with an electronic one, that is with a transition of the crystal from the normal state to an excited one or *vice versa*.

The probability of such a combined transition is determined by the matrix element of the perturbation energy with respect to the functions (21) and (21a). This perturbation energy seems at first sight to be identical with the mutual potential energy of all the atoms U , which has been considered above in connection with its influence on the electronic motion. It will be remembered however, that this influence has been examined on the assumption that the atoms were at rest at the lattice points of the crystal, which corresponds to definite equilibrium values $R_{\alpha\beta}^0$ of the interatomic distances $R_{\alpha\beta}$ entering as parameters in the expression (3) for U .

Since we are now concerned with transitions due to the interaction of the electronic and vibratory motion it is necessary to take account of the change of the $R_{\alpha\beta}$'s and consequently of U which are due to the displacements of the atom from their equilibrium positions. This could be done by expanding U in a power series with respect to the differences $R_{\alpha\beta} - R_{\alpha\beta}^0$ and expressing the latter through the normal coordinates $\xi_1, \xi_2 \dots \xi_{3n}$.

The series so obtained would contain next to the equilibrium value of U a sum of squares of the coordinates ξ which must be dropped out, since it represents nothing else but the potential energy of the oscillators (accounted for separately) and further higher powers of the ξ 's which should represent a certain degree of anharmonicity and of direct coupling between the oscillators and at the same time a certain alteration of the electronic states as a result of the vibrational motion.

If we did not take into account the indirect coupling (and anharmonicity) expressed by the dependence of the vibration frequencies on the excitation state, we should have to carry out the expansion of U up to terms of the 100-th (or even higher) degree in the ξ 's in order to get a nonvanishing probability for transitions involving a 100-fold jump of the oscillators (cf. Introduction). As a matter of fact, however, this is not necessary and we can safely stop at terms of the third order (as is done in the theory of the thermal expansion and thermal conductivity of solids) thus putting

$$U = U^0 + U''' \quad (23)$$

where

$$U''' = \sum_{k,l,m} A_{klm} \xi_k \xi_l \xi_m \quad (23a)$$

the coefficients A_{klm} being certain functions of the electronic (inner) coordinates $1, 2, \dots n$.

The probability of radiationless transitions from the r -th excited state to the normal one (or *vice versa*) is determined by the matrix element of U with respect to the wave functions (21) and (22)

$$M_r \equiv \int U \psi_0^* \psi_r = \int \cdots \int \cdots \int U \chi_0^* \chi_r d\tau_1 \cdots d\tau_n \\ \cdot \prod_{s=1}^{3n} f_{N_{0s}}(\xi_s) f_{N_{rs}} \left[\left(\frac{\nu_{rs}}{\nu_{0s}} \right)^{1/2} \xi_s \right] d\xi_s.$$

Of course only such states have to be considered which have the same or nearly the same energy (the corresponding transitions are usually denoted as "resonance" ones). The energy of the crystal in the normal state is equal to the sum of the energies of the separate atoms nW_I plus the equilibrium value of their mutual potential energy

$$W_0' = \int \cdots \int U(\chi_0)^2 d\tau_1 \cdots d\tau_n \\ = \sum_{\alpha < \beta} \iint V(\alpha, \beta; R_{\alpha\beta}) |\psi_1(\alpha)|^2 |\psi_1(\beta)|^2 d\tau_\alpha d\tau_\beta \quad (25)$$

plus the vibrational energy

$$E_0 = \sum_{s=1}^{3n} \hbar \nu_{0s} (N_{0s} + \frac{1}{2}). \quad (25a)$$

The energy of the same crystal in the excited state r is represented similarly by the sum

$$W_{II} + (n-1)W_I + W_r' + E_r$$

where W_r' is given by (8) and

$$E_r = \sum_{s=1}^{3n} \hbar \nu_{rs} (N_{rs} + \frac{1}{2}). \quad (25b)$$

The condition for the radiationless transition to be a resonance one is thus expressed by the equation

$$W_{II} - W_I + W_r' - W_0' + \sum_{s=1}^{3n} [\hbar \nu_{rs} (N_{rs} + \frac{1}{2}) - \hbar \nu_{0s} (N_{0s} + \frac{1}{2})] = 0. \quad (26)$$

This equation can be approximately satisfied for a given r in a number of different ways corresponding to different jumps of the vibrational quantum numbers n_s . The total probability for the crystal to pass from the excited state into the normal one will be proportional to the sum of the squares of the matrix elements (24) (or rather their moduli) for all such "nearly resonance" transitions (see next paragraph).

In computing the matrix elements (24) we must express the normal coordinates of the excited crystal through those of the unexcited one by means of the relation (18). It is however to be kept in mind that these relations hold for the case when the ξ_s 's are so normalized that $\sum_s \xi_s^2 = \Sigma \Delta x_s^2$, which corresponds to the value (19a) of the parameter α in the functions (19). If we put

$\alpha=1$ in (19), that is replace ξ_s by $\alpha^{1/2}\xi_s$ then in using the relations (18) we must multiply the right hand side by $\alpha^{1/2}$. Putting further $\nu_r/\nu_0 = 1 + \Delta\nu_r/\nu_0$ and noticing that $\Delta\nu_r/\nu_0$ is a small quantity of the order of $1/n$ we can expand $f_N[(\nu_r/\nu_0)^{1/2}\xi_{rs}] = f_N[(\nu_r/\nu_0)^{1/2}(\xi_s + \Delta\xi_{rs})]$ in a series of powers of $1/n^{1/2}$

$$f_N[(\nu_r/\nu_0)^{1/2}\xi_{rs}] = f_N(\xi_s) + \Delta\xi_{rs}f_N'(\xi_s) + O(1/n) \quad (27)$$

$O(1/n)$ denoting the sum of terms of the order of magnitude $1/n, 1/n^{3/2}$, etc. We shall presently see that all these terms can be dropped, their contribution to the total value of the transition probability (for all the possible individual transitions) decreasing with increase of n (as $1/n$ at least), whereas the contribution of the terms proportional to $\Delta\xi_{rs}$ that is to $1/n^{1/2}$ turns out to be independent of n (see below).

The change of the vibration frequencies connected with the excitation of the crystal is thus immaterial for the transitions we are considering, these transitions being due practically solely to the minute change of the equilibrium distance between the atoms.¹⁷

We shall first consider that part of M_r which corresponds to U^0 that is

$$M_r^0 = \int \cdots \int U^0 \chi_0^* \chi_r d\tau_1 \cdots d\tau_n \prod_{i=1}^{3n} \int f_{N_{0s}}(\xi_s) f_{N_{rs}}[(\nu_{rs}/\nu_{0s})^{1/2}\xi_{rs}] d\xi_s. \quad (28)$$

The contribution of each oscillator to M_r^0 is given according to (27) by the factor

$$I_r = \int f_{N_0}(\xi) f_{N_r}(\xi) d\xi + \Delta\xi_r \int f_{N_0}(\xi) f_{N_r}'(\xi) d\xi + O(1/n). \quad (29)$$

If $N_r = N_0$, this factor reduces practically to 1. If $N_r = N_0 \pm 1$ the first term on the right side vanishes but the second is different from zero, so that $I_r = O(1/n^{1/2})$. If $|N_r - N_0| > 1$ the second term vanishes too and I_r turns out to be of the order of $1/n$ or still smaller.

We thus see that *only such transitions have to be taken into account, for which each oscillator either remains in the same state or jumps to the next one.*

From the well-known relation for Hermitian polynomials

$$\frac{d}{d\xi} H_N(\xi) = 2N H_{N-1}(\xi)$$

it follows, according to (19) (with $\alpha=1$):

$$f_N'(\xi) = (2^N N! \pi^{1/2})^{-1/2} 2N H_{N-1}(\xi) e^{-\xi^2/2} - \xi f_N(\xi) = (2N)^{1/2} f_{N-1}(\xi) - \xi f_N(\xi)$$

whence for $N_r = N_0 \pm 1$

$$I_r = -\Delta\xi_r \int f_{N_0}(\xi) f_{N_r}(\xi) \xi d\xi = -\Delta\xi_r \xi_{N_r, N_0}$$

¹⁷ This result applies to some extent to the case of diatomic molecules, where however the frequency shift also plays a marked rôle.

ξ_{N_r, N_0} being the matrix element of ξ . This matrix element is equal to $(N/2)^{1/2}$ where N is the larger of the two numbers N_r and N_0 . We thus get for the s -th oscillator ($\Delta\xi_r$ being independent of s)

$$I_{rs} = -\Delta\xi_r(N_s/2)^{1/2} \quad (N_s = N_{0s}, N_{rs} \text{ if } N_{0s} = N_{rs} = \pm 1). \quad (29a)$$

(The same result can be derived directly from the well-known formula for the matrix element of the momentum, that is of the operator $(\hbar/2\pi i) \partial/\partial\xi$). Hence it follows that in case of a transition in which p of the $3n$ oscillators jump simultaneously (to one of the next states), while the rest remain in the same state,

$$M_r^0 = [-\Delta\xi_r(N/2)^{1/2}]^p U_r^0 \quad (30)$$

where N is the geometrical mean of the p numbers N_s and

$$U_r^0 = \int \cdots \int U^0 \chi_0 \chi_r d\tau_1 \cdots d\tau_n.$$

We shall now briefly examine the second part of M_r , corresponding to U''' (23a)

$$M_r''' = \sum_{klm} \int \cdots \int A_{klm} \chi_r \chi_0^* d\tau_1 \cdots d\tau_n \phi_{klm}^r \Pi'_{klm} \quad (31)$$

where ϕ_{klm}^r denotes the integral with respect to the coordinates ξ_k, ξ_l, ξ_m containing their product as a factor. This integral is a product of three simple ones with respect to the separate coordinates if the latter are all different, or of two simple ones if $k=l \neq m$; if $k=l=m$, it reduces to an integral with respect to one variable ξ_k containing its cube as a factor. Π'_{klm} denotes the product of factors (29) for all the other normal coordinates ξ . ϕ_{klm} is different from zero in that case only if the corresponding oscillators make together three elementary jumps ($|N_{rk} + N_{rl} + N_{rm} - N_{0k} - N_{0l} - N_{0m}| = 3$), one jump each if they are all different, or a double jump and a simple one if $k=l \neq m$, or a single triple-jump if $k=l=m$.

If the total number of jumps performed by all the oscillators in the transition considered is to be equal to p , then in the product Π'_{klm} only $p-3$ factors of the type (29a) must appear, so that M_r''' may be written in the form

$$M_r''' = \sum_{klm} A_{klm}^r \phi_{klm}^r [-\Delta\xi_r(N/2)^{1/2}]^{p-3} \quad (31a)$$

A_{klm}^r being the matrix element of A_{klm} (1, 2, \cdots , n) with respect to χ_0 and χ_r . One can say that in the product $\phi_{klm}^r \Pi'_{klm}$ the first factor refers to jumps which are due to the direct coupling between three or two oscillators (or their anharmonicity) and the second one to the indirect coupling provided by the dependence of the vibrations on the excitation state.

The coefficients A_{klm} can be obviously defined by the formula

$$A_{klm} = \sum_{\alpha\beta\gamma} \left(\frac{\partial^3 U}{\partial x_\alpha \partial x_\beta \partial x_\gamma} \right)_0 \frac{\partial x_\alpha}{\partial \xi_k} \frac{\partial x_\beta}{\partial \xi_l} \frac{\partial x_\gamma}{\partial \xi_m}$$

where $x_\alpha, x_\beta, x_\gamma$ denote the x, y, z coordinates of the atoms ($\alpha, \beta, \gamma = 1, 2 \dots 3n$), and the differential coefficients $\partial x_\alpha / \partial \xi_k$, etc., are the transformation coefficients which in the unidimensional case considered above were denoted by $c_{k\alpha}$, equation (17). Since these coefficients are of the order of magnitude of $1/n^{1/2}$, we see that M_r''' , so far as its dependence upon n is concerned, is of the order of magnitude $(1/n^{1/2})^3(1/n^{1/2})^{p-3} = (1/n^{1/2})^p$, that is, of the same order of magnitude as M_r^0 given by (30).

Now M_r^0 contains as factor the matrix element U_r^0 of the mutual potential energy of all the atoms in their normal equilibrium positions with respect to the functions χ_0 and χ_r , and this factor can be easily shown practically to vanish for all excited substates r with the exception of the one $r_1 = r_2 = r_3 = 0$ for which χ_r is symmetrical with respect to the inner coordinates $1, 2 \dots n$ of all the atoms, that is representing an excitation wave of infinite length (having the same phase throughout the whole crystal). In fact using the expressions (8) for $\chi_r = \chi_{r_1 r_2 r_3}$ and (22a) for $\chi_0 = \phi_0$, we have

$$U_r^0 = \sum_{k_1 k_2 k_3} c_{rk} \int \dots \int U^0 \phi_0^* \phi_k d\tau_1 \dots d\tau_n$$

where $\phi_0 = \psi_I(1)\psi_I(2) \dots \psi_I(n)$, and ϕ_k is obtained from ϕ_0 by replacing the factor $\psi_I(k)$ by $\psi_{II}(k)$. Introducing here the expression (3) for $U = U^0$ we get $\int \dots \int U^0 \phi_0^* \phi_k d\tau_1 \dots d\tau_n = \text{sum of integrals of the type}$

$$\iint U(k, l; R_{kl}) \psi_I^*(k) \psi_{II}(k) \psi_I^*(l) \psi_I(l) d\tau_k d\tau_l$$

with respect to all values of l . Now this sum must obviously be practically independent of k , that is of the location of the atom k within the crystal—so far as *surface effects can be neglected*. Thus the preceding expression for U_r^0 reduces to the product of a constant by the sum $\sum_k c_{rk}$ which vanishes (practically, again neglecting surface effects) unless $r_1 = r_2 = r_3 = 0$.

It seems questionable whether the excited substate $r_1 = r_2 = r_3 = 0$ has actually to be taken into account or not. But even if we do not exclude it, we see that the probability of a transition from this state to the normal one, so far as it is determined by U_r^0 need not be much larger than that determined by U_r''' for similar transitions from all the other excited substates, that is transitions involving the same number p of heat oscillators or rather of elementary jumps. The matrix component M_r for such transitions having the order of magnitude $(1/n^{1/2})^p$ the corresponding probability will be proportional to $(1/n)^p$. The coefficient of proportionality cannot be determined accurately unless we restrict ourselves to transitions from the substate $r_1 = r_2 = r_3 = 0$ and neglect U''' with respect to U^0 . In this rather fictitious case (which it will however be well to consider for the sake of illustrating that part of the theory which is connected with the dependence of the resulting total probability upon the number of atoms n), the probability of a transition involving the cooperation of p heat oscillators, or rather *the square of the corresponding matrix element*, is given, according to (30) and (18), by

$$M_r^2 = |U_r^0|^2 \mu_r^p \quad (32)$$

where

$$\mu_r = \frac{\alpha(\Delta L_r)^2}{8} \frac{N}{n} \quad (32a)$$

L_r being an abbreviation for the product $\Delta\delta_r n$, and α being defined by (19a). α is the reciprocal of the square of a distance which depends upon the frequency ν_s of the corresponding oscillator. For oscillators of the maximum frequency in the acoustical spectrum $\nu_0 \leq 10^{13}$ this distance $1/\alpha^{1/2}$ is equal to $3 \times 10^{-9}/m_H^{1/2}$ cm where m_H is the atomic weight of the crystalline element we are considering with respect to hydrogen. We thus see that the product $\alpha(\Delta L_r)^2$ must be of the order of magnitude 1, at least for the higher frequency oscillators. For oscillators of lower frequencies it must however be smaller, so that these oscillators must be less effective in the transformation of the excitation energy into heat energy not only because their share is smaller, but because they have a smaller probability of getting this share.

In (32a) α and N denote certain (geometrical) mean values for all the p oscillators participating in the transition. Denoting the value of α for oscillators of the highest frequency with α_0 , we can put

$$\mu_r = \frac{\alpha_0(\Delta L_r)^2}{8n} \left(\frac{\prod_p \nu_s}{\prod_p \nu_0} N_s \right)^{1/p} \quad (32b)$$

where \prod_p denotes the product over all the p oscillators we are considering.

6. THE RESULTING (STATISTICAL) VALUE OF THE PROBABILITY OF RADIATIONLESS TRANSITIONS

The minimum value of $p = p_0$ is obtained if only oscillators of the highest frequency or next to it are taken into account. This minimum value is given by

$$p_0 = \frac{E_0 - E_r}{h\nu_0} = \frac{W_{II} - W_I + W_r' - W_0'}{h\nu_0} \quad (33)$$

according to (26), and as was mentioned above is of the order of magnitude of 100. Now these oscillators can be picked up from a much larger number Q of oscillators whose frequencies are enclosed within an interval $\nu_0 - \nu = D\nu$ which can be extremely small with respect to ν but at the same time large enough to make Q exceedingly large compared with p . Limiting ourselves to longitudinal waves (which for the same wave-length possess a higher frequency than the transverse ones), we have

$$Q = \frac{4\pi v}{u^3} \nu_0^2 D\nu$$

where v is the volume of the crystal and u the velocity of the longitudinal waves, or since $v = n\delta^3$ and $(u/\nu_0)^3 = \lambda_0^3 = 4\pi\delta^3/3$

$$Q = 3nD\nu/\nu_0. \quad (33a)$$

It must be emphasized that for a given value of $D\nu$ (or $D\nu/\nu_0$) Q is proportional to the total number of atoms forming the crystal. Taking $n \cong 10^{21}$ (which corresponds to a crystal with a volume about 1 cm^3) and $D\nu/\nu_0 = 10^{-13}$, say, we get $Q = 3 \times 10^8$ which is still a million times larger than p_0 .

Our p_0 oscillators can be picked up from the set containing Q of them in a number of different ways, this number being equal to

$$\left(\frac{Q}{p_0}\right) = \frac{Q(Q-1) \cdots (Q-p_0+1)}{1 \cdot 2 \cdots p_0} \cong \frac{Q^{p_0}}{p_0!}$$

that is according to (33a) proportional to the p_0 -th power of the total number of atoms n .

The total probability of a transition of the crystal from the excited state to the normal one, in which the excitation energy will be shared by any p_0 of the Q high frequency oscillators will thus be proportional to the product

$$M_r^2 \left(\frac{Q}{p_0}\right) = |U_r^0|^2 \frac{(\mu_r Q)^{p_0}}{p_0!} = \frac{|U_r^0|^2}{p_0!} \left(\frac{3}{8} \alpha (\Delta L_r)^2 N \frac{D\nu}{\nu_0}\right)^{p_0} \quad (34)$$

that is, will be independent of n .

The fact that it turns out to be dependent upon the choice of the interval $D\nu$ is naturally explained by our having restricted ourselves to this interval. We can obtain some approximation to the value of the probability of any transition from the excited state to the normal one, or rather to the total value of ΣM_r^2 determining this probability by taking, in the above formula $D\nu/\nu_0 \cong 1/2$ and replacing p_0 by a somewhat larger number $p = 2p_0$ say.

The problem of the determination of the resulting transition probability P_r can be solved exactly by a method which we are presently going to describe. It must be remarked however that in deriving this probability we must not restrict ourselves to the consideration of such transitions only, for which all the participating oscillators jump to a higher level. On the contrary we must take account of such transitions (which are under some circumstances by far the more frequent) in which some of the oscillators jump to a higher level and others to the lower one, adding, so to say, their energy to the excitation energy.

Further it must be remembered that the "resonance condition" expressed by the equation (26) or

$$E_0 - E_r = W_{II} - W_I + W_r' - W_0'$$

need not be exactly satisfied. In fact we have to consider, theoretically, transitions for which the difference $E_0 - E_r$ has any value whatsoever. Let us denote the sum ΣM_r^2 for all transitions for which the value of $E_0 - E_r$ is enclosed between E and $E + dE$ by $S(E)dE$. Then the transition probability which is actually observed referred to unit time is given by¹⁸

$$P_r = \frac{4\pi^2}{h} S(E) \quad (35)$$

¹⁸ See, for instance, J. Frenkel, Einführung in die Wellenmechanik p. 211, formula (72a).

E being the resonance value of $E_0 - E_r$, that is, the excitation energy of the crystal, defined by the right hand side of equation (26). $E_0 - E_r$ can be expressed as the sum $\sum p_s \epsilon_s$ over all the $3n$ oscillators, where $\epsilon_s = h\nu_s$ are the corresponding energy quanta and $p_s = 0, +1$, or -1 for an oscillator not partaking in the transition, jumping to the next higher level, and the next lower level respectively. The total number of oscillators participating in the transition p is thus equal to $\sum |p_s|$, and the excess of oscillators gaining energy over those losing it $\sum p_s$. It must be remarked that for low temperatures, and in the case of the high frequency oscillators even for room temperatures jumps of the second kind (down) may not be possible, the corresponding oscillators being in the lowest state ($N_{rs} = 0$).

We shall first neglect these downward transitions, that is, restrict ourselves to the non-negative values of p_s (0, 1). We shall further, for the sake of simplicity, take the same value of μ_r given by (32a) for all the oscillators (see below).

Our problem then reduces to the determination of the value of the sum

$$\sum' \mu_r^p = S(\epsilon) d\epsilon / |U_r^0|^2$$

for all values of the p_s ($=0, 1$) satisfying the condition

$$E \leq \sum p_s \epsilon_s \leq E + dE \quad (36)$$

p being equal to the sum $\sum p_s$. This problem is quite similar to the familiar problem met with in the Pauli-Fermi statistics of a gas with a given total energy E the p_s representing the possible numbers of particles in the s -th state. From the physical point of view they differ by the fact that instead of calculating the *number of states* of the whole system, that is the sum $\sum 1$ under the restriction (36) (the logarithm of $\sum 1$ being defined as the entropy), we have to calculate the sum $\sum \mu_r^p$, and further by the fact that E does not actually represent the energy of the system of oscillators but the change of this energy, the *states* thus being replaced by the *transitions*.

The restriction (36) can be removed by considering instead of the sum $\sum' \mu_r^p$ the sum $\sum \mu_r^p e^{-\beta E}$ with suitably adjusted parameter β (corresponding to the reciprocal of the temperature), extended over all possible values of the p_s . The second (unrestricted) sum is of course different from the first (restricted) one, but there exists a simple approximate relation between them. Writing the unrestricted sum in the form

$$\sum \mu_r^p e^{-\beta E} = \int_0^\infty S(E) e^{-\beta E} dE$$

(the factor $1/|U_r^0|^2$ is dropped for the sake of brevity), we see that the integrand $S(E) e^{-\beta E}$ must have a maximum for some value of E , which by a suitable choice of β (>0) can be made to coincide with the given value E_m lying in the interval (36). If this maximum is sharp enough, which is actually the case when E_m is not too small, we can replace the function $S(E) e^{-\beta E}$ by a Gaussian function

$$S(E_m) e^{-\beta E_m} e^{-(E-E_m)^2/\gamma^2}$$

where the parameter γ measures the width (or sharpness) of the maximum.

This gives

$$\sum \mu_r^p e^{-\beta E} = S(E_m) e^{-\beta E_m} \int_{-\infty}^{+\infty} e^{-(E-E_m)^2/\gamma^2} d(E-E_m) = S(E_m) e^{-\beta E_m} \gamma \pi^{1/2}$$

or

$$S(E_m) = \frac{e^{\beta E_m}}{\gamma \pi^{1/2}} \sum \mu_r^p e^{-\beta E} \quad (37)$$

where the (unrestricted) summation on the right hand side has to be carried out exactly.

The specified value of the parameter β can be easily determined from the condition that the "average" value E for the curve $S(E)e^{-\beta E}$ practically coincides with the extremal value E_m . This gives

$$\bar{E} = \frac{\int E S(E) e^{-\beta E} dE}{\int S(E) e^{-\beta E} dE} = - \frac{\partial}{\partial \beta} \log \int S(E) e^{-\beta E} dE = E_m$$

or

$$E_m = - \partial \log Z / \partial \beta \quad (37a)$$

where

$$Z = \sum \mu_r^p e^{-\beta E} \quad (37b)$$

is the analogue of the "state-sum" (Zustandssumme) of the usual statistical theory. The determination of the parameter γ requires some approximate knowledge of the function $S(E)$ and can be effected after the evaluation of $S(E_m)$ according to (37).

We have

$$\begin{aligned} Z &= \sum_{p_1, p_2, \dots} \mu^{(p_1 + p_2 + \dots)} e^{-\beta(p_1 \epsilon_1 + p_2 \epsilon_2 + \dots)} = \prod_s \sum_{p_s} \mu_r^{p_s} e^{-\beta p_s \epsilon_s} \\ &= \prod_s (1 + \mu_r e^{-\beta \epsilon_s}) \end{aligned}$$

whence

$$\log Z = \sum_s \log (1 + \mu_r e^{-\beta \epsilon_s}) = \int_0^{\epsilon_0} \log (1 + \mu_r e^{-\beta \epsilon}) g(\epsilon) d\epsilon \quad (38)$$

$g(\epsilon) d\epsilon$ being the number of oscillators whose energy quanta $\epsilon = h\nu$ lie between ϵ and $\epsilon + d\epsilon$. Restricting ourselves to longitudinal waves we have

$$g(\epsilon) d\epsilon = 3n\epsilon^2 d\epsilon / \epsilon_0^3.$$

Now μ_r being a very small number (of the order of $1/n$) we can put with sufficient accuracy

$$\log(1 + \mu_r e^{-\beta\epsilon}) = \mu_r e^{-\beta\epsilon}$$

which gives

$$\log Z = \frac{3n\mu_r}{\epsilon_0^3} \int_0^{\epsilon_0} e^{-\beta\epsilon} \epsilon^2 d\epsilon. \quad (38a)$$

This formula shows at once that Z is *actually independent of n* ; the same follows from (37) and (37a) for β and for $S(E_m)$, the quantity which determines the probability for which we are looking.

The above results can be easily generalized to allow for the difference of the factor μ_r for different oscillators. Replacing μ_r^p by the product $\Pi \mu_{rs}^{p_s}$ we get formulae of the same type as before. In evaluating $\log Z$ according to (38) or (38a) we have to consider μ_r as a function of the index s or of the energy $\epsilon (= \epsilon_s)$.

Denoting the value of μ_{rs} for $\epsilon = \epsilon_0$ and $N_s = 1$ with μ_r we have

$$\mu_{rs} = \mu_r \epsilon_s N_s / \epsilon_0$$

so that instead of (38a) we get

$$\log Z = \frac{3n\mu_r}{\epsilon_0^4} \int_0^{\epsilon_0} e^{-\beta\epsilon} \epsilon^3 N(\epsilon) d\epsilon. \quad (39)$$

The average value of $N(\epsilon)$ at the temperature T under the assumption of statistical equilibrium is given by Planck's law $N(\epsilon) = 1/(e^{\epsilon/kT} - 1)$. If we assume this distribution to hold for the initial (excited) state of the crystal then (since $N_{rs} = N_{0s} - 1$) the preceding expression has to be increased by 1, the average value of $N(\epsilon)$ thus being

$$N(\epsilon) = 1/(e^{\epsilon/kT} - 1) + 1 = 1/(1 - e^{-\epsilon/kT}). \quad (39a)$$

The above theory can be applied to the estimation of the probability of transitions of the opposite character, that is from the normal state to the excited one, so far as all the participating oscillators jump in the same sense, that is downwards, their energy being converted into the excitation energy. In this case we have to put of course

$$N(\epsilon) = 1/(e^{\epsilon/kT} - 1). \quad (39b)$$

It can be easily shown that our simplified theory, which takes into account jumps of the same sense only, holds for the limiting case that the product $n\mu_r$ (which is independent of n and which is a measure of the change of atomic distance produced by excitation) is very small. The probability of transitions in which p oscillators take part being approximately proportional to $(\mu n)^p/p!$ (cf. equation (34)) a strict economy in the use of the different oscillators will be observed in this case, their number being reduced to the minimum $p_0 = (E_0 - E_r)/h\nu_0 = E_m/\epsilon_0$ and "useless" jumps in the wrong sense practically excluded.

To get a rough idea of what will take place in the opposite case, that is if μn is large, we have to sum up the preceding expression for all values of p starting with $p = p_0$. If $\mu n \ll p_0$ this sum will still practically reduce to the first term. If however $\mu n \gg p_0$ it can be replaced by the sum $\sum_{p=1}^{\infty} (\mu n)^p / p!$ giving $e^{\mu n}$. The same result is obtained by replacing the sum by its maximum term, which corresponds to $p = \mu n$ and putting $p! = (p/e)^p$.

The method applied above for the approximate evaluation of the restricted sum of the products $\mu_{rs} |p_s|^{p_s}$ is no longer applicable when the numbers p_s are allowed to take negative values (-1) , for the simple reason that the function $S(E)$ has no tendency to increase in this case with increase of E . To the contrary it has a very flat maximum for $E=0$ and vanishes for $|E| > \Sigma \epsilon_s$. One could get rid of this restriction $E < \Sigma p_s \epsilon_s < E + dE$ in this case by a more general method, involving the use of Dirichlet's disruptive multiplier.¹⁹ It does not seem worth while however to develop this method at a greater length here and we shall satisfy ourselves by making a direct calculation for the simplified case $\epsilon_s = \epsilon = \text{const}$. Our problem can then be stated as follows: The number n is expressed as the sum of three numbers $n' + n'' + n'''$, denoting respectively the number of positive, negative and zero values in the sequence $p_1, p_2 \dots p_n$; to determine the sum $\Sigma' \mu^{n'+n''}$ under the restriction that $n' - n'' = p_0 = E/\epsilon$.

Since each "partitio" $n = n' + n'' + n'''$ can be effected in $n! / n'! n''! n'''!$ different ways (by permuting the numbers p_i) we get

$$\Sigma' \mu^{n'+n''} = \sum_{n''=0}^{n-p} \frac{n!}{n'! n''! n'''!} \mu^{n'+n''} (n' = n'' + p_0, n''' = n - 2n'' - p_0).$$

The ratio of the n'' -th term of this sum to the preceding one is equal to

$$(n - 2n'' + p_0 + 1)(n - 2n'' + p_0 + 2) \mu^2 / n''(n'' + p_0)$$

or approximately so long as n'' is small compared with n

$$(n\mu)^2 / n''(n'' + p_0).$$

The maximum term is that for which this ratio is equal to 1, the condition $n'' \ll n$ being obviously satisfied for $n''(n'' + p_0) = (n\mu)^2$. Replacing the sum by its maximum term we have

$$\Sigma' \mu^{n'+n''} \cong (n\mu)^{n'+n''} / n'! n''!$$

This gives if $n'' \gg 1$ using Stirling's formula

$$\Sigma' \mu^{n'+n''} = \frac{(n\mu e)^{2n''+p_0-1}}{2\pi n'' n''(n'' + p_0)^{n''+p_0}} \quad (40)$$

where

$$n'' = [(n\mu)^2 + (p_0/2)^2]^{1/2} - p_0/2. \quad (40a)$$

¹⁹ That is the integral $\int_0^\infty \sin ax \cos bx \, dx/x$ which is equal to $\pi/2$ for $a > b$, $-\pi/2$ for $a < b$ and $\pi/4$ for $a = b$.

If $n\mu$ is much larger than p_0 we can put $n'' = n\mu$ and reduce the above sum to

$$\sum'_{\mu} n'^{n''} \cong e^{2n\mu+p_0}/2\pi n\mu.$$

In the opposite case ($n\mu \ll p_0$) we have $n'' \cong (n\mu)^2/p_0$, the result given by (40) being practically the same as in the case $n'' = 0$ which corresponds to one-sided jumps, that is

$$\sum'_{\mu} n'^{n''} \cong (n\mu)^{p_0}/p_0!$$

Which case is usually met with in practice, is difficult to say.

7. RADIATIVE TRANSITIONS (ABSORPTION AND EMISSION OF LIGHT)

We have considered heretofore only radiationless transitions of the crystal from the excited state to the normal one or vice versa. We must now briefly examine such transitions which are connected with the absorption or emission of light. As has been pointed out in the introduction the excitation of a crystal by incident radiation forms the first stage of the process of light absorption, the second stage being provided by the radiationless transition to the normal state.

The energy levels or spectral terms which have to be considered in this connection are those that have been discussed already in the preceding sections, the energy of one of the excited sub states with respect to the normal state being given by (26). Since there are n -substates, corresponding to one single excitation state of an isolated atom, there must appear in the spectrum of a solid body in general n lines, corresponding to one single line in the spectrum of the gas, so far of course as the initial or the final state is the normal one. The frequencies of these lines, which can be described as forming an "excitation multiplet" are given by

$$\nu_r = (1/h)(W_{II} - W_I - W_0') + W_r'/h \quad (41)$$

if vibrational transitions are not taken into account. Allowing for these transitions we get a still larger number of spectral lines with frequencies differing from the preceding ones by the amounts

$$\Delta\nu_r = \sum [\nu_{rs}(N_{rs} + \frac{1}{2}) - \nu_{0s}(N_{0s} + \frac{1}{2})]. \quad (41a)$$

The spacing between the main lines (41) is determined approximately by the expression (15) or (8a). It is the smaller, the larger the number of atoms in the crystal. The total width of the multiplet formed by all these lines, is however independent of n and equal approximately to $V_0 + 6V_1$, where

$$V_0 = \int \int U(k, l) |\psi_{II}(k)|^2 |\psi_I(l)|^2 d\tau_k d\tau_l \quad (42)$$

and (for the case of a simple cubical lattice)

$$V_1 = 6 \int \int U(k, l) \psi_{II}^*(k) \psi_I(k) \psi_I^*(l) \psi_{II}(l) d\tau_k d\tau_l \quad (42a)$$

k and l denoting two neighboring atoms. This width is of the same order of magnitude, or perhaps just a few times larger, than the shift in the spectral levels of two atoms, produced by their combining together into one molecule. The maximum spacing between the lines of such a multiplet is of the order of $2V_1/n$, that is, so small that they should appear in practice as a continuous band even if they had no satellites due to the accompanying vibrational jumps and no natural width, which is measured by the probability of radiationless transitions we have examined before. This natural width (equal to the "mean life" of the corresponding excited substate), being independent of n must be much larger than the spacing between the consecutive lines. We thus see that the resolution of the continuous (band) spectrum of a solid body into single lines, which has been observed by J. Becquerel in the spectra of some rare earths at the temperature of liquid air and recently by W. Obreimow²⁰ in iodine and other substances at very low temperatures (of liquid hydrogen or helium) cannot be explained without special assumptions about the separation of the lines of an excitation multiplet or their intensities.

It can occur, namely, that for some excitation state II the "exchange energy" (42a) is abnormally small, so that the whole multiplet will appear as a single line, accompanied by satellites due to the vibration jumps. Since the coupling of the electronic states with the vibrational ones is determined partially by the same energy V_1 , as the width of the excitation multiplet (see for instance formula (15a) for the change of the crystal lattice δ), these satellites will be rather faint. This may account for the lines observed by Becquerel, which were not very much influenced by the temperature.

Another possible explanation is that only a few of the excited sub-levels can combine with the normal one, these combinations forming a series of more or less widely spaced lines. Now the natural width of these lines due to radiationless transitions will be the smaller the lower the temperature, for as we have seen the coefficients μ_{rs} which determine the probability of such transitions are proportional to the average values of the quantum numbers N_s and must therefore decrease as the temperature decreases. At the same time and in the same measure will the intensity of the satellites decrease due to vibrational jumps. It can thus happen that for sufficiently low temperatures the continuous spectrum of the solid body will be resolved into separate lines, in accordance with Obreimow's observations.

It is however hardly possible to substantiate the above explanation by actual calculation of the intensities of spectral lines, that is of the probabilities of transitions connected with absorption or emission of radiation.

In the simple case of an atom or a molecule these probabilities are determined by the matrix elements of the resulting electric moment of the system. In the case of a molecule consisting of n identical atoms this sum is a symmetrical function of their electronic coordinates $1, 2, \dots, n$. Replacing the molecule by a crystal and considering pure electronic transitions not accompanied by vibrational jumps, we get for the matrix element of this

²⁰ W. Obreimow and Proc. Amsterdam Acad. de Kaas 31-3, p. 353 (1928).

symmetrical function $P(1, 2, \dots, n)$ with respect to the functions χ_r and χ_0 a value which can be shown to be zero for all the excited substates with the exception of the symmetrical one (by the same argument as in Section 5). It thus seems that, as a matter of fact, the whole multiplet will be reduced to one single line, or there will be no lines whatever if the symmetrical excitation state cannot be realized.

This argument is however fallacious, for in the case of a crystal whose linear dimensions are large or even comparable with the wave-length of the absorbed or emitted light the probability of absorption or emission will be determined not by the resultant electric moment $P(1, 2, \dots, n)$ but by a sum of the moments of the separate atoms $P_k(k)$ multiplied with *certain phase factors, which depend upon the positions of these atoms R_k* . In case of a system of plane electromagnetic waves (of resonance frequency) propagated within the crystals in the direction x , say, with the phase velocity w , these factors would be $e^{i2\pi vx_k/w}$, so that the probability of absorption of a single light quantum, that is of the excitation of a single atom, would be measured by the matrix elements with respect to the functions χ_r and χ_0 of the sum $\sum P_0(k)e^{i2\pi vx_k/w}$. There is no reason why these matrix elements should vanish for most of the substates r , remaining different from zero for a few others.

The computation of the excitation probabilities by the above method can hardly give perfectly correct results, a more consequent quantum-mechanical treatment being necessary in order to obtain them, but it seems fairly certain on the basis of these crude considerations, that nothing like a selection rule for the different terms of an excitation multiplet can be expected to exist.

It is possible that the phenomenon observed by Obreimow is limited to the case of compound substances, which lie outside the scope of this investigation. Preliminary results which I have obtained for such compound crystals, seem to support this conclusion.

BAND SPECTRUM INTENSITIES FOR SYMMETRICAL
DIATOMIC MOLECULES. II

BY ELMER HUTCHISSON

UNIVERSITY OF PITTSBURGH

(Received November 10, 1930)

ABSTRACT

In a previous paper the writer derived an approximate expression for intensities in the electronic vibrational bands of symmetrical diatomic molecules, based upon the Franck-Condon theory of transition probabilities. In the present paper the approximation is carried further, by removing the restriction that the oscillations be linear. An extended formula is given making use of the Schrödinger theory of perturbations.

Calculations using this perturbation theory formula are carried out for the hydrogen absorption band spectrum. It is shown that the agreement with experiment is much improved over that obtained on the assumption of harmonic oscillations. Calculations are also made using Morse's potential function in which case the agreement is still further improved, especially for the higher transitions.

I. INTRODUCTION

IN A recent¹ paper the writer derived a formula expressing the intensities of the electronic-vibrational bands of symmetrical diatomic molecules as a function of the change in separation of the atoms and the change in the binding force between the atoms caused by the electronic transition. Since the present paper is essentially an extension of the results there obtained, the above paper will be referred to as Part I. The formula developed in Part I was used to calculate the intensities in the absorption spectra of several molecules and approximate agreement with experiment was obtained. Exact agreement was not to be expected due to the fact that the experimental temperatures were unknown and because of the approximations which had to be made in order to carry through the calculations. Three essential assumptions in deriving the intensity formula were: (1) that the complete wave function could be expressed as a product of a function of the electronic coordinates only and a function of the nuclear coordinates only; (2) that the electric moment could be separated into two parts, one of which was constant over the electron integration and the other constant over the nuclear integration and; (3) that the oscillations of the nuclei were simple harmonic. The last assumption was made not because of any theoretical necessity but merely to simplify the algebraic evaluation of the integrals involved. It is the purpose of this second part to extend the formula developed in Part I to the case in which the nuclear oscillations are nonharmonic.

II. APPLICATION OF THE PERTURBATION THEORY

In order to take care of the deviation of the nuclear oscillations from simple harmonic motion, the potential energy between the nuclei may be

¹ E. Hutchisson, Phys. Rev. **36**, 410 (1930).

expressed as a power series in a factor depending upon the displacement of the nuclei from their equilibrium separation r_e^* . The Schrödinger equation in this case is:

$$\nabla^2\Psi + 8\pi^2\mu/h^2[W - 2\pi^2\omega_e^2I_e\{\xi^2 + c_3\xi^3 + c_4\xi^4 + \dots\}]\Psi \quad (1)$$

where Ψ = the Schrödinger wave function, W = total energy, μ = the equivalent mass, h = Planck's constant, $\xi = (r - r_e)/r_e$, I_e = moment of inertia at equilibrium separation and ω_e , c_3 and c_4 are constant coefficients in the potential energy. The radial part of the wave equation then has the following form²: (letting $\xi = [h^{1/2}/2\pi(\omega_e I_e)]\eta$)

$$F'' + [\{2W/h\omega_e - kK(K+1) - \eta^2\} + k^{1/2}\{2kK(K+1)\eta - c_3\eta^3\} + k\{-3kK(K+1)\eta^2 - c_4\eta^4\}]F = 0 \quad (2)$$

where $k = h/4\pi^2\omega_e I_e$ and K is the rotational quantum number.

The normalized solution of this equation in the first approximation, in which only the first term is considered since k usually has a value less than 0.01, is:

$$F_v^0 = (2^v v! \pi^{1/2})^{-1/2} e^{-\eta^2/2} H_v(\eta) \quad \text{and} \quad (3)$$

$$W_v^0 = h\omega_e(v + \frac{1}{2}) + (h^2/8\pi^2 I_e)K(K+1) \quad (4)$$

where v is the vibrational quantum number and H is the Hermitian polynomial.

The perturbation terms in the radial waves equation are therefore:

$$V_1 = (k^{1/2}h\omega_e/2)[2kK(K+1)\eta - c_3\eta^3] \quad (5)$$

$$V_2 = (kh\omega_e/2)[-3kK(K+1)\eta^2 - c_4\eta^4]. \quad (6)$$

According to Schrödinger's perturbation theory,³ we have for the complete wave function:

$$F_v = F_v^0 + F_v^1 + F_v^2 + \dots = F_v^0 + \sum_i A_{vi} F_i^0 + \sum_j B_{vj} F_j^0 + \dots \quad (7)$$

where

$$A_{vi} = \int V_1 F_v^0 F_i^0 d\eta / (W_v^0 - W_i^0) \quad (8)$$

and

$$B_{vj} = \frac{\int V_2 F_v^0 F_j^0 d\eta}{W_v^0 - W_j^0} + \sum_{e=0}^{\infty} \frac{\int V_1 F_v^0 F_e^0 d\eta \int V_1 F_e^0 F_j^0 d\eta}{(W_v^0 - W_j^0)(W_v^0 - W_e^0)} - \int V_1 F_v^0 F_j^0 d\eta \int V_1 F_v^0 F_e^0 d\eta / (W_v^0 - W_j^0)^2 \quad (9)$$

* r_e is used in this part in place of the r_0 of Part I in order that the notation conform with that recommended by band spectroscopists, c.f., R. S. Mullikan, Phys. Rev. 36, 611 (1930.)

² E. Fues, Ann. d. Physik 80, 367 (1926).

³ E. U. Condon and P. M. Morse, Quantum Mechanics, pp. 118 ff.

where $v \neq i$ and $v \neq j$ and the limits of integration are taken from $\eta = -\infty$ to $+\infty$ instead of from -1 to $+\infty$ since the addition of the region from -1 to $-\infty$ will not appreciably affect the value of the integral for small quantum numbers. Also we have:

$$A_{vv} = 0 \text{ and } B_{vv} = -\frac{1}{2} \sum_i (A_{vi})^2. \quad (10)$$

To evaluate the integrals in the perturbation terms we make use of the recursion formulas

$$\begin{aligned} \eta F_v^0 &= [(v+1)/2]^{1/2} F_{v+1}^0 + [v/2]^{1/2} F_{v-1}^0 \\ \eta^2 F_v^0 &= [(v+1)(v+2)/2^2]^{1/2} F_{v+2}^0 + [(2v+1)/2] F_v^0 + [v(v-1)/2^2]^{1/2} F_{v-2}^0 \\ \eta^3 F_v^0 &= [(v+1)(v+2)(v+3)/2^3]^{1/2} F_{v+3}^0 + [3^2(v+1)^3/2^3]^{1/2} F_{v+1}^0 \\ &\quad + [3^2 v^3/2^3]^{1/2} F_{v-1}^0 + [v(v-1)(v-2)/2^3]^{1/2} F_{v-3}^0 \\ \eta^4 F_v^0 &= [(v+1)(v+2)(v+3)(v+4)/2^4]^{1/2} F_{v+4}^0 \\ &\quad + [(v+1)(v+2)]^{1/2} [(2v+3)/2] F_{v+2}^0 + 3[(v+1)^2 + v^2]/2^2 F_v^0 \\ &\quad + [v(v-1)]^{1/2} [(2v-1)/2] F_{v-2}^0 + [(v-3)(v-2)(v-1)v/2^4]^{1/2} F_{v-4}^0. \end{aligned}$$

The values obtained from these recursion formulas are now substituted in the integrals occurring in (8) and (9). The terms in V_1 and V_2 which depend upon the rotational quantum numbers may be neglected if we apply our results to only transitions between the first few rotational quantum states, since for actual molecules k is much smaller than c_3 or c_4 . We then obtain the following values for the constants:

$$\begin{aligned} B_{v,v+4} &= C_{v,v+4} = (1/128) [kc_3^2(4v+7) + 4kc_4] [(v+1)(v+2)(v+3)(v+4)]^{1/2} \\ A_{v,v+3} &= C_{v,v+3} = (k^{1/2}c_3/12 \cdot 2^{1/2}) [(v+1)(v+2)(v+3)]^{1/2} \\ B_{v,v+2} &= C_{v,v+2} = (1/64) [kc_3^2(7v^2 + 33v + 27) + 8kc_4(2v+3)] [(v+1)(v+2)]^{1/2} \\ A_{v,v+1} &= C_{v,v+1} = (9k^{1/2}c_3/12 \cdot 2^{1/2}) [v+1]^{3/2} \\ B_{v,v} &= C_{v,v} = -(kc_3^2/576) [164v^3 + 246v^2 + 256v + 87] \\ A_{v,v-1} &= C_{v,v-1} = -(9k^{1/2}c_3/12 \cdot 2^{1/2}) [v]^{3/2} \\ B_{v,v-2} &= C_{v,v-2} = (1/64) [kc_3^2(7v^2 - 19v + 1) - 8(2v-1)] [v(v-1)]^{1/2} \\ A_{v,v-3} &= C_{v,v-3} = -(k^{1/2}c_3/12 \cdot 2^{1/2}) [v(v-1)(v-2)]^{1/2} \\ B_{v,v-4} &= C_{v,v-4} = (1/128) [kc_3^2(4v-3) - 4kc_4] [v(v-1)(v-2)(v-3)]^{1/2}. \end{aligned}$$

Since all the A 's and B 's except those given above are equal to zero we may write the complete wave function in the simple form

$$F_v = \sum_{j=v-4}^{v+4} C_{vj} F_j^0. \quad (11)$$

To obtain a complete expression for the intensity amplitudes it is only necessary to substitute our new wave function into the final expression

(Eq. 11)⁴ of Part I. It is hardly worth while to make the substitution explicitly since the resulting expression would take up too much space and would be too cumbersome to use efficiently. However if we have a set of values calculated from the formula of Part I we may immediately obtain the corrected intensity amplitudes from:

$$I_{v'v''} = \sum_{k=v'-4}^{v'+4} \sum_{j=v''-4}^{v''+4} C_{v'k} C_{v''j} I_{kj}^0. \quad (12)$$

This expression contains in general 81 terms and therefore requires long calculations to get the required corrected intensities. The expression may be greatly simplified in many cases of absorption since then the lower electronic level is usually in a low state of vibrational excitation and may therefore be quite accurately represented by a harmonic wave function. In this case the expression becomes

$$I_{v'v''} = \sum_{k=v'-4}^{v'+4} C_{v'k} I_{kv''}^0 \quad (13)$$

which contains only nine terms.

III. APPLICATION TO HYDROGEN ABSORPTION BANDS

There are no absorption spectrum measurements which are precise enough to determine how nearly Eq. (12) represents reality for the intensities of vibrational electronic bands. However, to see what changes are introduced by removing the restriction of linear oscillations, computations are carried out for hydrogen. Hydrogen is especially suitable because at room temperatures nearly all of the molecules are in the first vibrational level so that the distribution factor does not enter into the intensity calculations and furthermore Eq. (13) instead of Eq. (12) may be quite accurately applied.

In order to have some comparison between the calculated and observed results the experimentally estimated intensities are given in Table I. They are taken from Schaafsma and Dieke⁵ and differ somewhat from those given in Part I. Estimated intensities are given for each rotational transition and show the hopelessness of exact comparisons between theory and experiment. Schaafsma and Dieke especially emphasize the difficulty of making intensity estimates for hydrogen due to the strength of the continuous spectrum in that region.

The constants used in the harmonic oscillator calculations are:

$$\begin{array}{lll} \omega_e' = 1357.3 & r_e' = 1.300 & \alpha = 0.557 \\ \omega_e'' = 4376.0 & r_e'' = 0.750 & \delta = -0.209 \end{array}$$

where α and δ are the constants in Eq. (13) of Part I. These values differ somewhat from the more recent values given by Hyman⁶ but small changes in these constants will not change the calculated intensities very much.

⁴ The constant term C_3 is given wrong on page 415 of Part I. It should read $[2/\alpha(1+\alpha^2)]^{1/2} e^{-\delta^2/2(1+\alpha^2)}$. This factor is the same for all transitions and therefore has no effect on the value of the relative intensities.

R(4)								0		
P(1)	2	3	4	5	4	4	2	3	2	3
P(2)	2	2		0	00	0	1	1	1	
P(3)	2	2		0	00	0		0		
B. Calculated										
Harmonic Oscillations	1.00	7.19	22.2	37.7	37.0	19.4	3.58	0.05	1.32	0.03
Perturbation Theory	1.00	6.6	14.1	5.2	4.7	27.4				
Morse's Function	1.00	4.28	10.7	15.5	16.4	12.5	6.96			

The above table gives the estimated relative intensities of many lines in the H_2 absorption bands which have a common initial level A_0 . Below are given the corresponding calculated intensities obtained from three different approximations. The occurrence of many gaps in the experimental part of this table is probably due to the intensity of the continuous spectra in this region.

To determine the coefficients in the power series expansion of the potential energy, formulas may be derived if one assumes the relation between the total energy and the quantum numbers as given by Fues.² If the potential energy is given by

$$U(\xi) = k(\xi^2 + c_3\xi^3 + c_4\xi^4)$$

we have

$$k = 0.1774 \cdot 10^{-11} \omega_e^2 J_e \text{ ergs}$$

$$c_3 = -(0.2179 \alpha' \omega_e J_e^2 + 1)$$

$$c_4 = 1.250 c_3^2 - 2.410 \omega_e x J_e$$

where α and x are the band spectra constants occurring in the expression for energy as a function of the quantum numbers; (the prime on the α' is used merely to distinguish it from α used in Part I). We then obtain for the potential energy expansions⁷

$$U'(\xi) = 0.459(\xi^2 - 1.560\xi^3 + 2.380\xi^4) \times 10^{-11} \text{ ergs}$$

$$U''(\xi) = 1.587(\xi^2 - 1.561\xi^3 + 1.770\xi^4) \times 10^{-11} \text{ ergs}$$

in which the following constants are used

$$J_e' = 1.404 \times 10^{-40} \text{ gm cm}^2 \quad \alpha' = 0.96 \text{ cm}^{-1} \quad \omega_e' x' = 19.54 \text{ cm}^{-1}$$

$$J_e'' = 0.467 \times 10^{-40} \text{ gm cm}^2 \quad \alpha'' = 2.7 \text{ cm}^{-1} \quad \omega_e'' x'' = 113.5 \text{ cm}^{-1}.$$

⁷ These expressions are approximately the same as those given by O. W. Richardson and P. M. Davidson, Proc. Roy. Soc. A125, 23 (1929) in which higher powers are included.

From the values of c_3 and c_4 obtained above for U' the coefficients in Eq. (13) are calculated and finally the values given in the table are obtained.

It is desirable to obtain analytical expressions for the intensities calculated by using the wave functions derived from the potential energy given by Morse.⁸ The writer has been unable to carry through the necessary integrations in this case. However in order to determine the effect of assuming such a potential function the integrations were carried out graphically and the results are given in Table I. The potential energy function in this case has the form:

$$U(\xi) = D(e^{-2a r_0 \xi} - 2e^{-a r_0 \xi})$$

where $D = c\omega_e^2 h / 4\omega_e x$ and $a = (8\pi^2 \mu c \omega_e x / h)^{1/2}$. The same band spectrum constants are used in this case as before. The fundamental constants are taken from Birge.⁹

It is apparent from Table I that the extremely high intensities given by the harmonic oscillator calculations are reduced in both of the more exact calculations in agreement with experiment. The power series calculations are only given as far as the transition $B_5 - A_0$ since even for the last two given the perturbations are so large that scarcely any faith can be placed in the results. When the coefficients c_3 and c_4 in the power series expansion are large as they are in hydrogen, the perturbation theory, even when carried out to two approximations, gives reliable results only for transitions between the lowest vibrational quantum levels.

The calculations based upon Morse's potential energy function are probably more accurate than those using the perturbation theory. This is partly due to the fact that the "A" level as well as the "B" level is corrected for deviations from simple harmonic oscillations. It is probable also that Morse's function approaches reality nearer than a three term power series for the higher transitions. Higher calculations than those given involve small differences between large quantities and are therefore subject to large errors.

These calculations were carried out at the University of Michigan and the writer wishes to express his gratitude to Professor H. M. Randall for the opportunity of spending an extremely interesting and profitable summer in Ann Arbor. The writer wishes also to thank Professor Ruark of the University of Pittsburgh for many helpful suggestions in the preparation of the manuscript.

Note added in proof: J. L. Dunham (Phys. Rev. **36**, 1553 (1930)) has pointed out that since the electric moment does not change nearly as rapidly as the eigenfunctions, the results of Part I and hence Part II, do not need to be restricted to symmetrical molecules for small quantum numbers. The correction given in footnote 4 is noted in his article also.

DERIVATION OF HYPERFINE STRUCTURE FORMULAS FOR ONE ELECTRON SPECTRA

BY G. BREIT

DEPARTMENT OF PHYSICS, NEW YORK UNIVERSITY

(Received November 24, 1930)

ABSTRACT

A short but rigorous derivation is given for the energy level separations caused by a nuclear magnetic moment in a one electron spectrum. Formulas (5) and (7) are general. For weak coupling between the orbital angular momentum and the electron spin formula (6) may be used.

FORMULAS for the hyperfine structure of one electron spectra have been derived by numerous authors.¹ The calculations are in most cases very lengthy and are carried out for special cases. The results may be obtained by the following short and yet rigorous consideration. The interaction energy of a nucleus with an electron of charge $-e$ may be represented by

$$H' = g\mu_0(A \cdot \mathbf{u}) \quad (1)$$

where \mathbf{u} is the angular momentum matrix vector of the nucleus in units $\hbar/2\pi$ and $g\mu_0\mathbf{u}$ is its magnetic moment. μ_0 is the Bohr magneton and g is a numerical factor to be determined by comparison with experiment. Here

$$A = 2\mu_0[r^{-3}L - \delta r^{-3} + 3\mathbf{r}(\mathbf{r}\delta)r^{-5}]/[1 + (eA_0/2mc^2)] \\ + 2\mu_0[\delta r^{-2} - \mathbf{r}(\mathbf{r}\delta)r^{-4}]\frac{d}{dr}[1 + (eA_0/2mc^2)]^{-1} \quad (2)$$

L is the orbital angular momentum in units $\hbar/2\pi$, 2δ is Pauli's spin vector so that $(\hbar/2\pi)\delta$ is the angular momentum of the electron spin, r is the distance from the nucleus and A_0 is the electrostatic potential. Expression (2) may be derived from the Dirac equation by eliminating two wave functions. The first part of (2) is the only important one except for s terms where the second part is responsible for all of the effect. The total angular momentum is

$$F = J + \mathbf{u} = L + \delta + \mathbf{u}. \quad (3)$$

The quantum number of F , J , L , \mathbf{u} we write as f , j , l , i . By well-known theorems about angular momenta we have for the perturbed energy

$$w = g\mu_0(AJ)_j[f(f+1) - i(i+1) - j(j+1)]/[2j(j+1)]. \quad (4)$$

Here $(AJ)_j$ is the value of any diagonal element in the matrix (AJ) in that part of it which belongs to the quantum number j . Substituting $J=L+\delta$ into (AJ) we have except for s terms

¹ J. Hargreaves, Proc. Roy. Soc. 124, 568 (1929); 127, 141, 407 (1930). E. Fermi, Zeits.f. Physik 60, 320 (1930). Unpublished calculations of Casimir quoted in Pauling and Goudsmit's book.

$$(AJ)/2\mu_0 = -\delta^2 r^{-3} + 3(\mathbf{r}\delta)^2 r^{-5} + 3(\mathbf{r}L)(\mathbf{r}\delta) r^{-5} + r^{-3} L^2.$$

The denominator of the first part of (2) being set here = 1 since $eA_0/2mc^2$ is in this case small. We note that $\mathbf{r}L=0$ and that $3(\mathbf{r}\delta)^2 - r^2\delta^2=0$. We have then

$$w = g\mu_0^2(r^{-3}L^2)_i [f(f+1) - i(i+1) - j(j+1)]/[j(j+1)]. \quad (5)$$

This is exact since the coupling to the nucleus is weak. If in addition the coupling of L and δ is weak we may write $L^2=l(l+1)$ so that

$$w = g\mu_0^2 \frac{l(l+1)}{j(j+1)} [f(f+1) - i(i+1) - j(j+1)](\overline{r^{-3}}) \quad (6)$$

For s terms the denominator $1 + (eA_0/2mc^2)$ insures the disappearance of the first part of (2) in the approximation of formula (5). In this case

$$(AJ)_i = 2\mu_0 \int_0^\infty \psi^2(r)(1/2r^2) \left\{ \frac{d}{dr} [1 + (eA_0/2mc^2)]^{-1} \right\} 4\pi r^2 dr \cong 4\pi\mu_0 \psi^2(0) \quad (6')$$

in the same approximation as Fermi's.² If therefore we add to (6) the statement that for $l=0$

$$[(\overline{r^{-3}})l(l+1)]_{l=0} = 2\pi\psi^2(0) \quad (7)$$

formula (6) becomes complete.

These results in the approximation of equation (6) are in complete agreement with the statements made in Pauling and Goudsmit's book where the calculations of Casimir have been used.

² The exact formula for a Coulomb field is found in G. Breit Phys. Rev. 35, 1447 (1930).

THE DIFFRACTION OF AN ELECTRON-WAVE AT
A SINGLE LAYER OF ATOMS

BY M. v. LAUE*

(Received October 20, 1930)

ABSTRACT

This paper undertakes to estimate the influence of the gradual transition between the field exterior to, and in the interior of a crystal, on the diffraction of electrons. This gradual transition is required by electrostatics. The result is, that this influence may be neglected for electrons whose energy is two hundred volts or more. One can then treat the transition as discontinuous. In the case of slower electrons it seems doubtful, if such a treatment is permissible.

INTRODUCTION

THE theory of the diffraction of electrons by a space-lattice has been discussed by Bethe and later, under simplifying assumptions by Morse.¹ These authors integrate the Schrödinger-equation for the internal field in so complete a manner, that little more is to be said. Their treatment of the incidence and reflection at the surface cannot be considered as equally satisfactory. They treat the triply periodic internal field as though it ceases suddenly at a certain plane. This is in complete contradiction to electrostatics, as one may not consider this plane as charged without coming into conflict with the atomistic foundations of the whole theory. The field certainly dies off asymptotically as one proceeds outward. This is doubtless a lack in the theory which, as it seems to us,—might cast doubt on its applicability to the experiments. At least it should be examined to see if and under what circumstances this approximation is justifiable. As a matter of fact it will appear that this is not always the case.

Properly one should treat the atoms as having a finite extension but then the calculations based on the Schrödinger-equation would encounter a difficulty which is only too well known in optics, namely the reflection and refraction at a plane plate with continuously variable refractive index. Of necessity, then, we will treat the atoms as point charges. The order of magnitude of our results will probably not be influenced.

To obtain a comparison let us glance at the theory of Röntgen-interference which is similar to Bethe's in many points. In this treatment one considers the space-lattice of diffracting centers to be bounded by a definite lattice-plane; one can also object to this since the atoms in the boundary planes actually do not occupy exactly the position which they would have if the crystal were continued beyond the boundary. But since a single layer of atoms contributes very little to the resultant intensity of Röntgen-rays this

* Translated from the German by C. Eckart.

¹ H. Bethe, *Ann. d. Physik* **87**, 55 (1928); P. M. Morse, *Phys. Rev.* **35**, 1910 (1930).

assumption can have little influence. In the case of electron-diffraction things are essentially different.

Let the primitive periods of the lattice-plane be the vectors \mathbf{a}_1 and \mathbf{a}_2 ; the reciprocal vectors $\mathbf{b}_1, \mathbf{b}_2$ which lie in the same plane are defined by the equations

$$(\mathbf{a}_1\mathbf{b}_1) = 1, (\mathbf{a}_1\mathbf{b}_2) = 0, (\mathbf{a}_2\mathbf{b}_1) = 0, (\mathbf{a}_2\mathbf{b}_2) = 1. \quad (1)$$

The surface-density of electricity in this plane will be

$$\rho = \sum_1 \rho_m e^{2\pi i(\mathbf{b}_m \mathbf{r})} \quad (2)$$

where \mathbf{r} is the vector drawn from an arbitrary origin in the lattice-plane to the point of consideration, and

$$\mathbf{b}_m = m_1 \mathbf{b}_1 + m_2 \mathbf{b}_2. \quad (3)$$

The coefficient ρ_0 is zero, since the total charge must vanish. The other coefficients are given by the equation

$$\rho_m = \frac{1}{F} \int \rho e^{-2\pi i(\mathbf{b}_m \mathbf{r})} d\sigma,$$

in which F is the area of the parallelogram subtended by $\mathbf{a}_1, \mathbf{a}_2$, and the integration is to be extended over such a parallelogram. If a positive pole of charge Z lie at $\mathbf{r}_+ = \delta_1 \mathbf{a}_1 + \delta_2 \mathbf{a}_2$ a negative pole of the same strength at $\mathbf{r}_- = -(\delta_1 \mathbf{a}_1 + \delta_2 \mathbf{a}_2)$ then according to 1):

$$\rho_m = -\frac{2Z\epsilon}{F} i \sin 2\pi(m_1 \delta_1 + m_2 \delta_2). \quad (4)$$

We assume that the lattice plane has the equation $z=0$. Then these charges produce the potential

$$\phi = \sum \phi_m e^{2\pi i(\mathbf{b}_m \mathbf{r})} e^{-2\pi |\mathbf{b}_m| |z|} \quad (5)$$

in which²

$$\phi_m = \frac{\rho_m}{|\mathbf{b}_m|}. \quad (6)$$

The coefficient ϕ_0 vanishes. It would have to be—because of $\Delta\phi=0$ —a linear function of z and this must vanish because of the boundary conditions at $z = \pm \infty$.

It would be otherwise if we had, e.g., two parallel planes of which the one had a net positive charge, the other an equal negative: then ϕ_0 would be different from zero between the two planes. Also if the atoms were not taken to be point-charges there would be regions in which ϕ_0 did not vanish.

² This series is naturally double. The index m represents the pair of indices m_1 and m_2 which occur in (3) explicitly.

The Schrödinger-equation of the free electron

$$\Delta\psi + \frac{8\pi^2\mu}{h^2}E\psi = 0$$

is integrated by the function

$$\psi = e^{2\pi i(K_0 R)}, \quad (K_0) = \frac{1}{h}(2\mu E)^{1/2} \quad (7)$$

in which \mathbf{R} is the three-dimensional vector to the point under consideration (Aufpunkt); \mathbf{r} is the component of \mathbf{R} parallel to the plane $z=0$, μ the mass of electron. We also resolve the vector \mathbf{K}_0 into a component k_0 parallel to this plane and one parallel to the z axis— z the magnitude of the latter is $\kappa_0 = (K_0^2 - k_0^2)^{1/2}$. Then Eq. (7) becomes

$$\psi = \psi_0(z) e^{2\pi i(k_0 \mathbf{r})}, \quad \psi_0(z) = e^{2\pi i\kappa_0 z} \quad (8)$$

We assume that κ_0 is positive; the wave then proceeds from positive to negative z -values.

The Schrödinger-equation of the electron as perturbed by the lattice-plane

$$\Delta\psi + \frac{8\pi^2\mu}{h^2}(E - \epsilon\phi)\psi = 0$$

we attempt to resolve in the form

$$\psi = \sum \psi_m(z) e^{2\pi i(k_0 + b_m, \mathbf{r})}.$$

It then reads

$$\Delta\psi = \sum \left(\frac{d^2\psi_m}{dz^2} - 4\pi^2(k_0 + b_m)^2\psi_m \right) e^{2\pi i(k_0 + b_m, \mathbf{r})} \quad (9)$$

from which we can cancel the factor $e^{2\pi i k_0 \mathbf{r}}$. The remaining equation is then:

$$\begin{aligned} \sum_m \left(\frac{d^2\psi_m}{dz^2} + 4\pi^2(K_0^2 - (k_0 + b_m)^2)\psi_m \right) e^{2\pi i(b_m, \mathbf{r})} \\ = \frac{8\pi^2\epsilon\mu}{h^2} \sum_{p,q} \psi_p(z) \phi_q e^{-2\pi i|b_q||z|} e^{2\pi i(b_q + b_p, \mathbf{r})} \end{aligned}$$

According to Eq. (3)

$$b_p + b_q = b_{p+q}.$$

Since this equation must be true for every value of the vector \mathbf{r} , the separate terms on each side which have the same exponential factor must be identical, i.e.

$$\frac{d^2\psi_m}{dz^2} + 4\pi^2(K_0^2 - (k_0 + b_m)^2)\psi_m = \frac{8\pi^2\epsilon\mu}{h^2} \sum_p \psi_p(z) \phi_{m-p} e^{-2\pi i|b_{m-p}||z|} \quad (10)$$

To solve this system of infinitely many differential-equations with infinitely many unknowns $\psi_m(z)$ we use a method of approximation. As first approximation one will substitute for ψ_0 the value (8) of the wave-function of the unperturbed incident wave, and retain only the term in ψ_0 on the right side of (10). The weaker the intensity of the diffracted waves comes out, the better will be this approximation. Since $\phi_0 = 0$ we then obtain the equation:

$$\frac{d^2\psi_m}{dz^2} + 4\pi^2(K_0^2 - (k_0 + b_m)^2)\psi_m = \frac{8\pi^2\epsilon\mu}{h^2}\psi_0(z)\phi_m e^{-2\pi|b_m||z|} \quad (11)$$

of which the solution satisfies the condition that it must represent *emergent* waves at $z = \pm \infty$ is

$$\psi_m(z) = 2\pi i \frac{\epsilon\mu}{h^2} \frac{\phi_m}{\epsilon_m} \left\{ e^{2\pi i \epsilon_m z} \int_z^\infty \psi_0(\xi) e^{-2\pi|b_m||\xi|} e^{-2\pi i \epsilon_m \xi} d\xi + e^{-2\pi i \epsilon_m z} \int_{-\infty}^z \psi_0(\xi) e^{-2\pi|b_m||\xi|} e^{+2\pi i \epsilon_m \xi} d\xi \right\}. \quad (12)$$

The abbreviation

$$\epsilon_m = (K_0^2 - (k_0 + b_m)^2)^{1/2} \quad (13)$$

has been used. That this is a solution of Eq. (11) will be seen on substitution. For $z = +\infty$ we obtain from (12):

$$\psi_m = 2\pi i \frac{\epsilon\mu}{h^2} \frac{\phi_m}{\epsilon_m} e^{-2\pi i \epsilon_m z} \int_{-\infty}^{+\infty} \psi_0(\xi) e^{-2\pi|b_m||\xi|} e^{+2\pi i \epsilon_m \xi} d\xi \quad (14)$$

At $z = -\infty$ correspondingly

$$\psi_m = 2\pi i \frac{\epsilon\mu}{h^2} \frac{\phi_m}{\epsilon_m} e^{+2\pi i \epsilon_m z} \int_{-\infty}^{+\infty} \psi_0(\xi) e^{-2\pi|b_m||\xi|} e^{-2\pi i \epsilon_m \xi} d\xi. \quad (15)$$

These are the emergent waves required by the boundary conditions, at least, if ϵ_m is real and positive.

The latter may always be assumed to be the case, as the sign is not defined by (13). The former is not always true according to (13). In addition to the diffracted homogeneous waves there are also inhomogeneous ones which are propagated along the lattice-plane and die off asymptotically in a direction perpendicular to this plane. For every pair with indices m with real ϵ_m there are always two emergent waves on each side of the lattice-plane.

It will be remarked that Eq. (12) is still valid for such index pairs, m , for which $i\epsilon_m$ is positive and real.³ If one draws the factor $e^{\pm 2\pi i \epsilon_m z}$ under the integral sign, then the bracket in (13) has the value

$$\int_z^\infty \psi_0(\xi) e^{-2\pi|b_m||\xi|} e^{2\pi i \epsilon_m (z-\xi)} d\xi + \int_{-\infty}^z \psi_0(\xi) e^{-2\pi|b_m||\xi|} e^{-2\pi i \epsilon_m (z-\xi)} d\xi$$

³ Negative real values may be left out of account since the sign of the root in (13) is arbitrary; they must be left out of account, because Eq. (12) is not longer valid when $i\epsilon_m < 0$.

in the first of these integrals $z - \zeta$ is negative, in the second positive. They both exist therefore. Only Eqs. (14) and (15) must be changed for this case; but our interest is only for the homogeneous waves, i.e., real values of ϵ_m .

For the justification of this calculation it is essential that Eq. (11) applied to the index pair 0,0 possesses the solution $\psi_0(z)$ as given in Eq. (8). This would not be the case, if ϕ_0 did not vanish. In that case we would encounter the problem of the plane parallel plate as remarked in the introduction and would have to use its solution in evaluating the other ψ_m .

The integrals in (14) and (15) are to be evaluated for real values of ϵ_m and ψ_0 as in (8). They are

$$\begin{aligned} & \int_{-\infty}^{+\infty} e^{2\pi i(\kappa_0 \pm \epsilon_m)\zeta} e^{-2\pi |b_m| |\zeta|} d\zeta \\ & \int_0^{\infty} e^{2\pi i(\kappa_0 \pm \epsilon_m)\zeta} e^{-2\pi |b_m| \zeta} d\zeta + \int_{-\infty}^0 e^{2\pi i(\kappa_0 \pm \epsilon_m)\zeta} e^{+2\pi |b_m| \zeta} d\zeta \\ & = 2 \int_0^{\infty} \cos(2\pi(\kappa_0 \pm \epsilon_m)\zeta) e^{-2\pi |b_m| \zeta} d\zeta = \frac{1}{\pi} \frac{|b_m|}{(\kappa_0 \pm \epsilon_m)^2 + b_m^2} \end{aligned}$$

If we now use the value of ϕ_m given by (6) and ρ_m given by (4), we obtain

$$\psi_m(z) = \frac{4Z\epsilon^2\mu}{h^2} \frac{\sin 2\pi(m_1\delta_1 + m_2\delta_2)}{F} \frac{e^{\mp 2\pi i\epsilon_m z}}{\epsilon_m[(\kappa_0 \pm \epsilon_m)^2 + b_m^2]} \text{ for } z = \pm \infty \quad (16)$$

in which the abbreviations

$$\begin{aligned} \kappa_0 &= (K_0^2 - k_0^2)^{1/2} = |K_0| \cos \theta, \quad |K_0| = \frac{1}{h}(2\mu E)^{1/2} \\ \epsilon_m &= (K_0^2 - (k_0 + b_m)^2)^{1/2} = (K_0^2 \cos^2 \theta - 2(k_0 b_m) - b_m^2)^{1/2} \end{aligned}$$

have been used. The angle θ is the angle of incidence of the original electron wave. Only the last of the three fractions in (16) depends on the energy of the electrons, and it diminishes with increasing E approximately as $E^{-3/2}$. For sufficiently fast electrons the amplitude of every ψ_m -wave is so small, that the diffracting-power of the single atomic layer is insignificant. The neglect of the surface layers is then justified. To obtain an estimate of the lower limit above which this is true we will later evaluate Eq. (16) numerically.

One can best estimate the strength of an inhomogeneous wave if one determines its amplitude in the lattice-plane itself ($z=0$). We designate the real positive quantity $i\epsilon_m$ by η_m . From (12), (6) and (4) it then follows without difficulty that:

$$\psi_m(0) = \frac{4Ze^2\mu}{h^2} i \sin 2\pi(m_1\delta_1 + m_2\delta_2) \frac{|b_m| + \eta_m}{|b_m|(\eta_m)[(b_m + \eta_m)^2 + \kappa_0^2]}.$$

One notices the diminution of the amplitude with increasing indices m_1, m_2 .

For numerical purposes we suppose the vectors a_1, a_2 perpendicular the one to another and both of length 4×10^{-8} cm. Then the reciprocal vectors b_1, b_2 will also be perpendicular and of the magnitude 2.5×10^7 cm $^{-1}$. In each square formed by a_1, a_2 we suppose one positive and one negative charge—each of $Z=1$, but we do not determine their positions more definitely, i.e., the numbers δ_1, δ_2 are thus undetermined. Then the first factor in (16) is

$$\frac{4e^2\mu}{h^2F} = 1.25 \times 10^{22} \text{ cm}^{-3}.$$

We suppose an electron beam of 150 volts energy to be incident normally on this lattice plane. The de Broglie wave-length is 10^{-8} cm, also $\kappa_0 = |k_0| = 10^8$ cm $^{-1}$. Then only those homogeneous waves can appear, for which the indices m_1, m_2 are any combination of the numbers ± 1 and 0. This results in 8 emergent beams from each side of the lattice plane. If one index is 0, the other ± 1 Eq. (16) gives

$$\frac{|\psi|^2_{z=+\infty}}{\sin^2(2\pi(m_1\delta_1 + m_2\delta_2))} = 10^{-5}, \quad \frac{|\psi|^2_{z=-\infty}}{\sin^2(2\pi(m_1\delta_1 + m_2\delta_2))} = 4 \times 10^{-2}$$

If both indices are ± 1 , then one finds

$$\frac{|\psi|^2_{z=+\infty}}{\sin^2(2\pi(m_1\delta_1 + m_2\delta_2))} = 1.5 \times 10^{-5}, \quad \frac{|\psi|^2_{z=-\infty}}{\sin^2(2\pi(m_1\delta_1 + m_2\delta_2))} = 3 \times 10^{-3}$$

$\sin^2(\)$ is the structure factor and obviously depends on the position of the two pointcharges in the elementary parallelogram. Since we set the intensity of the incident wave equal to 1, the foregoing numbers represent the relative intensity of the diffracted rays. As they are small compared with 1, one will conclude firstly, that the present approximation is sufficient, and secondly, that the diffracting-power of the single plane is so small that it is justified to neglect the surface fields as Bethe and Morse have done.

The result is quite different if we consider electrons of energy 37.5 volts, other things remaining the same (wave-length $\lambda = 2 \times 10^{-8}$ cm). Then the only possible homogeneous waves are those for which one index is 0, the other ± 1 . At $z = +\infty$ the fraction $|\psi|^2/\sin^2(\)$ has a sufficiently small value, namely 10^{-5} ; but for $z = -\infty$ it becomes even greater than 1, which naturally means that the present approximation is useless. In this case it seems that space lattice theories of Bethe and Morse require extension by considerations regarding the surface layers.

In summary we may safely say, despite the fact that the case here considered is far from the real one, that for electrons of 200 or more volts energy

the neglect of the surface action in the space lattice theory of electron diffraction is justified, but that this is not obviously true at smaller velocities.

In the experiments of Stern and his collaborators on the diffraction of atoms and molecules by crystals, the plane-grating-action of the surface is the only thing observed, no space-lattice effects. The theory of these phenomena one must probably attempt to carry through in a similar manner to the above. The essential difference will be in a different value of the coefficients ϕ_m of the Fourier-series for the potential energy. The form (9) for the wave-function and the approximation introduced in (11) may probably be retained.

SOME PHOTOELECTRIC AND THERMIONIC PROPERTIES OF RHODIUM

BY E. H. DIXON

DEPARTMENT OF PHYSICS, UNIVERSITY OF GEORGIA

(Received November 19, 1930)

ABSTRACT

A thin ribbon of rhodium was subjected to rigorous heat treatment at 950°–1450°C for 1050 hours in a final vacuum of 10^{-8} mm of Hg in order to put it in a stable condition for photoelectric and thermionic measurements. During this period the long wave limit shifted from about 2530Å to 3150Å and then shifted back to 2509Å where it remained during the latter 375 hours of heat treatment.

The photoelectric current was found to increase about 130% as a result of increasing the temperature of the rhodium from 25°C to 950°C. A rather sudden increase took place at about 240°C.

The photoelectric work function at 25°C was determined from the final long wave limit of 2482–2536Å to be 4.92 ± 0.06 volts. The long wave limit at 240°C was 2652–2752Å which gave a photoelectric work function of 4.57 ± 0.09 volts for this temperature. No further change in long wave limit was observed up to 650°C.

An anomaly was observed at 1100°C where the thermionic current was irregular and where the rate of change of the resistance of the rhodium with temperature changed on increasing the temperature.

The thermionic work function of rhodium, as determined from observations and with Richardson's equation, was 4.58 ± 0.09 volts. This value agrees with the photoelectric work function at 240°C.

Pure hydrogen and oxygen were introduced separately into the experimental tube while the rhodium was in its outgassed equilibrium condition. In the case of hydrogen the wave limit was changed from 2482–2536Å to 2378–2482Å. In the case of oxygen the wave limit was changed from 2482–2536Å to a value so low that it could not be determined by the method used in this work.

AMONG the photoelectric and thermionic studies of metals which have been subjected to rigorous heat treatment, or distillation, there are: DuBridge's¹ extensive study of the thermionic and photoelectric properties of platinum; Cardwell's² work with iron and cobalt; Martin's³ thermionic and photoelectric study of molybdenum; Warner's⁴ work with tungsten; the work of Kazda,⁵ Dunn,⁶ and Hales⁷ on mercury; and Goetz's⁸ study of tin.

The object of this investigation has been (1) to investigate the photoelectric and thermionic properties of rhodium during and after subjection

to rigorous heat treatment and (2) to introduce known gases in order to determine their effects upon the photoelectric properties of rhodium in the outgassed condition.

APPARATUS

The experimental tube was similar to that used by DuBridge⁹ with a few exceptions. Charcoal was not used in this work. Potential leads, spot-welded about a quarter of an inch below the ends of the filament, permitted the measurement of the P. D. across the filament. A grounded guard ring was installed between the collecting cylinder lead and all of the other leads of the experimental tube. The fact that Pyrex was sufficiently conducting at 100° C to prevent an accurate measurement of the photoelectric current immediately after cutting off the heating current made this device compulsory. The rhodium, purchased from the American Platinum Works, Newark, N. J. in the purest state that they could furnish, was in the form of ribbons 10 cm long by 0.4 cm wide by 0.004 cm thick. Each ribbon, bent in the form of a loop, was suspended inside a molybdenum collecting cylinder from two fifty mil tungsten leads through which current could be sent to heat the specimen to any desired temperature. All of these devices were enclosed in a Pyrex tube which was connected through two liquid air traps, a mercury cut-off, and a water-cooled mercury diffusion pump to a "Cenco" fore pump. The molybdenum cylinder was provided with two one half inch holes, one for illuminating the specimen and the other for pyrometric measurements of the temperature. A shutter, operated by an external magnet, could cover the opening through which the photo-active light had to pass. A quartz window, attached to the experimental tube by means of a graded quartz-Pyrex seal, served to admit radiation from a Cooper-Hewitt quartz mercury arc which was operated by a current of 3.1 amperes. The vertical arc was enclosed in a metal housing. Pressures lower than 10^{-6} mm of Hg were measured with an ionization manometer which was calibrated by extrapolating from data obtained by means of a McLeod gauge. The extrapolation was based on the work of Dushman and Found.¹⁰ The photoelectric currents due to the full radiation of the mercury arc were measured by means of a Compton¹¹ electrometer shunted with a resistance of 10^9 ohms, thus permitting the use of the steady deflection method of measuring current. The sensitivity of the electrometer was determined at the time of each observation. The rate of charge method of detecting current was used in getting the long wave limit.

OUTGASSING TREATMENT

For 48 hours the molybdenum collecting cylinder was heated by electron bombardment in an auxiliary vacuum system at 800–1000°C before it was introduced into the experimental tube. When the experimental vacuum system was apparently free from leaks and the pressure was as good as could

be read on the McLeod guage (of the order of 10^{-7} mm of Hg), the ionization manometer, the experimental tube, and the second liquid air trap were heated for 94 hours at approximately 400, 500, and 500 degrees C respectively. At the end of this period the pressure was again of the order of 10^{-7} mm of Hg while the tubes were hot. Then, in order to avoid excessive evaporation of the specimen, it was heated by a current at temperatures which were gradually increased from about 900°C to 1250°C and finally to 1450°C . The high vacuum end of the system up to the first liquid air trap was heated with a torch.

FATIGUE

In Fig. 1 the photoelectric current due to the full arc is plotted as a function of the time of rest after cutting off the heating current. After fifty hours heating of the specimen there is a marked fatigue which becomes more pronounced until 250 hours of heating. Then it becomes rapidly less marked until

Fig. 1. Decrease of photoelectric sensitivity with time, using full arc.

Curve #1, taken after 50.5 hours of heat treatment.

Curve #2, " " 116.5 " " " "

Curve #3, " " 250.5 " " " "

Curve #4, " " 276.9 " " " "

Curve #5, " " 372.2 " " " "

there is practically no fatigue except for the first four or five minutes after cutting off the heating current. The drop in sensitivity during this short interval can be reasonably attributed to the fact that it required four or five minutes for the filament to cool to approximately room temperature. That this is the probable cause of the rapid initial change was shown by correlating the rate of cooling of the filament, as determined from resistance measurements, with the temperature change of photo-sensitivity. In determining a fatigue curve the first photoelectric observation was taken one minute after the heating current was stopped, and from the above mentioned comparison it was concluded that the filament was at this instant at a temperature of about 240°C . The change in the photo-current during the next

few minutes is associated with a phenomenon discussed in the next paragraph.

VARIATION OF PHOTOELECTRIC SENSITIVITY WITH TEMPERATURE

Rhodium, like Pt, Co, W, and Fe in the γ form, has a positive temperature coefficient after it has been subjected to severe outgassing conditions. There is an increase of 130% in the photoelectric current in going from room

Fig. 2. Total photo-current as a function of heating current.

temperature to a temperature of 950°C. In Fig. 2 the photoelectric current due to the full arc is plotted as a function of the heating current. The temperature was decreased slowly from 1100°C to 950°C and then readings were taken as indicated in Fig. 2. The data for this curve were taken after the filament had been heated for 640 hours at approximately 1250°C. The pressure was 10^{-8} mm of Hg. For each reading five minutes were allowed for

Fig. 3.

Fig. 4.

attaining temperature equilibrium. The photo-current variation with temperature between 240°C and 950°C can be reproduced without serious difficulty. The difference between the two curves in Fig. 2 between 240°C and 950°C is due to the fact that the specimen was cooled slowly from 1100°C where rhodium exhibits an unusual characteristic. This will be discussed in connection with the thermionic current as a function of temperature. The factors affecting the behavior of rhodium below 240°C are complicated and it

is not always possible to predict in advance the exact type of curve that will result when the temperature is decreased from 240°C to room temperature. The data for the curves in Figs. 3 and 4 were taken under apparently the same conditions, yet the final currents at room temperature are very different. In the case of the curve in Fig. 3—the more frequent type of curve—the final photo-current observed with zero heating current was not stable, but decreased in approximately one hour from the value at *A* to the value at *B*. Under the conditions of Fig. 4 on the other hand a stable condition was reached at once by the same gradual reduction of the heating current to zero. If the heating current was instantly reduced to zero when the filament was at about 1250°C (heating current of 12 amperes) the stable condition represented by *B* would always be reached in about 10 minutes. As mentioned above, almost half of this delay is accounted for by the time required for the filament and its surrounding cylinder to cool to room temperature. The behavior in the range from 240°C down depends also upon the vacuum conditions, a sequence such as that of Fig. 4 occurring only under the best conditions. The complicated situation which these curves suggest will be discussed later.

THE PHOTOELECTRIC LONG WAVE LIMIT

During the early stages of outgassing, the long wave limit was obtained by means of Corning glass filters. The final value, however, was located by using various solutions of tartaric acid, acetic acid, and the glass filters. Spectrograms of all filters were made at the same time that they were used. The wave limit was between 2378Å and 2482Å before any heat treatment. The specimen was heated for five hours at 500°C after which the long wave limit was between 2536Å and 2752Å. During the baking period of 94 hours it decreased to about 2536Å. Then, on heating the rhodium at temperatures

TABLE I.

Time of heating specimen (hours)	Heating temperature (degrees C)	Long wave limit (angstroms)
25	900	2967
59	1025	2804–2967
81	1025	2804–2967
144	1025	2967–3341
190	1250	2967–3341
213	1250	(2536)–2752
267	1250	(2536)–2752
419	1250	2652–2752
676	1250	2482–2536
1051	1450	2482–2536

varying from 900°C to 1450°C, its long wave limit varied with time of outgassing as indicated in Table I. During the latter 375 hours the long wave limit remained between the 2482Å and 2536Å lines. Both of these lines are very intense and the limit could be very definitely located between them. If this limit is taken to be characteristic of outgassed rhodium, Einstein's¹² photoelectric equation gives for its photoelectric work function at 25°C

¹² Einstein, Ann. d. Physik 17, 132 (1905).

$$V = \frac{ch\nu_0}{e} = \frac{c^2h}{e\lambda_0} = \frac{12335}{\lambda_0} = 4.92 \pm 0.06 \text{ volts,}$$

where Birge's¹³ values for the constants are used and λ_0 is $(2482 + 2536)/2\text{\AA}$. The long wave limit for the rhodium at approximately 240°C (corresponding to a heating current of 2.5 amperes) was found to lie between the 2652\text{\AA} and 2752\text{\AA} lines. The average of these values gives for the photoelectric work function at 240°C

$$V = \frac{12335}{2702 \pm 50} = 4.57 \pm 0.09 \text{ volts.}$$

No further change in long wave limit has been observed up to 650°C . Nevertheless, the photo-current continues to increase up to 950°C . An increase in temperature, therefore, appears to increase both the surface work function and the quantum efficiency.

THERMIONIC CURRENT AS A FUNCTION OF HEATING CURRENT

The thermionic current was measured with a Leeds and Northrup galvanometer which had a sensitivity of 1.57×10^{-10} amperes per mm deflection at a scale distance of 1.5 meters. In Fig. 5 the thermionic current is plotted

Fig. 5.

Fig. 6.

as a function of the heating current in amperes. The most interesting part of the curve is at approximately 10.7 amperes (about 1100°C) where the thermionic current is irregular. In the case of gradually decreasing the heating current and observing the thermionic current at short intervals of heating

¹³ Birge, Phys. Rev. Supplement 1, 1 (1929).

current, the writer has been able to obtain at about 10.7 amperes of heating current a gradual increase in the thermionic emission (heating current kept constant) until it reached a maximum value corresponding to an increase of temperature of approximately 25°C and then a gradual decrease in emission until equilibrium was reached at a value very close to what it was before the gradual increase began (see Fig. 6). This phenomenon indicates that at about 1100°C a change which liberates heat takes place on cooling rhodium.

Cardwell¹⁴ published a similar thermionic curve for iron in which the thermionic current was irregular at 910°C , where the crystal structure changes from the body centered cubic to the face centered cubic type. One would think that the similar break in the thermionic curve for rhodium is due to the same cause; that is, to a change in the crystal structure. However, it is possible that the break is due to absorption or evolution of gas at this temperature. Nevertheless, it must be remembered that this specimen of rhodium had had more than 600 hours of heat treatment at about 1250°C in a final vacuum of 10^{-8} mm of Hg when the data for this curve were taken, and also that it has been impossible to detect any change in pressure peculiar

Fig. 7.

to this particular temperature while increasing or decreasing the heating current. The crystal structure of rhodium at various temperatures is now being determined in this laboratory by means of x-rays.

Mendenhall and Ingersoll¹⁵ observed an anomaly at about 1050°C , consisting of an easily reversible change in the radiation of the surface of a small sphere of rhodium heated on a Nernst glower. They reported further that, as the temperature was lowered, the sphere became rather suddenly brighter—the change being seen to spread rapidly over the globule—and that, if the temperature was raised again, the reverse change took place. The fact that these observations were in air at normal pressure, while the present observations were in a very high vacuum, favors the view that the cause is a structure change rather than a gas action.

RESISTANCE AS A FUNCTION OF HEATING CURRENT

In Fig. 7 the resistance of the specimen of rhodium is also plotted as a function of the heating current. It is interesting to observe that, at about

¹⁴ Cardwell, Nat. Acad. Sci. 14, 439 (1928).

¹⁵ Mendenhall and Ingersoll, Phil. Mag. 15, 205 (1908).

10.3 and 10.7 amperes of heating current, a definite change in slope occurs in the resistance curve. It is reasonable to suppose that the two breaks are due to unevenness of the temperature of the filament, because this curve was taken after the filament had been heated for 575 hours at approximately 1250°C. The fact that the slope of the resistance curve changes abruptly suggests the idea that a change in the structure may be taking place in the rhodium.

THE THERMIONIC WORK FUNCTION

The black-body temperatures of the rhodium strip were measured with a disappearing filament type of optical pyrometer which had been calibrated at the gold and palladium points and sectored down from the palladium point to the gold point. The readings were corrected for the transmission of the Pyrex window by means of data taken before it was sealed to the experimental tube. Then the true temperatures were computed from the relation

$$1/T - 1/S = \lambda \log \epsilon / c_2 \log e,$$

where T is the true temperature, S the apparent temperature, λ the wavelength used, ϵ the emissivity,¹⁶ c_2 a constant in Wien's equation, and e the

Fig. 8.

Naperian base. Fig. 8 gives the relation between $(\log i - 2 \log T) / (\log e) + C$ and $1/T$. The slope of this curve is the b in Richardson's relation

$$i = AT^2 e^{-b/T},$$

where i is the thermionic current and A is a constant.

$$b = 53,100^\circ \text{K}.$$

Hence, the thermionic work function is

$$V = \frac{bk}{e} = \frac{53100 \times 1.371 \times 10^{-16} \times 299.8}{4.770 \times 10^{-10}} = 4.58 \text{ volts.}$$

¹⁶ Bulletin of Bureau of Standards 11, 595 (1914-15).

From other curves it is estimated that the result can be reproduced easily within 2%. Therefore, the thermionic work function is 4.58 ± 0.09 volts. This value agrees with the value given for the photoelectric work function at 2.5 amperes of heating current (approximately 240°C).

THE EFFECT OF PURE HYDROGEN AND OXYGEN ON OUTGASSED RHODIUM

Extreme care was given to the purification of the hydrogen and oxygen used in this work. Hydrogen, admitted to the experimental tube after 500 hours of heat treatment for the rhodium, changed the long wave limit from the equilibrium value of 2482–2536Å (a value characteristic of rhodium after 1000 hours of heat treatment in a final vacuum of 10^{-8} mm of Hg) to 2378–2482Å; that is, the limit was changed to approximately the original value characteristic of the specimen before it had received any heat treatment. The photo-current was decreased very quickly from 100 mm deflection to 2 mm. Heating the specimen at 1000°C for one minute in hydrogen at a pressure of one mm of Hg increased the photo-current from 2 mm to 100 mm deflection, but the photo-sensitivity dropped to 3 or 4 mm in 4 minutes after reducing the heating current to zero. Allowing the pumps to remove as much of the hydrogen as possible without heating the rhodium increased the photo-current from 2 mm to 4 mm. Light from the mercury arc increased the photo-current from 2 mm to 4 mm in two hours. The long wave limit characteristic of the rhodium after 1000 hours of heat treatment was attained in 100 hours of heating at 1250°C after this exposure to hydrogen. It is evident that rhodium occludes and adsorbs hydrogen quite well since its photoelectric properties are radically affected by the presence of hydrogen.

Oxygen, admitted to the system after the specimen had regained its stable condition after the introduction of hydrogen, changed the long wave limit from its equilibrium value of 2482–2536Å to a value below 2300Å. Oxygen was more effective in decreasing the long wave limit than hydrogen. Heating the specimen at 1000°C for one minute in oxygen at a pressure of 1 mm of Hg did not restore the photo-current to its original 100 mm deflection. In order to attain stable conditions again it was necessary to heat the specimen at 1250°C for 100 hours and to heat by means of a torch the high vacuum end of the system several times during this interval.

The following peculiarities of the photoelectric behavior below 240°C require further consideration:

- (1) The stable value of the work function at room temperature is 4.92 volts; at 240°C this has changed to 4.57 volts, but no further change is observed from there on up to 650°C.

- (2) When the rhodium was cooled as rapidly as possible from 1250°C to room temperature, the stable condition would be reached in 10 minutes after stopping the heating current.

- (3) When the temperature was varied slowly from above 240°C, the more usual form of ascending and descending photo-current curve is shown in Fig. 3. Condition *A* is not stable, but changes to *B* in the course of an hour.

(4) Under the best attained vacuum conditions (10^{-8} mm of Hg) a different cycle is observed (Fig. 4) and with the same rate of change of temperature as in Fig. 3, the stable condition (*B*) is reached at once.

(5) It is to be noticed that the better the vacuum (Fig. 4) the more sudden are the changes in photo-current with temperature.

The question is, are these peculiarities caused by changing surface contamination, or do they indicate a structure change in the rhodium occurring at or below 240°C ? A simple calculation shows that with a pressure of 10^{-8} mm of Hg and assuming no molecular reflection, it would take from one-half to several hours to form a monomolecular layer on the metal, according to the density one assumes for the gas layer. Hence from (2) above it does not seem likely that condition *B* is due to a gas covered surface, unless the gas layer is stable at high temperatures (1250°C) as well as at room temperature, being perhaps a hydride. Furthermore, in order to account for (1) and (3) this gas layer or hydride must be assumed to be unstable from 240°C up to some higher temperature, the relatively rapid rise in the ascending curve of Fig. 3 being due to the breaking up of the layer. But this does not fit (5), for the sudden drop in the descending branch of Fig. 4 would have to be attributed to the partial formation of the layer, and such rapid formation would be *less* likely to occur under the extremely high vacuum conditions of Fig. 4 than under the somewhat lower vacuum conditions of Fig. 3—which is contrary to fact. The sudden changes so prominent in Fig. 4 strongly suggest that there is an allotropic change at 240°C , and that the structure stable above this temperature can be carried down to lower temperatures in an irregular way, depending upon circumstances. A comparison of Figs. 3 and 4 suggests furthermore that the influence of this change in structure can be easily obscured by changing contamination except under the very best vacuum conditions. This is, however, not a completely satisfactory interpretation of the results.

In conclusion, the writer wishes to express his sincere thanks to Dr. C. E. Mendenhall, under whose direction this work has been done, to Mr. J. B. Davis, the glass-blower, and to Mr. J. P. Foerst, the mechanician.

THE EFFECT OF RESOLVING POWER ON MEASUREMENTS OF THE ABSORPTION COEFFICIENT OF ELECTRONS IN GASES

BY R. RONALD PALMER

DEPARTMENT OF PHYSICS, UNIVERSITY OF MINNESOTA

(Received November 26, 1930)

ABSTRACT

The absorption coefficient of electrons has been studied as a function of the resolving power of the experimental apparatus. An electron beam of 0.4 mm radius was used in a Mayer type of apparatus in which the opening at the end of the scattering chamber was of variable aperture. Values of the absorption coefficient were obtained in helium and in mercury vapor for 20, 40, 80 and 135 volt electrons over an angular aperture range of from 2° to 11° as measured from the end of the electron gun. All curves showed a definite decrease in the absorption coefficient with increase in angular aperture. These curves were corrected for the positive ion current, from the efficiency of ionization data of Bleakney and Smith, to give curves for the total number of electrons collected as a function of the size of the opening. These showed also a definite decrease with increase in aperture, corresponding to a preference for scattered electrons to be deflected through small angles. In helium the curves were steeper the higher the electron velocity, indicating that this preference is more decided for fast electrons than for slower electrons. In mercury vapor the curves were more nearly alike. The results do not indicate as decided a preference for small angle scattering as is indicated by the angular distribution curves of Arnot in mercury vapor. This discrepancy is not explained.

INTRODUCTION

EXPERIMENTS^{1,2,3,4} designed to determine the angular distribution of electrons after collision with gas molecules indicate a decided preference for small angle scattering. In fact, most of the published curves show a continued increase in the probability of scattering with decrease in angle, down to as small angles as have been obtained. Such curves for slow incident electrons are not so steep, in general, as are those for faster electrons, but in all cases the scattered electrons show this definite tendency to be concentrated about the forward direction.

The term "absorption coefficient" as applied to electron scattering by gas molecules has concerned itself with a determination of α from the relation $I = I_0 e^{-\alpha x}$. In such experiments electrons of a definite velocity are caused to move in a beam (whose size and shape depend on the defining electrode system) through a scattering chamber of length x which contains a gas at a known pressure, p . On passing through this scattering chamber certain

encounters with gas molecules cause some of the electrons to leave the beam, and so the beam of initial current strength, I_0 , is reduced to the value I as given above. Experimentally two general methods have been used to determine α . The path of the electron beam may be a straight one as in a Mayer⁵ type of apparatus, or the beam may be focused over a semicircular path by means of a magnetic field as was first done by Ramsauer.⁶

If $I' = I_0 - I$ is the current to the scattering chamber, then, for low pressures, from the exponential relation given above, α is proportional to I'/I_0 . Thus a determination of α for a particular apparatus is equivalent to measuring the fractional current to the scattering chamber. For low velocity electrons this current is composed merely of those electrons which have been deflected through an angle greater than some average minimum angle, $\bar{\theta}$. This angle is a function of the size of the opening at the end of the scattering chamber and of the length of the path. For electrons with a velocity greater than a certain value there may be ionization at an encounter which will result in at least three charged particles. A certain fraction of these will be collected, depending on the apparatus. If $\Phi_s(\theta)$, $\Phi_e(\theta)$ and $\Phi_i(\theta)$ are the probabilities that the initial electron, the ejected electron and the ion, respectively, will move in the direction θ after such an encounter, and if F^+ is the probability of ionization taking place, then for a Mayer type of apparatus the fractional current to the scattering chamber is

$$I'/I_0 = \int_{\bar{\theta}}^{\pi} (\Phi_s + F^+ \Phi_e + F^+ \Phi_i) d\theta \quad (1)$$

where the integral is taken over the possible angles of collection. If it is assumed that the ion has an equal probability of moving in any direction, Φ_i is a constant and the integral of the third term does not change much with a small change in the lower limit of integration, $\bar{\theta}$. The second term, representing the angular distribution function for the ejected electrons has not, to the author's knowledge, been investigated. This distribution may be uniform but it seems more probable that it would be somewhat similar to the distribution for the scattered primary electrons. The first term in the integrand is the probability function, $F(\theta)$, which is measured in angular scattering experiments. As has already been mentioned this function is one which in general increases with decreasing θ , being of particular weight for values of θ near $\bar{\theta}$. Hence one would expect that a small change in the lower limit of integration would produce a large change in the value of Eq. (1). Any distribution of the ejected electrons other than a uniform distribution would enhance this effect. Thus the current collected by the scattering chamber is very decidedly a function of the resolving power of the apparatus. In the Ramsauer type of apparatus the integrals of the second and third terms of Eq. (1) will probably just balance each other. Both the ejected electron and ion will have such energies that their paths will have a smaller radius of curvature than that of

⁵ H. F. Mayer, *Ann. d. Phys.* **64**, 451 (1921).

⁶ C. Ramsauer, *Ann. d. Phys.* **66**, 547 (1921).

the main electron beam, and hence even if initially they were directed along the electron beam they would soon leave it and balance each other at the walls of the scattering chamber. At such an encounter, or any encounter in which the initial electron loses an appreciable amount of energy it too will be removed from the beam regardless of its direction of motion immediately following the encounter. Thus a Ramsauer type of apparatus measures not only the integral of the first term of Eq. (1) but also an additional negative current due to those electrons which lose energy even though they are deflected through angles less than $\bar{\theta}$. On the other hand, in a Mayer type of apparatus the integral of the first term is partially balanced by a part of the positive ion current.

From these considerations one would expect that the magnitude of the absorption coefficient as obtained by various observers using apparatus with different resolutions should exhibit quite a wide range of values. But this does not seem to be the case. Recent measurements by Maxwell,⁷ Jones⁸ and Brode⁹ on the absorption coefficient for electrons in mercury vapor agree much better than would be expected. The author* has also carried out a determination with a Mayer type of apparatus (separate from that used for the work reported in this paper) in which electrons scattered through angles down to 3° , on the average, were counted as having collided. The absorption coefficient was determined for electrons of from 5 to 100 volts velocity and the values agreed within a few percent with those obtained by Brode with a Ramsauer apparatus. These values are but 25 percent greater than those reported by Maxwell. His apparatus defined a collision only if it resulted in a very much larger deflection of the electron. Arnot³ has obtained an angular scattering curve for electrons in mercury vapor, and a numerical integration of this curve as applied to each individual apparatus indicates that there should be a much greater divergence in the results. Similarly for other gases various observers obtain results more in accord with each other than would be expected.

It was then decided to build a Mayer type of apparatus in which the opening at the end of the scattering chamber could be changed in size, so that the absorption coefficient could be studied in one particular apparatus as a function of the resolving power. Such a study should throw light on the probability of angular scattering, and should enable a check of existing curves. Recently Metta Clare Green¹⁰ carried out a similar investigation, but found no consistent variation of the absorption coefficient with opening. Inasmuch as such a result is so definitely in opposition to the results of angular distribution experiments and as the magnitudes of the values obtained for the absorption coefficient differed, in most cases, so radically from accepted values,

such a study should still be fruitful. Measurements were accordingly made in helium and in mercury vapor.

APPARATUS

The apparatus used is shown diagrammatically in Fig. 1. It was constructed of copper. Electrons from the tip of the filament, F , were accelerated to a definite velocity between the plates D_1 and D_2 , and made to travel in a beam of small cross-section through the scattering chamber, sc , and into the Farady cage, FC . The diameters of the circular openings in the gun, G , were 0.75, 0.50, 0.50 and 0.75 mm for D_1 , D_2 , D_3 and D_4 respectively. D_5 was about 1.5 mm in diameter, and less than 1 mm from D_4 . The distance from D_1 to D_2 was 5.0 mm and from D_1 to the end of the gun, D_4 , was 45 mm. The scattering chamber, from D_4 to D_6 , was 4.0 cm in length, and the Farady cage was 16 cm in length. The hairpin filament was a small tungsten wire bent sharply at the opening D_1 . It required about 1.5 amperes for satisfactory electron emission. All diaphragms were slightly bevelled, and important surfaces were given a light coat of soot.

Fig. 1. Diagram of apparatus.

The variable aperture at D_5 was obtained by the use of a 30 cm strip in which were cut a series of holes of different size. The strip could be slid freely back and forth by means of a special magnetic control, which was constructed such that all magnetic material could readily be removed for each reading.

The apparatus was sealed in a Pyrex tube free from wax joints, and vacuum conditions were such that a pressure of less than 10^{-6} mm mercury would build up in 24 hours when the tube was cut off from the pumps. For the measurements in mercury vapor, a trap containing mercury was maintained at a definite temperature, and the calculations were based on the vapor pressure corresponding to that temperature as recorded in the International Critical Tables. Pressures corresponding to various temperatures up to about 20°C were used. The gas pressures for helium were determined from McLeod gauge readings. A side tube containing carbon which had been baked out for several hours at 500°C was used in conjunction with the helium measurements. This tube and the mercury trap were kept at the temperature of liquid air.

A pair of large Helmholtz coils was used to neutralize the earth's field, and the tube was mounted such that the electron beam traveled along the axis of the coils.

METHOD

In a determination of α from the exponential decrease in the intensity of an electron beam a constant, K , must be introduced to account for those electrons which would be collected by the scattering chamber regardless of gas pressure. This constant should depend only on the geometry of the apparatus. The beam of initial strength I_0 is then reduced to $I = KI_0 e^{-\alpha x p}$ after traveling a distance x in a gas at pressure p . The current ratio I/I_0 was measured by the galvanometers, G_2 and G_1 (Fig. 1) for different gas pressures and for different openings at the end of the scattering chamber. From the above equation

$$\log I/I_0 = \log K - \alpha x p / 2.3 \quad (2)$$

in which the logarithms are taken to the base 10. If K is a constant, independent of the pressure and electron current for a particular resolution, the $\log I/I_0$ should exhibit linearity when plotted against the pressure. The

Fig. 2. To show linearity between $\log I/I_0$ and pressure. (80 volt electrons in mercury vapor.)

slope of such a straight line relationship being $\alpha x / 2.3$ makes it possible to calculate α . If the pressure used is the observed pressure corrected for thermal diffusion and reduced to the corresponding pressure at 0°C , α is obtained in the usual units, cm^2/cm^3 per mm pressure at 0°C .

Fig. 2 shows the relation between $\log I/I_0$ (plus an arbitrary constant) and the pressure for 80 volt electrons in mercury vapor; each curve was obtained with a different opening at the end of the scattering chamber. These curves indicate that K was independent of the pressure in each case. The value of $\log K = \log I/I_0$ when $p=0$ shows that K was greater than 0.99 for all openings. Thus at least 99 percent of the original beam was collected by

the Faraday cage when no gas was present. This means that the number of secondary electrons reflected into the scattering chamber from the end of the gun or the end of the Faraday cage was at a satisfactory minimum.

By applying a retarding field between the Faraday cage and the scattering chamber (Fig. 1) the velocity distribution of the electron beam was found to be quite satisfactory. For a 40 volt electron beam, over 95 percent of the electrons had velocities within a few tenths of a volt of the mean. Though this differed from 40 volts by a small amount, the beam will nevertheless be designated as a 40 volt electron beam. The correction will also be disregarded for the other velocities used.

Fig. 3. "Absorption coefficient," α , as a function of the resolving power of the apparatus, in mercury vapor. (X-values given by Metta Clare Green for 37.5 volt electrons.)

The values of α in mercury vapor were for the most part obtained from such curves as those in Fig. 2, which in turn had been determined by four different pressures. Those for helium and some of the mercury values were obtained with but two pressures, one of which was usually zero. The path length value of $x = 4.0$ cm was used for all the calculations.

RESULTS AND DISCUSSION

The results of the measurements in mercury vapor are given graphically in Fig. 3, and those for helium in Fig. 4. α is plotted for 20, 40, 80 and 135 volt electrons against the limiting angle, θ_0 , giving curves I, II, III and IV respectively. Referring to Fig. 1, this limiting angle is defined as $\theta_0 = \tan^{-1} r/l$

where r is the radius of the opening and l is the length of the scattering chamber. If any electron is deflected through an angle less than this it will not be counted as having collided. The range of values for θ_0 corresponds to a range of diaphragm radii of from 1.4 to 7.6 mm. The experimental points for mercury are averages of two complete sets of readings, differing from each other in most cases by less than 2 percent. The values for helium are averages of

Fig. 4. "Absorption coefficient," α , as a function of the resolving power of the apparatus, in helium. (X-values given by Metta Clare Green for 97 volt electrons.)

four sets of readings with a somewhat larger experimental error. All of the curves show a definite decrease in the absorption coefficient as the size of the opening increases. This, of course, corresponds qualitatively to the tendency for scattering to take place in the forward direction.

If $K=1$, which has been seen to be practically the case, the current to the scattering chamber is $I' = I_0 - I = I_0(1 - e^{-\alpha xp})$. For low pressures this becomes

$$I'/I_0 = \alpha xp \quad (3)$$

or, α is numerically equal to the negative current to the scattering chamber in terms of a certain number of electrons per primary electron per cm path per mm pressure at 0°C. Thus the curves of Figs. 3 and 4 give the relative negative current collected by the scattering chamber when the size of the opening is changed. As has already been seen, this negative current is the resultant of a positive ion current combined with the scattered and ejected

electron current, the fraction which is due to positive ions depending on the probability of ionization. Hence if these curves are to be discussed with regard to the characteristics of electron scattering they must be corrected for the positive ion current. This correction is made possible by the recent work of Bleakney¹¹ and of Smith¹² who have determined the efficiency of ionization of electrons in various gases. If F^+ is this efficiency of ionization

Fig. 5. Number of electrons collected by the scattering chamber, per cm path per primary electron per mm pressure at 0°C , as a function of the resolving power, in mercury vapor. (Curve A predicted, as the number of primary electrons scattered, by Arnot's results for 80 volt electrons.)

(given in terms of the number of units of positive charge formed per cm path per primary electron per mm pressure at 0°C) and we assume that the ion has an equal probability of going in any direction,* the positive current to the scattering chamber can be obtained by a simple integration. It is of course a function of θ_0 and is found to vary from $1.10F^+$ at $\theta_0=2^\circ$ to $1.03F^+$ at

¹¹ Walker Bleakney, Phys. Rev. **35**, 139 (1930).

¹² P. T. Smith, Phys. Rev. **36**, 1293 (1930).

* This assumption seems valid providing the interior of the scattering chamber is a field-free space. A recent investigation by Arnot (Proc. Roy. Soc. **A129**, 361 (1930)) indicated that the positive ions tend to move out perpendicularly to the electron beam. It is doubtful whether his results may be applied here, for they were obtained under different conditions. Intense electron beam currents up to 25 micro-amperes were used, whereas in the work reported here this current did not exceed a tenth of a micro-ampere. However, the results to follow would be substantially the same, even though we accepted Arnot's distribution for the positive ions.

$\theta_0 = 10^\circ$. The values of F^+ given by Bleakney for 20, 40, 80 and 135 volt electrons in mercury vapor are 12.0, 21.2, 25.0 and 22.5 respectively; those given by Smith for the respective voltages in helium are 0.00, 0.63, 1.18 and 1.24. With these values the corrections can be calculated and applied to the curves of Figs. 3 and 4. The corrected curves, representing the total number of electrons collected by the scattering chamber (per primary electron per cm path per mm pressure at 0°C), are given in Figs. 5 and 6, for mercury vapor and helium, respectively. Since these curves deal only with the electrons which are collected they may be used in a comparison of electron scattering.

Fig. 6. Number of electrons collected by the scattering chamber, per cm path per primary electron per mm pressure at 0°C , as a function of the resolving power, in helium.

To get a better idea of the relative dependence of this scattering on angular aperture for the different primary velocities, the 20, 80 and 135 volt curves in helium (Fig. 6) have been multiplied by the proper factors to make them coincide with the 40 volt curve at $\theta_0 = 2^\circ$, giving the new curves I', III' and IV' respectively. From this set of curves we notice that as the velocity of the primary electrons becomes greater, the curves become relatively steeper; i.e., a small change in the size of the opening cuts out a relatively greater number of the scattered electrons if the primary electrons have high velocity than if they have a lower velocity. This indicates that scattering of fast electrons is more definitely concentrated in the forward direction than that for slow electrons, and corresponds to the decrease in steepness

of the angular scattering curves with decrease in primary electron velocity, as observed by McMillen.⁴ Mercury vapor however, does not exhibit such a marked relative preference. The curves in Fig. 5 show about the same relative change over the range of angles used, being much more alike than are those in helium. This indicates that the angular distribution of scattered electrons in mercury vapor is quite similar over the velocity range of from 20 to 135 volts. This does not imply, however, that the angular distribution for the scattering of primary electrons would be the same over this velocity range. To say anything about this, the distribution of the ejected electrons must be taken into consideration, and it is not likely that this distribution would be the same for primary electrons of different velocities. These relations cannot be checked with existing data for, aside from our lack of knowledge of the behavior of the ejected electron, no investigation has as yet been published in which the angular distribution has been studied as function of electron velocity in mercury vapor.

From the angular scattering curves of Arnot for 80 volt electrons in mercury vapor it is possible to predict the number of primary electrons which should be collected by the scattering chamber for any size opening. He determined the angular distribution for electrons which had not lost energy and also for those which had lost energy. He assumed that these electrons were all primary electrons, even though there is the possibility that an ejected electron may be given sufficient energy such that it will be confused with the group of primary electrons which had lost energy. The calculation for the number of primary electrons collected according to his results can be done in the following way.

Let $F(\theta)d\theta$ be the number of electrons scattered between θ and $\theta+d\theta$ per primary electron per cm path at a definite temperature and pressure. The effective length of path over which electrons deflected through angle θ are collected is $l_s = l - r/\tan \theta$, as can be seen from Fig. 1. Then for N_0 primary electrons the number of electrons deflected between θ and $\theta+d\theta$ which are collected by the scattering chamber is $N_0 p F(\theta) l_s d\theta$ for a gas pressure p which is sufficiently small. The total number collected will then be

$$N' = N_0 p \int_{\theta_0}^{\pi} F(\theta) (l - r/\tan \theta) d\theta. \quad (5)$$

It may be noted that this includes all electrons scattered into the chamber, even those which are deflected through angles greater than 90° giving for them the proper effective path length which is greater than 1. If $F(\theta)$ be known, the function $F(\theta) (l - r/\tan \theta)$ can be plotted against θ for different values of r , and the areas under the resulting curves will represent the relative numbers of primary electrons collected by the scattering chamber for openings of different size. The only assumption which has been made is that the scattering takes place along the axis of the apparatus.

Compton¹³ has tabulated Arnot's values for the scattering of 80 volt

¹³ K. T. Compton, Rev. Mod. Phys. 2, 123 (1930).

electrons in mercury vapor in terms of the number of electrons scattered per unit solid angle at angle θ per primary electron per cm path at 20°C and 0.001 mm pressure. $F(\theta)$ is then this function multiplied by $2\pi \sin \theta$. By using these values for $F(\theta)$ and performing the numerical integrations outlined above, $N/N_0\phi$ was obtained for different values of the diaphragm radius. On correcting this result to 0°C and 1 mm pressure (since $F(\theta)$ was given for a temperature of 20°C and a pressure of 0.001 mm) and dividing by the path length, $x=4.0$ cm, one obtains the predicted values for the number of primary electrons which should be collected by the scattering chamber for various apertures. Curve A of Fig. 5 is the result of this work, plotted in terms of $\theta_0 = \tan^{-1} r/l$. Curve III of the same figure represents the actual number of electrons which were collected experimentally. Assuming the validity of both curves, the difference between their ordinates for a particular value of θ_0 would represent the number of ejected electrons collected by the scattering chamber for that value of θ_0 . This difference increases with increasing θ_0 which means that a larger ejected electron current would be collected the larger the diaphragm opening. Such a result can be interpreted only if the ejected electrons obey a distribution which favors scattering in the backward direction, which does not seem reasonable. It is of interest to compare the curves if we assume a uniform distribution for the ejected electrons. The correction to be made to curve III will be practically the same as (but opposite to) the correction which was made for the positive ions, and the resulting curve will be similar to the curve for α . This is given in Fig. 5 as curve III'. To compare this curve with Arnot's the latter has been plotted to a different scale giving curve A'. Both curves, of course, show the preference for small angle scattering, but Arnot's curve makes this preference much more decided. If we had assumed an angular scattering for the ejected electrons favoring scattering in the forward direction, curve III' would have differed much more decidedly from Arnot's predicted curve. It is to be mentioned that Arnot's results were obtained with primary electron currents of several micro-amperes, whereas in the present work no currents greater than a tenth of a micro-ampere were used. As was noted above, the only assumption made in the calculation was that the scattering should take place along the axis. This was approximated quite well, for tests at the end of the scattering chamber indicated that the beam was but 0.8 mm in diameter and hence all of the scattering took place within 0.4 mm of the axis. Thus there remains a definite discrepancy between the two curves which is difficult to explain.

It is of interest to note that the procedure we have just outlined may be reversed, and $F(\theta)$ may be obtained from the experimental curve. Thus, if the experimental curve gives the result

$$f(\theta_0) = \int_{\theta_0 = \tan^{-1} r/l}^{\pi} F(\theta) \cdot (l - r/\tan \theta) d\theta \quad (6)$$

then $F(\theta)$ can be determined by differentiating this equation twice. This gives

$$F(\theta_0) = \sin \theta_0 / l \left(\cos \theta_0 \frac{d^2 f(\theta_0)}{d\theta_0^2} - 2 \sin \theta_0 \frac{df(\theta_0)}{d\theta_0} \right). \quad (7)$$

This equation, however, is rather impractical of application for the second derivative bears too much weight. A small error in the experimental determination of $f(\theta_0)$ is amplified in the calculation, which makes $F(\theta)$ very uncertain.

The results of Metta Clare Green¹⁰ which were previously mentioned are given by the crosses in Figs. 3 and 4, for certain electron velocities in mercury vapor and helium. These values are also plotted in terms of $\theta_0 = \tan^{-1} r/l$ where $l = 7.5$ cm in her apparatus. For a given electron velocity she found no definite variation in the absorption coefficient with change in aperture, all the values for a given curve lying within the experimental error of the mean of that group. However such a result is in direct opposition to all angular scattering experiments. In addition, the magnitudes of the values obtained for the absorption coefficient differed in most cases so radically from those obtained by any other observer that it is difficult to place much weight on the results. This may, in part, have been caused by the penetration of electric fields into the scattering chamber at both ends. Such experiments necessitate that the scattering be studied in a field-free space. Otherwise it is difficult to determine the cause of this discrepancy.

This investigation has given further evidence that when electrons are scattered by gas molecules they exhibit a preference for deflection through small angles. It has also been shown that, over the velocity range studied, fast electrons show a greater relative tendency to be deflected through small angles than do slower electrons. This is quite definitely the case for scattering in helium, whereas it is not so marked in mercury vapor. Further, the results in mercury vapor do not indicate as decided a preference for forward scattering as do those of Arnot.

The author wishes to express his gratitude to Professor Tate for his many helpful suggestions and continued interest throughout this work.

HIGH FREQUENCY DISCHARGES IN MERCURY, HELIUM
AND NEON*BY CHARLES J. BRASEFIELD
UNIVERSITY OF MICHIGAN

(Received November 15, 1930)

ABSTRACT

Measurements were made of the potential drop at the electrodes and the electric force in the positive column of high frequency discharges in mercury, helium and neon for a large number of gas pressures and for frequencies of oscillation between 1.25 and 22.5 megacycles. The results showed that in general, the magnitude of the electric force was too small to produce electrons whose velocity would be sufficient to ionize or excite the gas. It was observed that as the frequency of oscillation increases, the potential drop at the electrodes decreases. Considering the total voltage between electrodes it was found that the high frequency discharge in mercury has its maximum conductivity when operated at a frequency of 17.5 megacycles (17.15 meters) and at a pressure of 0.002 mm; the discharge in helium has its maximum conductivity at 17.5 megacycles and 0.33 mm pressure; the discharge in neon has its maximum conductivity at 7.5 megacycles (40 meters) and 1.0 mm pressure.

INTRODUCTION

PREVIOUS work¹ on the conductivity of a high frequency discharge in hydrogen showed that a knowledge of the variation of the total voltage across the discharge with the gas pressure and the frequency of oscillation is not sufficient to determine the mechanism of the discharge, for the potential difference between electrodes consists of two parts. The first is the drop in potential in the body of gas. The second is the drop in potential at the electrodes which includes the dielectric loss in the glass under the electrodes and the drop in potential at the electrodes due to the accumulation of positive space charge, if any. In order to compare experimental results with any theory of the mechanism of the discharge, it is necessary to study the electric field in the positive column of the discharge, in particular, its variation with gas pressure and frequency of oscillation.

The apparatus used and the experimental procedure followed were essentially the same as in the work on hydrogen. Measurements were made of the voltage between electrodes necessary to produce a current of 100 milliamperes in the gas, the distance between electrodes being varied from 40 to 100 cm in 10 cm steps. If the values of the total voltage between electrodes are plotted against the corresponding distances between electrodes, a curve is obtained which, in general, approximates a straight line. Assuming that as the distance between electrodes increases, the drop in potential at the electrodes remains constant, then the slope of the line gives the electric field in

* Publication of the Research Organization of the Grigsby-Grunow Company, Chicago, Illinois.

¹ C. J. Brasefield, Phys. Rev. 35, 1073 (1930).

the positive column which when multiplied by $2^{1/2}$ gives the amplitude of the electric force. Extrapolating the curve to zero distance between electrodes, the potential drop at the electrodes is found. Values of the electric force in the positive column of the discharge as well as the potential drop at the electrodes were in this way obtained for a large number of gas pressures and for ten frequencies of oscillation between 1.25 and 22.5 megacycles.

RESULTS

1. *Experiments on mercury.* The discharge tube used was 120 cm long, 5.2 cm internal diameter while the electrodes surrounding it were of sheet copper 5 cm wide. Except for a mercury reservoir at one end, the whole tube was surrounded by an electric furnace which kept it at a temperature of about 150°C. To regulate the vapor pressure of the mercury, the reservoir

Fig. 1. The variation with pressure of the electric force (solid curves) and the potential drop at electrodes (broken curves) in a high frequency discharge in mercury operated at 5 and 15 megacycles.

was immersed in a water bath which was kept at a constant temperature within 0.2°C during a given run. Measurements were taken at 5° intervals from 0° to 95°C.

Fig. 1 shows, for two typical frequencies of oscillation, the variation with pressure of the electric force and the potential drop at electrodes when a current of 100 milliamperes is passing through the tube. It was observed that as the frequency of oscillation increases, the potential drop at the electrodes decreases from approximately 800 volts at 1.25 megacycles to 200 volts at 15 megacycles. This, without doubt, accounts for the fact that the spark spectrum of mercury was quite pronounced in the region under the electrodes when the discharge was operated at frequencies below 5 megacycles. Considering the total voltage between electrodes, it was found that the discharge

we find $E_{0\min} = 0.34 \times 10^{-6} \times f$ volts per cm. For 25 volt electrons (helium and neon) we find $E_{0\min} = 0.53 \times 10^{-6} \times f$ volts per cm. A glance at Figs. 1, 2, and 3 shows that the majority of the experimental values of E_0 are still less than these minimum values. It appears, therefore, that in the high frequency discharge, electrons whose velocity is sufficient to ionize (or even excite) a gas molecule cannot be produced in the positive column of the discharge.

Of course, it is not necessary that ionization processes in the high frequency discharge be very efficient since the only way ions can disappear is by recombination or diffusion to the walls. The same cannot be said of the excitation processes, however, for the intensity of the light produced in the positive column is quite comparable with the intensity of the light emitted by the positive column of an ordinary Geissler tube carrying the same current. The only source of high velocity electrons imaginable is the region under the electrodes; but it is hard to believe that these electrons should be responsible for all the ionization and excitation in the positive column of the discharge. The writer confesses that he is unable to suggest any reasonable solution of the problem from a consideration of the mechanics of individual electrons; whether or not an explanation of the phenomena can be worked out by considering the volume of ionized gas as a plasma has not as yet been determined.

The writer is indebted to Professor O. S. Duffendack and Professor R. A. Sawyer for advice rendered and also to Mr. J. S. Owens who assisted in the experimental work.

LETTERS TO THE EDITOR

Prompt publication of brief reports of important discoveries in physics may be secured by addressing them to this department. Closing dates for this department are, for the first issue of the month, the twenty-eighth of the preceding month; for the second issue, the thirteenth of the month. The Board of Editors does not hold itself responsible for the opinions expressed by the correspondents.

The Diffraction of Hydrogen Atoms by the Mosaic Structure of Crystals

The de Broglie wave spectra of a beam of hydrogen atoms produced by reflection from a crystal of lithium fluoride have been photographed under conditions of improved technique with the primary features described in abstract No. 2 of the 1930 Chicago Meeting of the American Physical Society. Still more recent plates with higher resolution show another type of spectrum which will be referred to as the secondary spectrum. Although the resolution is still too low in this spectrum to separate the maximum of its wave-length distribution from the specularly reflected zero order beam, it is sufficient to show that the secondary spectrum has four branches lying in the directions corresponding to diffraction by a grating whose lines are parallel to the cleavage planes of the crystal. The fact that the maximum of the wave-length distribution is not resolved permits it to be said that the spacing of the secondary lattice is greater than

50A, and the observations are not in disagreement with a spacing of more than 100A.

These facts are believed to support Zwicky's theory of the mosaic structure of crystals (*Helvetica Physica Acta* III, 269, 1930). Although the writer is not familiar with any calculations applying to the structure of LiF the spacing of the secondary lattice of these crystals should not differ in order of magnitude from that of rock salt for which Zwicky calculates 110A.

In the experiments the crystals were heated before the exposure was started to the point that the secondary structure of the crystal might well have been developed on the surface by evaporation.

On Some of the New Ultra-Ionization Potentials of Mercury Vapor

In view of the recent interest in the ultra-ionization potentials of mercury vapor (A. L. Hughes and C. M. Van Atta, *Phys. Rev.* 36, 214, 1930, Philip J. Smith, 166th Meeting of the American Physical Society and Curtis R. Haupt, 167th Meeting of the American Physical Society) I would like to call attention to some observations of Mr. R. D. Potter, made at Duke University under my direction and published in the *Journal of the Elisha Mitchell Scientific Society*, 44, 31, 1928. Inasmuch as the results of the experiment described in this paper do not seem to have come to the attention of other workers in this field, a brief statement of the results may be of interest.

Electrons from a tungsten filament were projected parallel to the axis of a tube and were collimated by means of a coaxial mag-

netic field of approximately 250 gauss. Collisions between electrons and mercury atoms occurred in a space midway between two rows of parallel and plane electrodes symmetrically placed with respect to the electron beam. A small electric field between these plates served to draw out positive ions formed in the region of the beam. The electrons after passing between the sets of parallel plates were collected by an electron trap. An accelerating potential of 125 volts inside the electron trap made it a good absorber of electrons. Since the primary electrons were collimated into a beam by the magnetic field they did not strike the edges of the slits in the accelerating plates. This prevented the formation of secondary electrons.

The procedure was to measure the saturated positive ion current and total electron

current for successive values of the accelerating potential, observations being taken at 0.10 volt intervals.

A plot of the ratio of positive ion to total electron current showed a series of abrupt changes in slope which resembled the familiar ones of Franck and Einsporn rather than those reported by J. C. Morris (Phys. Rev. **32**, 447, 1928). Critical potentials were observed at 10.40, 10.66, 11.00, 11.41, 11.72, 12.06, 12.40, 12.80 and 13.25 volts. The values given have been corrected for initial thermal energies,

etc., by assuming the potential at which ions were first detectable to be 10.40 volts.

An examination of the results indicates that in the main there is good agreement between the above critical ultra-ionization potentials and those reported in subsequent work mentioned at the beginning of this letter.

Projective Relativity and the Quantum Field

A recent paper¹ by O. Veblen and the present writer showed that the "five-dimensional" relativity theory of Kaluza and O. Klein is to be regarded as a four-dimensional projective theory; a natural generalization of the formalism from this point of view led to a set of field equations which contained not only gravitational and electromagnetic field equations as in the usual relativity theory but also the relativistic Schrödinger equation.

The formalism was based on the symmetric projective tensor $G_{\alpha\beta}$ which may be decomposed as

$$G_{\alpha\beta} = \gamma_{\alpha\beta}\Phi^2 = (\delta_{\alpha}^a\delta_{\beta}^bg_{ab} + \phi_{\alpha}\phi_{\beta})\Phi^2,$$

as explained in P. R.

I have been able to obtain a set of four-dimensional projective field relations which is to the field relations of P. R. what the Dirac wave equation is to the relativistic Schrödinger equation.

The basic quantity of space-time is taken to be a projective vector, H_{α} , of index N with which is associated one of zero index denoted by h_{α} . The components of these vectors are not assumed to obey the commutative law of multiplication; they may be regarded as matrices. The restrictions are imposed that

$$H_{\alpha}H_{\beta} + H_{\beta}H_{\alpha} = 2G_{\alpha\beta} \quad (1)$$

$$h_{\alpha}h_{\beta} + h_{\beta}h_{\alpha} = 2\gamma_{\alpha\beta} \quad (2)$$

where $G_{\alpha\beta}$ and $\gamma_{\alpha\beta}$ commute with everything they multiply. $\gamma_{\alpha\beta}$ are now associated tentatively with the similar quantities of P. R.

Indices of the h 's are raised by means of the γ 's and the field equations are taken to be

$$h^a\left(\frac{\partial H_{\beta}}{\partial x^a} - \frac{\partial H_{\alpha}}{\partial x^{\beta}}\right) = 0. \quad (3)$$

A realization of (1) and (2) may be obtained in terms of projective ennuples of vectors in

the tangent spaces² and a basis consisting of five four-rowed square matrices satisfying³

$$E_{\sigma}E_{\tau} + E_{\tau}E_{\sigma} = 2\delta_{\sigma\tau}1.$$

Denoting the components of the vectors of an ennuple by $h_{\alpha\sigma}$ we set

$$h_{\alpha} = h_{\alpha\sigma}E_{\sigma}.$$

Realization of the H 's is effected by the introduction of a one-columned four-rowed matrix, Ψ , by

$$H_{\alpha} = h_{\alpha}\Psi$$

together with a suitable definition of matrix multiplication.

With the above realization the field Eqs. (3) can be shown to contain Dirac's wave equation for a single electron as a special case (i.e. when gravitation is neglected) of the scalar part of the projective set.

If we inserted the relations

$$G_{\alpha\beta} = \gamma_{\alpha\beta}\Phi^2 \quad (4)$$

together with (1) and (2) we would be unable to obtain a satisfactory realization on account of the difference between spatial and temporal coordinates. A realization in terms of eight-rowed square matrices for the E 's avoids this difficulty but introduces the new difficulty that although the scalar part is still equivalent to Dirac's wave equation the whole set of equations numbers forty and we have merely twenty-eight functions entering them.

The Dirac equation is obtained as a special

case of part of a system of field relations constructed in close analogy with the system of P. R. There is thus a possibility that the complete system will constitute an improved unification within the relativity theory of the gravitational electromagnetic and quantum aspects of the field.

The complete set of field relations (1), (2) and (3) (and others not mentioned here), can be shown to be invariant under general relativity transformations.

Thermal Fluctuations of the Surface Potential of a Cathode as Affecting Electron Emission

There are at present two groups of thermionic phenomena in which theory and experiment lie rather far apart. These are (1) the departures of the constant A from the theoretical value, particularly in the case of surface films, and (2) the anomalously large values of the Schottky effect (increase of emission with field) which are also most marked for surface films. The following considerations offer a possible explanation of these difficulties.

Let us select a conductor, one of whose ends is a circular patch of radius r on the surface of the electron emitter, the other end being the surrounding surface. Current may flow from the patch into the underlying material and out again to the surrounding surface. We shall suppose the surface layers of the emitter to have much higher resistance than the underlying material, partly because the surface is a discontinuity, and partly because the surface may be covered purposely with contaminating layers. The resistance of our conductor will then be $R_0 = R_s/\pi r^2$ where R_s is the surface resistance per cm^2 encountered by electrons flowing through the surface. Our conductor is shunted by the capacity C across its end surfaces (infinite for a perfect conductor) which may reasonably be taken as of the form βr . Hence the expression for the effective resistance of our conductor at a frequency ω radians per second is

$$R = \frac{R_0}{1 + R_0^2 \omega^2 C^2} = \frac{R_s}{\pi r^2 + \beta^2 (\omega^2/\pi) R_s^2}.$$

Johnson¹ has shown that as a result of thermal agitation there will be a mean square e.m.f. across the ends of our conductor given by

$$\bar{V}^2 = 3.48 \times 10^{-20} T R (\text{volts})^2$$

where T is the absolute temperature.

We shall take r approximately equal to the critical distance (x_m) which an electron must reach in order to escape from the surface.

Hence the fluctuations of the potential of our patch will change appreciably the work function (ϕ) for the escape of electrons from the patch. These fluctuations are equally positive and negative, but since the emission (i) is an exponential function of ϕ , they will give rise to a net increase in emission (a sort of rectification action).

If i_0 is the "normal" electron emission from the patch (including the normal Schottky correction), the relative increase in emission produced by the fluctuations is found to be

$$\frac{i - i_0}{i_0} = 2.41 \times 10^{-12} \frac{R}{T} = \alpha \frac{R}{T}. \quad (1)$$

The surface may be regarded as made up of a number of such patches, so that the emission from the whole surface will be given by an expression like that above.

For the fluctuation effect to make an appreciable change in emission, the term $\alpha R/T$ must be at least of the order one tenth. If we consider the pure resistance part of R only, and remember that r is of the order 10^{-8} cm, we find that R_s must be of the order 100 ohms/ cm^2 . There appears to be no definite experimental evidence against the existence a surface resistance of this order in vacuum. Experiments are projected for measuring this surface resistance and its temperature coefficient. Ionization effects at the surface must modify this resistance in the case of anodes in gas discharges.

The anomalous Schottky effect has been discussed recently by Langmuir.² To compare our theory with this effect we form the partial derivative

$$\frac{\partial \ln i}{\partial (F)^{1/2}} = \frac{4.39}{T} + \frac{\alpha}{T + \alpha R} \frac{\partial R}{\partial (F)^{1/2}}. \quad (2)$$

For weak fields the critical distance is large, r is large, and R approaches zero. Hence

¹ J. B. Johnson, Phys. Rev. 32, 97 (1928).

² I. Langmuir, Reviews of Modern Physics 2, 150 (1930).

$\partial R/\partial(F)^{1/2}$ is zero, and we have the normal Schottky slope. This is the region in which Nottingham's³ emission measurements at zero field lie, and also Langmuir and Kingdon's⁴ measurements of contact potential. The effect we are considering is absent in this range. As the field is increased, the critical distance decreases, r decreases, R increases, and the increase in $\partial R/\partial(F)^{1/2}$ gives an increased Schottky slope. Finally for very large fields the term involving r in R becomes negligible, and the effective resistance of our conductor becomes independent of the field. Hence $\partial R/\partial(F)^{1/2}$ approaches zero, and the slope approaches the normal Schottky value, as observed.

If we measure the Schottky slopes for ThW at moderately strong fields and for different filament temperatures, we find that the departure from the normal slope is greatest at the lowest temperatures (reference 2, page 156). This is in agreement with the occurrence of the factor $(T + \alpha R)$ in the denominator in Eq. (2).

It is evident that the introduction of a surface resistance, which will vary with temperature, may be made to account for the observed vagaries of the emission constant A by a suitable choice of the temperature coefficient of this resistance. It is hardly profitable to discuss this point without some experimental knowledge of these surface resistances.

Mean Value Theories in Quantum Mechanics

It is known¹ that in some cases there exists a close connection between the equation of classical dynamics and corresponding relations between mean values of quantities in quantum mechanics. Thus, for instance, it has been shown by Ehrenfest that according to Schroedinger's non-relativistic equation the mean momentum \bar{p} is related to the mean position \bar{q} by $\dot{\bar{p}} = m\dot{\bar{q}}$ and also that the rate of change of the mean momentum \bar{p} is equal to the mean of $-\text{grad } V$ where V is the potential energy. This theorem has also been generalized to more dimensions by Ruark. While it is satisfactory to see the similarity of classical and quantum relations in such special instances it is nevertheless desirable to bear in mind also a somewhat more general point of view. It is readily seen that according to the transformation theory the reason for the validity of mean value theorems is that the equations of classical theory hold, in the above instance, also in the quantum theory between

In conclusion we may note that these thermal fluctuations of surface potential are perhaps connected with the "flicker" effect.⁵ It is evident that such a theory would bear some resemblances to the theory of this effect advanced by Johnson⁶ and developed by Schottky,⁶ which ascribes the flicker to fluctuations in the composition of the surface. In our case the frequency variation of the effect would be introduced by the variation of R with frequency, the fluctuations of surface potential presumably approaching a maximum value as ω is decreased.

It is hoped to discuss these questions in more detail later, particularly if some experimental evidence can be obtained about the surface resistance and its temperature coefficient.

The writer is indebted to Dr. Langmuir and to Dr. Tonks for discussion of these ideas.

⁶ W. Schottky, Phys. Rev. **28**, 74 (1926).

corresponding matrices. Thus as a consequence of the Hamiltonian form $H = p^2/2m + V(q)$ we have $\dot{p} = -\partial V/\partial q$ holding as equations between matrices. If we refer all the matrices to the same reference system e.g. that of q and if we write the probability amplitude as $S(q')$ then we also have

$$\begin{aligned} \int S^*(q') p(q', q'') S(q'') dq' dq'' \\ = m(d/dt) \int S^*(q') q(q', q'') S(q'') dq' dq'' \end{aligned}$$

or

$$\dot{\bar{p}} = m\dot{\bar{q}}.$$

We are allowed to use here the equation

$$\begin{aligned} \frac{d}{dt} \int S^*(q') q(q', q'') S(q'') dq' dq'' \\ = \int S^*(q') \frac{d}{dt} q(q', q'') S(q'') dq' dq'' \end{aligned}$$

¹ P. Ehrenfest, Zeits. f. Physik **45**, 455 (1927); A. E. Ruark, Phys. Rev. **31**, 533 (1928).

because (1) we may work with $S(q')$ independent of t provided the matrix $q(q', q'')$ involves t as a parameter, (2) the equation is obviously true in the reference system of the energy where $q_{nm}(t) = q_{nm}(0) \exp[(2\pi i/\hbar)(W_n - W_m)t]$ (3) the values of the integrals on the right and left of the above equation are independent of the reference system used for matrix representation. In a similar way we have

$$\frac{d\bar{p}}{dt} = \bar{p} = -\frac{\partial \bar{V}}{\partial q}.$$

The way in which we use the matrices $q(q', q'')$ is explained very clearly in Schroedinger Sitzungsberichte der preussischen Akademie XXIV p. 417, 1930, and is treated in Weyl's book, chapter II section 15. Remembering that Schroedinger's $\psi(0)$ is our S , it is seen that at any time the averages $\partial \bar{V} / \partial q$ is taken weighing every element of the configuration space in proportion to $\psi^*(t)\psi(t)$ at that point at the particular time i.e. the average is taken in the same way as by Ehrenfest and Ruark. The same can be done for any other equation which holds between matrix as well as classical quantities. The only doubtful point of this shorthand proof lies in dealing with singular matrices which must be expressed by means of the δ function. This however, is usually only a formal objection since throwing away the "surface integral" contributions of partial integrations is also a necessary part of the purely wave-mechanical proof such as that of Ehrenfest quoted above.

Although the above statement is simple enough to be called trivial it seems that its physical implication is not always realized. Thus for instance the motion of a non-relativistic spinless electron in a magnetic field is governed by the same equations in quantum and

in classical dynamics. The center of mass is therefore moving as the classical center of mass under the action of the mean electromagnetic field in the wave package. This has already been proved a long time ago by Kennard and elucidated by Eckart in connection with a recently suggested explanation of discrepancies between the values of e/m . Similarly with the relativistic Dirac equation the rate of change of the mechanical momentum is known to be given by a formula having the same structure as the classical formula, the classical velocities being replaced by $-c\alpha_i$. Again the mean value theorem holds. The equation which proves this is the one derived by Fock.²

$$\begin{aligned} \frac{d}{dt}(p_1 + eA_1/c) &= e \frac{\partial A_0}{\partial x_1} \\ &+ e\alpha_2 \left(\frac{\partial A_2}{\partial x_1} - \frac{\partial A_1}{\partial x_2} \right) - e\alpha_3 \left(\frac{\partial A_1}{\partial x_3} - \frac{\partial A_3}{\partial x_1} \right) \\ \frac{dx_1}{dt} &= -c\alpha_1. \end{aligned}$$

Here $p_1 + eA_1/c$ is the momentum in the direction x_1 , A_0 is the scalar potential, (A_1, A_2, A_3) is the vector potential and $\alpha_1, \alpha_2, \alpha_3, \alpha_4$ are Dirac's four-row matrices. The equation proves that the rate of change of the average of $p_1 + eA_1/c$ of a wave package is related to the average force on the wave package by the equation of classical electrodynamics

$$F = \rho \{ E + [\mathbf{v}H]/c \}.$$

Block Structure and Ferromagnetism

In the following a model is proposed for ferromagnetic substance based on the assumption of the existence of a "block structure" in solids as postulated by Smekal and Zwicky, and some of the properties of this model are pointed out. In a future communication it is hoped to give a more detailed and comprehensive account of the derivations and results indicated below.

A block, according to Zwicky,¹ is a region having the properties of a perfect crystal, surrounded by a surface physically different from the volume. This difference is connected with

a local rearrangement of atoms such that along the surface the average interatomic distance is not that prevailing inside of a block. If such blocks exist, it is not unreasonable to assume that each one is spontaneously magnetized as predicted by the Weiss-Heisenberg theory

$$\frac{I_T}{I_0} = \tanh \frac{\mu_B N I_T}{KT}. \quad (1)$$

¹ F. Zwicky, Helvetica Physica Acta 3, 269 (1930).

In this expression the dependence on H is omitted as it is negligibly small for the field strengths used in most experiments, and its inclusion would add nothing to the following discussion. μ_B is a Bohr magneton. The assumption is now made, and this is the only new assumption, that various blocks may be magnetized in various directions, or what amounts to the same thing, any particular block may change the direction in which it is magnetized, and its magnetic moment need not be parallel to those of its neighbors. This is equivalent to saying that the electrons on opposite sides of a block surface are not ferromagnetically coupled to each other. Such a situation is not unthinkable, as such a coupling depends on Heisenberg's resonance integral which is known to be extraordinarily sensitive to variations in inter-atomic spacing, and such variations actually define the surface of a block.

Our model, then, is a group of permanent magnets, having primarily a thermomagnetic interaction. For the present, surface phenomena are neglected. In order to simplify the problem, the blocks are assumed isotropic, so that there are no "directions of easy magnetization." These last two assumptions should be dropped in a more exhaustive discussion. Under these conditions the blocks may be expected to interact in such a way that the magnetization is approximately given by

$$\frac{I}{I_T} = \coth x - \frac{1}{x} \quad x = \frac{\mu}{KT}(H + LI). \quad (2)$$

Here μ is the block moment and is given by $I_T v$, the saturation intensity at the temperature T multiplied by the volume of a block. L is a factor varying between 0 for long thin blocks whose axis is parallel to H , and 4π for disk shaped blocks. LI represents the internal field. Eqs. (1) and (2) define the behaviour of our model.

The first point of interest is that this model is essentially that of Ewing, with the exception that the elementary magnets, instead of being of atomic dimensions, are somewhat larger. Thus the model is fundamentally capable of describing a magnetization curve and a hysteresis loop, as Ewing demonstrated experimentally. The details are determined by the only two arbitrary constants, appearing in the equations, μ and L . To get an idea of their order of magnitude it is possible to assign

values to them which will give observed values for K_0 , the initial susceptibility. Using experimental data obtained on iron, nickel and cobalt for K_0 and I_0 , and substituting extreme values of L , we find that the block volume contains between 10^2 and 10^6 atoms. An intermediate value of L would give an intermediate block size.

The next point of interest is that this model gives the approach to saturation correctly. In a very thorough investigation Weiss² showed that most substances approach saturation according to the formulae

$$I = I_T(1 - a/H) \quad (3)$$

$$I_T = I_0(1 - AT^2). \quad (4)$$

The first of these formulae follows immediately from Eq. (2), and from the constant a it is possible to compute the number of atoms per block. ($a = KT/\mu$; $\mu = vI_T$). With Weiss's data for nickel and iron we get approximately 10^5 atoms per block. Weiss examined the approach to saturation as a function of the temperature between 100°K and 300°K . In this region I_T/I_0 as given by Eq. (1) is very approximately a straight line if plotted as a function of T^2 . From the constant A it is possible to compute the molecular field constant N , and the values obtained are quite reasonable. It is true that an extrapolation of (4) for $T=0$ leads to somewhat too high values for I_0 , but in general the error so committed will be small.

Further, this model has two Curie-points, a property of most ferromagnetic substances as pointed out by Forrer.³ θ_p the paramagnetic Curie-point is defined by the modified Curie Equation $x = c/(T - \theta_p)$ for $T > \theta_p$. θ_f , the ferromagnetic Curie-point is in general less than θ_p , and is the temperature at which spontaneous magnetization disappears. θ_p is given in the usual way by Eq. (1). On the other hand Eq. (2) will itself have a Curie-point

$$\theta_f = \frac{\mu LI_T}{3K}.$$

That is, for $T > \theta_f$ the spontaneous magnetization of the whole material⁴ will disappear, whereas for $T > \theta_p$ the blocks themselves lose their moments. From this it is evident

² P. Weiss, Ann. de Physique 12, 20 (1929).

³ R. Forrer, Journ. de Ph. et le Rad. 1, 49 (1930).

that $\theta_f|_{T=\theta_p} < \theta_p$ as it is actually observed in most substances. A detailed examination shows that $\theta_p - \theta_f = \text{approximately } 15^\circ\text{C}$ is consistent with blocks containing about 10^8 atoms.

Such an interpretation of θ_f brings with it the necessity of a new explanation of the thermal phenomena at the Curie-point. Such an explanation it is impossible to give until more definite assumptions can be made regarding the surface energies of the blocks, the effect of strains, etc. The fact that acceptance of the proposed model would require the abandonment of our present explanation of thermomagnetic phenomena at the Curie-point, would be a telling argument against such a model, were it not that just here the Weiss Theory is in part not quite satisfactory (in its interpretation of the change in specific heat for $T=0$) and in part purely thermodynamic (in the relationship it establishes between the specific heat and the magnetocaloric effect).

In conclusion I wish to point out that blocks containing approximately 10^8 atoms, as here postulated for the explanation of three ferromagnetic phenomena, are of the same order of magnitude as those postulated by Smekal and Zwicky to explain certain mechanical and electrical phenomena.

⁴ Spontaneous magnetization of the sample need not, of course, include the whole sample. It may be spontaneously magnetized in different directions in different regions. It would be sufficient that large groups of units, in this case larger groups of blocks, should possess a resultant moment in the absence of externally applied fields.

Secondary Electrons from Molybdenum

The writer has continued work begun by Soller (Phys. Rev. 36, 664, 1930) on the distribution in energy of electrons emitted by a molybdenum target bombarded by a narrow, homogeneous beam of electrons of relatively low energy (20 to 100 volts).

The apparatus was a modification of that of Soller, employing the method of magnetic analysis. The target was heated by electron bombardment for a total of 700 hours. Observations were taken at intervals throughout this outgassing period. With the primary energy held constant, measurements were taken of the number of secondary electrons (N_s) of energy ϵ . By changing the magnetic field, ϵ was made to vary in steps of 0.1 to 0.2 volts from zero up to the primary energy. Curves were plotted for $N_s/N \times \text{const.}$ as a function of ϵ where N is the total number of primary electrons.

Curves plotted from the results obtained for a cold target show, in addition to the usual large group of secondary electrons with energy approximately that of the primaries, a low maximum in the region 5 to 15 volts and a second very broad and somewhat higher maximum at an energy approximately one-half that of the primaries. For low primary energies these two groups become merged. In addition there are three well defined maxima corresponding to electrons possessing ener-

gies 4.7, 11.2, and 23.2 (± 4) volts less than the energy of the true reflection maximum. These last maxima are similar to those found by Rudberg (Proc. Roy. Soc. A127, 111, 1930) for various metals and indicate the presence of reflected primary electrons which have lost a discrete amount of energy in the process of reflection. The height of these peaks increases as the velocity of the primary electrons decreases. These peaks appeared only after considerable outgassing and became more and more marked with further heating.

In attempting to eliminate the effects due to gas occluded on the surface of a cold target, the following procedure was adopted. With the magnetic field set to correspond to a given value of ϵ the target was heated to a bright yellow for thirty seconds and N_s measured thirty seconds after the bombarding current was cut off. (The target ceased to be visibly red after about 20 seconds.) This procedure was followed through the whole range of values of ϵ . A typical curve obtained from these data was that for a primary energy of 60 volts. Observations taken in this way show a very large group of low velocity secondaries of energy from three to twenty-five volts, and N_s/N now reaches a maximum value at 8 volts which is 27 times as great as the corresponding maximum at 8 volts for a cold target. For higher values of ϵ the values

of N_e/N are more nearly alike for the hot and the cold target, the ratio being 2 at a point just short of the full velocity maximum. The three discrete peaks are greatly enhanced in the case of the freshly heated target.

The large low velocity group disappears rapidly with time, the value of N_e/N at eleven volts changing from 27 to 3 during the first three minutes but there is no such rapid change for higher values of ϵ . After the first three minutes there is no further change for as much as thirty minutes, following which there is a gradual decrease over a period of three or four hours. The gradual decrease after 33 minutes is believed due to the occlusion of gases. The first rapid decrease is of unknown origin but, since it is independent of pressure and occurs in such a short time, it does not seem possible that it can be due to the adsorption of gas. The best vacua were of the order of 10^{-7} mm of Hg.

In addition curves were plotted for the height of the full velocity peak as a function of the primary velocity. These show marked

minima at 9.3 and 20.6 volts. The difference between these is 11.3, about the same as the difference between the values of ϵ for the 11.2 and 23.2 volt discrete energy-loss maxima. Corrections for work functions etc., necessary to bring 9.3 and 20.6 into agreement with 11.2 and 23.2 are not unreasonable. The full velocity data were not reliable for primary voltages below 6 volts so that no check was obtained for the 4.7 discrete loss group. It is suggested that these minima in the number of elastically reflected electrons are due to some sort of excitation within the metal, the efficiency of which increases as the energy of the primary electrons approaches that necessary for the excitation. On this assumption the three discrete groups of secondaries are composed of reflected primary electrons which have lost a definite amount of energy in the process of reflection.

On Collisions of Photons

According to the modern concepts of matter and energy, practically all the properties which are usually attributed to matter, can be associated with radiation. The source of solar and stellar energy can be traced to the "annihilation" of matter. However it is not certain that energy is transformed into matter, but with the help of this hypothesis it is possible to calculate correctly the relative mass of the elementary particles of matter. The identity of matter and energy would thus appear to be almost complete and the principles of the conservation of mass and of energy to be but two aspects of one universal principle.

Following up these considerations one would naturally be led to expect the existence of mutual collisions of photons. Thus the paper "Attempt to Detect Collisions of Photons" by Hughes and Jauncey, which appeared in *Physical Review* 36, 773, 1930, is of special interest.

About two years ago this same idea occurred to me and I communicated it to Professor G. Angenheister, Director of the Geophysikalisches Institut, Göttingen, in whose laboratory I was working at the time. But the resources of that institution were not adequate to an experimental verification of the idea. The nature of the effect which I expected was

similar to that expected by Hughes and Jauncey. In the calculations regarding the possibility of observing the effect, the faintest star clearly visible by the naked eye, was taken to be of the sixth magnitude, as is usually assumed. Using Zöllner's estimate of the ratio of the magnitude of the sun and Capella (magnitude 0.2) and using Exner's value for the vertical illumination of the sun, the limit of human vision was calculated to be 3 millimicrolux. The sensitivity of the eye is maximum for the frequency 0.58×10^{15} , the quantum of which is 3.8×10^{-12} erg. So the number of quanta received by the eye when receiving the minimum visible light is about 360 per second. This number seemed to be too high to be obtained by the scattering of photons due to the mutual collisions which one would expect at the point of crossing of two beams of light under ordinary conditions. I concluded that the expected effect could not possibly be detected with certainty by an optical method, visual or photographic. (A selenium detector might be better suited for the purpose). My plan, therefore, was to look for the theoretically expected effect with the help of some instrument that would record the elementary effect of single photons and not simply the integrated effect of a multitude. Such

an instrument I recognized in the "Elektro-nenzählrohr" or even in the so-called "Glimmlampe." For this purpose I wanted to utilize the "Elektronenzählrohren," which I had constructed (with the collaboration of K. Wölcken) primarily for the investigation of gamma and cosmic rays.

Instead of using ordinary light (as Hughes and Jauncey have done) my intention was to use x-rays or gamma-rays, but I could not put my intention into practice for lack of necessary equipments. The negative result of Hughes' and Jauncey's experiment need not necessarily lead to the conclusion that mutual collisions among photons do not occur. Those

who have the advantage of a good physical laboratory, may find it worthwhile to try the experiment on the lines indicated above.

In conclusion, I would like to mention that sometime ago I found out that the theoretical possibility of the existence of the nature of the effect in question was pointed out by L. de Broglie as early as 1926 in his book "Ondes es Mouvements" pp. 96-98 (Gauthier-Villars, Paris).

BOOK REVIEWS

Optical Rotatory Power A general discussion held by the Faraday Society. Pp. 198. Aberdeen University Press, 1930. Price 10s 6d.

The contributions to this discussion cover practically all phases of the subject and are grouped under the following headings:

- I. The Physical Basis of Optical Rotatory Power (8 papers)
- II. Apparatus and Methods (2 papers)
- III. The Rotatory Power of Solutions (7 papers)
- IV. The Chemical Aspects of Optical Rotatory Power (4 papers).

A considerable portion of the discussion centers about the physical theories of optical activity which are presented in articles by Kuhn, Malleman, Ewald, Temple, and others. The wave mechanics of rotatory polarization is shown to be at present in an unsatisfactory state, the principal short-coming being the lack of a connection between optical activity and structure. Experimental methods especially applicable to the ultra-violet region of the spectrum are reviewed by Descamps. As is shown by Cotton and others, this region of the spectrum is an important one in the study of rotatory dispersion and circular dichroism. Many interesting compounds are discussed in the chemical part of the report.

J. VALASEK

Röntgenographie der Metalle und ihrer Legierungen. M. C. NEUBERGER. Pp. 278, figs. 66. Price RM 25.

This book is a fit companion volume to the author's excellent *Röntgenographie des Eisens und seiner Legierungen*, which appeared about a year ago. Because of this previous work, the author confines himself in the present volume to a treatment of the non-ferrous metals and alloys in the light of x-ray data.

The present work supplies a long-felt want in that it renders available at hand in one volume a mass of x-ray data relating to metals and alloys, which is widely scattered, and which can otherwise be obtained in case of need only by an extensive searching of the literature. These data are critically discussed by the author and, wherever a structure is in dispute, he gives not only the result which he considers as probably correct, but also the conflicting results of other workers. A liberal use of tables of x-ray data and reproductions of original x-ray photographs add to the value of the book.

WILLIAM P. JESSE

Les Applications des Rayons X. J. J. TRILLAT. Pp. 298, figs. 108. Les Presses Universitaires de France, Paris, 1930. Price, 85 francs.

This book, as the title indicates, is written for the benefit of the rapidly growing group who would know something of the recent developments of x-rays as a tool in physics, chemistry and metallurgy. With this practical end in view, the author avoids as much as possible all theoretical aspects of the subject which do not bear directly on the technical uses of x-rays and frequently discusses in detail manipulative methods which may prove valuable to one contemplating work in this field.

The book is divided into two sections. In the first of these, which comprises the first third of the book, the author has an introductory chapter on the elementary principles of crystal structure and of x-ray diffraction. Then follows an extended discussion of various types of x-ray tubes and apparatus and a survey of the different methods of x-ray spectroscopy.

The second part of the book deals with recent advances in the use of x-rays in widely different fields. The first chapter on the metals, while not entirely comprehensive, is probably as complete as the enormous mass of work on the subject will allow in such a limited space. This chapter is followed by a very good account of work on the long chain carbon compounds, the material for which is in a large part taken from the author's own researches. The following chapters deal with cellulose and its derivatives, rubber and resins, the diffraction of x-rays by liquids and a short discussion of colloids. The last section makes a very brief mention of radio-

graphic applications to metals and of chemical analysis by x-rays. A very good bibliography at the end of each chapter is a valuable feature of the book.

The book is clearly written and is by an author who has added something to almost every field discussed. It should prove valuable to anyone interested in the technical uses of x-rays.

WILLIAM P. JESSE

The Principles of Quantum Mechanics. P. A. M. DIRAC at the Clarendon Press, Oxford, 1930. Pp. 257.

A book on quantum mechanics written by Dirac must be of great and in many ways unique interest to physicists. The quantum mechanics of today is not the work of one man; but since the foundation of the theory by Heisenberg and Schroedinger, there have been few cardinal advances which have not been made by Dirac; and in his papers alone one may find the key to the solution of almost any problem which the theory is competent to treat. The fact that a book on quantum mechanics must necessarily be largely an account of Dirac's own work, assures us that his account will be unitary and coherent, and that it will be given in just those terms which have shown themselves most useful to the understanding and the development of the theory.

The title of the book tells us that we shall not find here the detailed solution of many specific problems; what we do find is the development and exposition of the methods by which such problems may most simply be attacked. In this respect Dirac's book is very complete—for so short a book, astonishingly complete. In many cases the methods used by Dirac are considerably simpler and more direct than any to be found elsewhere; this is true of his treatment of angular momentum, of the theory of collisions and of radiation, and of the theory of systems containing similar particles. In this last problem, it is true, Dirac's method does not give Wigner's complete reduction of all matrices; and this renders the application of his method to many problems unnecessarily laborious. A few developments of theoretical significance are not included in the book; of these omissions, possibly the most important are the theory of quantized waves for systems satisfying the exclusion principle, the unitary theory of electromagnetic field and matter, and the theory of the electron in a gravitational field. But these things belong perhaps rather to the quantum mechanics of the future; and their omission will hardly be found to diminish the value of the book.

In some very fundamental respects Dirac's book is like Gibbs' "Elementary Principles of Statistical Mechanics": it is clear, with a clarity dangerous for a beginner, deductive, and in its foundations abstract; its argument is predominantly analytical; the virtual contact with experiment is made quite late in the book. The difficulty which this would present for many readers is largely reduced by Dirac's introductory descriptive chapter, and by conscientious efforts to translate all results into physical terms. But physical ideas are seldom used to advance the argument, and occur chiefly as an aid to exposition. The book remains a difficult book, and one suited only to those who come to it with some familiarity with the theory. It should not be the sole text, nor the first text, in quantum theory, just as that of Gibbs' should not be the first in statistical mechanics. Every part of the theory may be understood from more than one point of view; to see it always and only from one point of view, even if that be the most general, is to understand it only partially.

We must say a few words of Dirac's quasi-postulate-theory foundation of the quantum mechanics. Dirac begins his argument by introducing certain symbols, said for picturesqueness to "represent" states and observable variables of a system, and by laying down axioms for the manipulation of these symbols. These symbols do not represent, as do those more current in mathematical physics, a class of numbers defined by some specific measurement on a system; they represent the class of such classes of numbers, defined by any measurement on the system. Thus Dirac's axioms,—and, in fact, most of his earlier chapters—have an extreme generality; but because the meaning of any equation, in physics, is ultimately to be derived from the numbers given by specific observations, they have also a higher grade of abstractness. This is the price that must be paid for the generality. And Dirac's book will be for many of us so satisfying, that we shall be glad to pay it.

J. R. OPPENHEIMER

PROCEEDINGS OF THE AMERICAN PHYSICAL SOCIETY

MINUTES OF THE CHICAGO MEETING, NOVEMBER 28 AND 29, 1930

The 166th regular meeting of the American Physical Society was held in Chicago, Illinois, at the Ryerson Physical Laboratory and Eckhart Hall of the University of Chicago on Friday and Saturday, November 28 and 29, 1930. The presiding officers were Professor Henry G. Gale, President of the Society, Dr. W. F. G. Swann, Vice-president and Professor O. M. Stewart.

On Friday evening the Physical Society had a dinner at the Hotel Win-dermere. There were one hundred and ten present. President Gale presided. The after dinner speakers were Dr. A. J. Dempster, Dr. Paul D. Foote, Dr. Herbert E. Ives, Prof. R. Ladenburg, Prof. M. von Laue and Professor R. Scherrer.

At the regular meeting of the Council held on Friday, November 28, 1930 at 10:30 a.m. seventy were elected to membership. *Elected to Membership:* John M. Aitchison, Gerald M. Almy, W. N. Arnquist, John V. Atanasoff, Michael Balas, Willard H. Bennett, J. C. Betz, Paul H. Boots, Robert A. Boyd, James M. Bradford, Maurice J. Brevoort, H. T. Byck, R. W. Carson, Lawrence H. Cook, Winston Cram, C. F. DeVoe, Laurance H. Donnally, J. S. Evans, Robley D. Evans, George Forster, Amelia Frank, Wendell H. Furry, Otto Halpern, R. R. Hancox, Helen Harms, H. Harold Hartzler, Arthur B. Hersey, D. M. Hill, Joseph O. Hirschfelder, Winston L. Hole, Walker Kinkaid, John R. Kerry, William S. Klein, Emeran J. Kolkmeier, M. R. Krasno, Jules A. Larrivee, Rose LeD. Mooney, Robert Morgan, John M. Nordquist, M. Ostrofsky, Ralph G. Owens, Lyman G. Parratt, R. W. B. Pearse, W. D. Phelps, Lloyd B. Phillips, E. R. Piore, Frank W. Pote, Kurt F. Ritzau, Edward R. Schmid, Frederic A. Scott, Robert Serber, Robert S. Shankland, J. A. Sharpe, J. H. Simons, Albert Smith, Chauncey G. Suits, Shinji Togo, Philander B. Taylor, Melvin C. Terry, Rayen W. Tyler, Oliver G. Vogel, John H. Wanamaker, Mary D. Weber, Donald F. Weekes, George L. Weil, M. F. Weinrich, Lester V. Whitney, Violet Wu, H. M. Zenor and George E. Ziegler.

The regular scientific session consisted of fifty four papers, eight of which—Nos. 17, 18, 20, 26, 32, 33, 43 and 46—were read by title. The abstracts of these papers are given on the following pages. An AUTHOR INDEX will be found at the end.

W. L. SEVERINGHAUS, *Secretary*

1. **Measuring the intensity of molecular beams.** A. ELLETT AND R. M. ZABEL, *University of Iowa*. A sensitive Pirani gauge has been developed and used to measure the intensity of a molecular beam defined by 0.5 mm circular openings 22 mm apart. The gauge is situated 35 mm from the last opening. A beam of air gives a galvanometer deflection of 1000 cm with a pressure of 1 mm behind the first opening. H_2 produces a deflection of 2000 cm. The galvanometer sensitivity is 11.6 mm per micro-volt. The time lag of the gauge is less than the period of the galvanometer (7 seconds). The limits within which the beam forming system may be expected to give a Maxwellian distribution of velocities are discussed. The final pressure in the gauge due to a given beam depends upon the size of the gauge opening as kinetic theory predicts. The reduction in intensity of beams of air and H_2 by collision with either air or H_2 present in the experimental chamber at various pressures has been measured. The data show that the gauge may be used to measure mean free paths and to obtain more detailed information that has previously been possible as to the probability of scattering through various angles by collision.

2. **Diffraction of atomic hydrogen.** THOMAS H. JOHNSON, *Bartol Research Foundation, Swarthmore, Pa.* Improvements in the technique of photographing the de Broglie wave diffraction patterns, produced by the reflection of a beam of atomic hydrogen from a cleaved crystal of lithium fluoride, have considerably increased the intensity of these patterns over that of the patterns previously reported. In consequence, new features have been recorded. The patterns obtained by reflection at normal incidence consist (a) of four intense lines radiating from the central specularly reflected spot in directions perpendicular to the two mutually perpendicular sets of rows of similar ions on the surface of the crystal and (b) of four relatively weak, but plainly visible, lines radiating from the same point but perpendicular to the two sets of diagonal rows of alternately dissimilar ions. The gradation of intensity along the "a" lines corresponds to the dispersion of the various wave lengths of the Maxwellian velocity distribution by the grating whose lines are the rows of similar ions spaced at intervals of 2.83Å. The "b" lines have a greater dispersion corresponding to the closer spacing of 2.00Å between the rows of alternately dissimilar ions. Similar patterns observed at 45° incidence appear with branches corresponding to the various combinations of the values of 0, -1, +1 for m and n in the plane grating formulae $\cos \phi_0 - \cos \phi = m\lambda/d$ and $\cos \theta_0 - \cos \theta = n\lambda/d$.

3. **The value of e/m by deflection experiments.** G. E. UHLENBECK AND L. A. YOUNG, *University of Michigan*. To clarify the discussion as to whether or not a quantum mechanical treatment of the motion of electrons in magnetic fields will lead to a formula for e/m , differing from that obtained by classical electrodynamics the following problem was solved. A uniform magnetic field in the z -direction exists in the half-space $x > 0$. A plane monochromatic de Broglie wave, travelling in the positive x -direction representing electrons of arbitrary energy, impinges normally on the plane $x = 0$. Solutions of the wave equation were found fulfilling appropriate boundary conditions at the plane $x = 0$. Currents are calculated quantum mechanically and compared with the corresponding classical expressions. It was found that for electrons possessing energies of the order of magnitude used in deflection experiments, no observable deviations from classical results are predicted. Another quantum mechanical effect is diffraction at slits. Simple approximate calculations show that this effect can produce a fractional error in e/m of the order of the de Broglie wave-length divided by the slit width. These results are opposite to the conclusions reached by Page (Phys. Rev. 36, 444). We may remark that he solved a problem of "stationary states" which does not represent the actual experiments.

4. **The diffraction of an electron-wave at a single layer of atoms.** M. v. LAUE, Visiting Professor from the University of Berlin. (Introduced by A.H. Compton). This paper undertakes to estimate the influence of the gradual transition between the field exterior to, and in the interior of a crystal, on the diffraction of electrons. This gradual transition is required by electrostatics. The result is that this influence may be neglected for electrons whose energy is two-hundred volts or more. One can then treat the transition as discontinuous. In the case of slower electrons it seems doubtful if such a treatment is permissible.

5. Frequency variations due to the electrodeless discharge. J. T. TYKOCINER AND J. KUNZ, *University of Illinois*. Experiments were carried out to show that an oscillator which excites electrodeless discharges undergoes variations of its frequency due to the reaction of the discharges. These variations were measured by means of a heterodyne method and the results were applied for a study of the intensity and character of the electrodeless discharge currents. The fact was thus disclosed that contrary to a relation calculated on the basis of J. J. Thomson's theory of the ring discharge which demands an increase of frequency, the "ring" discharge causes a decrease of frequency. An extension of the theory was undertaken which takes into account the effect of the capacitance of the excitation coil itself and of the influence of the ionized dielectric in the discharge tube subjected to the action of electrostatic fields. It can thus be shown that due to the electrostatic forces always predominating over the electromagnetic induction, a decrease of frequency must result, whenever the inner conductance of the discharge is small enough to suppress the formation of ring discharges.

6. Interpretation of negative volt ampere characteristics of neon positive column. CLIFTON G. FOUND, *General Electric Co., Schenectady, N. Y.* The voltage gradient in the positive column of a discharge in neon decreases rapidly with increase in current. The decrease in gradient runs parallel to the increase in concentration of metastable atoms and to the increase in light efficiency. Moreover, observations show that the electrons in the positive column have velocities corresponding to a Maxwellian distribution in which electrons with a velocity greater than the resonance potential are absent. This deficiency of electrons with energy sufficient to produce ionization indicates that the positive ions are not formed by a single electronic collision but must be the result of a two stage process such as ionization of metastable atoms by slow electrons. These characteristics indicate that the negative resistance of the positive column is connected with the presence of metastable atoms. This assumption permits an explanation of the inductive impedance of a hot cathode neon tube as measured by W. F. Westendorp by a method which will be described in the near future.

7. The efficiency of ionization of mercury vapor by electron impact near the ionization potential. PHILIP T. SMITH, *University of Minnesota*. Direct measurements of the efficiency of ionization by electron impact, using an electron beam with a very narrow velocity distribution show a series of discontinuous changes in the slope of the efficiency curves as the energy of the impacting electrons is increased. Most of these discontinuities or "ultra-ionization potentials" agree with those previously observed by E. O. Lawrence, (*Phys. Rev.* **23**, 947 (1926)) and A. L. Hughes and C. M. Van Atta, (*Phys. Rev.* **36**, 214 (1930)), although several new ones have been observed. Lawrence's values were 10.40, 10.60, 11.29, 11.70, 12.06 volts. Hughes' and Van Atta's 10.40, 10.62, 10.88, 11.28, 11.40, 11.77, 12.16, 12.76. Our values, 10.40, 10.60, 10.76, 10.88, 11.07, 11.27, 11.40, 11.55, 11.70, 11.78, 11.90, 12.06, 12.17, 12.38.

8. Doppler effects in hydrogen with canal rays of uniform velocity. H. F. BATHO AND A. J. DEMPSTER, *University of Chicago*. Positive ions were produced by bombarding hydrogen with low voltage electrons from a hot cathode. The ions formed passed beside the cathode into a strong field where they were accelerated by potentials up to 15,000 volts. The ions then passed into an observation chamber, where the light emitted by the accelerated particles was photographed with a large three-prism spectrograph. With the usual canal-ray tubes broad displacements are obtained as Doppler effects due to the velocity distributions in the ions, maxima are sometimes present suggesting ions of various masses, and the observed displacement is always considerably less than that calculated from the potential difference on the tube. With the present tube sharp displaced lines of the Balmer series are obtained indicating homogeneous velocities, the displacements agree with those calculated from the potential for atomic ions, molecular ions and triatomic molecular ions. These ions break up in the observation chamber giving hydrogen atoms which emit the Balmer series lines with Doppler effects corresponding to the velocities of the ions. At low pressures the displaced line due to the molecule ion becomes the strongest as suggested by previous experiments on the positive-ray analysis of ionization products.

9. A study of the velocities of ions formed in nitrogen by electron impact. W. WALLACE LOZIER, *University of Minnesota*.—In a recent paper (Phys. Rev. 36, 1285 (1930)) there was described a method which is suitable for a measurement of the velocities of ions formed in molecular gases by electron impact. This method is employed in a study of nitrogen. Above 35 volts electron velocity there are two groups of ions, these being N_2^+ and N^+ . The N_2^+ ions possess very little kinetic energy while the majority of the N^+ ions possess about 3.0 equivalent volts velocity, these latter ions resulting from dissociation of molecular ions. The number of N^+ ions increases so rapidly with electron velocity that at about 60 volts electron velocity they actually occur in greater numbers than the N_2^+ ions, a fact which is in striking contrast to the results obtained in hydrogen.

10. The effect of resolving power on the absorption coefficient of electrons in gases. R. RONALD PALMER, *University of Minnesota*.—The absorption coefficient of electrons in helium and in mercury vapor has been studied as a function of the geometry of the experimental apparatus. An electron beam of 0.4 mm radius was used in a Mayer type of apparatus in which the opening at the end of the scattering chamber was of variable aperture. Values of the absorption coefficient were obtained for 20, 40, 80 and 135 volt electrons over an angular aperture range of from 2° to 11° as measured from the end of the electron gun. All curves showed a definite decrease in the absorption coefficient with increase in angular aperture. These curves were corrected for the positive ion current, from the efficiency of ionization data of Bleakney and Smith, to give curves for the total number of electrons collected as a function of the size of the opening. These showed also a definite decrease with increase in aperture, corresponding to a preference for scattering to take place at small angles. In helium the curves were steeper the higher the electron velocity, whereas they were more alike in mercury vapor. From Arnot's angular distribution results it is possible to predict such a curve for 80 volt electrons in mercury vapor. The predicted curve is much steeper, showing a sixty-five per cent decrease as against a thirty-two percent decrease over the same range experimentally. This discrepancy is as yet unexplained.

11. The motion of electrons in argon. H. B. WAHLIN, *University of Wisconsin*.—The mean free path λ of electrons in argon has been determined for the case where the electrons are in thermal equilibrium with the gas, using the alternating potential method for determining mobilities. The value thus found is $\lambda = 0.385$ cm at a pressure of 1 mm. This value is 9.2 times the kinetic theory value $(4/2)^{1/2}$ times the atomic free path). The mobility curves obtained when the current is plotted against the alternating voltage definitely show the influence of the Ramsauer effect.

12. Specific resistances of zinc single crystals. E. P. T. TYNDALL AND A. G. HOYEM, *University of Iowa*.—Measurements made on fourteen single crystals prepared from Kahlbaum's best zinc by the Czochralski-Gomperz method yield values of specific resistance which verify the Voigt-Thomson symmetry relation with considerably more accuracy than has been the case previously. The scattering of results of previous observers (Bridgman, Ware) appears to have been avoided here by more careful attention to experimental conditions, particularly in the determination of cross-sectional area and its variation along the crystal rod, and in temperature control. The increase in resistance due to slight strains found by Bridgman does not exist for these crystals. The specific resistances, perpendicular and parallel to the vertical axis are: $\rho_{\perp} = 5.88 \times 10^{-6}$, $\rho_{\parallel} = 6.20 \times 10^{-6}$ ohms/cm². For a series of 22 crystals prepared from "spectroscopically pure" zinc (from the New Jersey Zinc Co.) the values $\rho_{\perp} = 5.83 \times 10^{-6}$, $\rho_{\parallel} = 6.15 \times 10^{-6}$ are obtained. The results, however, are more scattered than for the Kahlbaum crystals, but it is believed that this may be due largely to increased experimental difficulty in handling these much more easily deformable crystals. Thus, the purer zinc shows lower values of specific resistance throughout, but the ratio $\rho_{\parallel}/\rho_{\perp}$, is the same for both 1.055.

13. Electromotive force of paraffin membranes. KARL LARK-HOROVITZ AND J. E. FERGUSON, *Purdue University*.—With the method developed by Horovitz some time ago (Proc. Vienna Acad. Sci. 134, 345 (1925)) thin films of paraffin were sealed to glass tubing of known electrode function. These paraffin films are used as one electrode in aqueous solutions of dif-

ferent ionic concentrations. Measuring the change of electro-motive force of the paraffin film as a function of the concentration of ions in the solution by using a binant-electrometer (Dolezalek), the following results were obtained: Paraffin acts as a reversible electrode in respect to cations only. It behaves in solutions of HCl, KCl, NaCl, AgNO₃ and NaOH like a reversible electrode in respect to any of the cations contained in the solution after a certain range of concentration has been reached. In solutions of mixtures of electrolytes, paraffin behaves like a mixed electrode, its behavior being in all respects similar to the behavior of glass as described before by Horovitz and collaborators.

14. Contact potential between iron and nickel. G. N. GLASOF, *University of Wisconsin (Introduced by C. E. Mendenhall)*.—Specimens of electrolytic iron and electrolytic nickel were outgassed by intensive heat treatment in a high vacuum and the contact potential between them was measured by the Kelvin null method. Photoelectric long wave limits of the specimens were measured by using filters in the path of the light from a quartz mercury arc. The light transmitted by each filter was photographed with a quartz spectrograph immediately after each determination of the photoelectric effect. The results of the measurements made after the Fe and the Ni had been heated for 300 hours were the same as those obtained after some 750 hours of heating. The plates were heated at a temperature of about 900°C at first and then the temperature of the Fe was raised to 1000°C and that of the Ni to 1100°C with no measurable change in the values obtained for the contact potential and long wave limits. The equilibrium value of the contact potential was Fe-Ni +0.20 volt \pm 0.01 volt. The long wave limit of the Fe was found to be 2646Å and that of the Ni to be 2537Å. The work functions of the specimens corresponding to these long wave limits are: Fe 4.662 volts, and Ni 4.862 volts. The difference in these values gives the contact potential Fe-Ni +0.20 volt.

15. On the electrical resistance of contacts between solid conductors. J. FRENKEL, *Visiting Professor from Leningrad, University of Minnesota, (Introduced by H. A. Erikson)*.—A contact between two solid conducting bodies is visualized as a small gap between them. This gap can be described as a potential hill, over which the electrons, according to the wave mechanical theory, can pass even with insufficient kinetic energy. There must be in general a steady flow of electrons across the gap in both directions, the difference between the two flows being the actually observed current intensity I . The general expression of I as function of the applied potential difference is obtained and discussed for the case of two identical bodies in connection with the resistance of granular structures (thin metallic films, obtained by cathodic pulverisation) and for the case of two different bodies in connection with the rectifying (valve) action.

16. Photoelectric properties of oxide cathodes. W. S. HUXFORD, *Grigsby-Grunow Research Staff, Department of Engineering Research, University of Michigan*.—The effect of applied fields on the photoelectric work function of barium-strontium oxide cathodes has been investigated in the light of recent theories on electron emission from adsorbed metallic films. Photo-currents of the order of 10^{-11} ampere were obtained when the cathodes were illuminated by light from a glass monochromator. The potentials employed were of the order of magnitude of those commonly applied to the electrodes of radio receiving tubes. As the activation of the cathode is carried to a maximum the photoelectric threshold, as measured at room temperatures, moves towards the red end of the spectrum, and the tendency to a condition of non-saturation in the emission increases. The currents due to the electrons emitted under the action of blue light saturate better than those caused by red light. A striking dependence of the photoelectric work-function upon the applied fields has been found. In the case of one cathode, the long wave limit of the photoelectric effect occurred at 9200Å with a field of 40 volts per cm and at approximately 10,800Å with a field of 8000 volts per cm. A quantitative estimate is made of the modification of the intrinsic surface fields by the impressed fields.

17. Photovoltaic effects in Grignard solutions. II. R. T. DUFFORD, *The University of Missouri*.—New observations are reported which bring out several new facts about the Becquerel effect in Grignard cells. Most important among these are the behavior on closed circuit, and the remarkable effect of certain depolarizers in increasing the current obtainable; and the

evidence that at least two types of response may occur with platinum electrodes. The effect is noted in several compounds not before tested. The work was done at the Research Laboratory, Incandescent Lamp Department of General Electric Co., Cleveland, Ohio.

18. The dielectric polarization of castor oil, linseed oil and tung oil. W. N. STOOPS, *Westinghouse Research Laboratories, East Pittsburgh, Pa.* (Introduced by C. F. Hill).—The dielectric constants and densities of castor oil, linseed oil and tung oil have been measured over the temperature range between 100°C and their freezing points. The dielectric constant and polarization data indicate the presence of polar molecules in the oils. Accordingly the dielectric constants and densities of their dilute solutions in benzene have been measured, and the electric moments calculated by means of the Debye equation. They are 3.7, 3.0 and 2.8×10^{-18} e.s.u. respectively for castor oil, linseed oil and tung oil. From the standpoint of their molecular structure, these oils may be considered as derivatives of the triglyceride of stearic acid. The above values of the electric moment agree well with what would be expected on the basis of the accepted chemical composition of the oils.

19. Orientation of hydrocarbon crystals by an electric field. RALPH D. BENNETT, *University of Chicago*.—Ewing has shown (Phys. Rev. 36, 378 (1930)) that as regards scattering power for x-rays an electret consisting of a mixture of different waxes is anisotropic. The writer has obtained results in agreement with his. Further, paraffin shows a similar anisotropy when allowed to crystallize in an electric field. Müller and his collaborators (Proc. Roy. Soc. A120, 437 (1928); Jour. Chem. Soc. 127, 599 (1925); *et al.*) have shown that the normal hydrocarbon crystals have the form of thin flakes, the long axes of the molecules being perpendicular to the face of largest area. The writer's x-ray measurements indicate that the effect of the electric field is to align these crystals edgewise, i.e. the hydrocarbon chains are perpendicular to the electric field.

20. Change of frequency of x-rays scattered by bound electrons. D. P. MITCHELL AND A. J. O'LEARY, *Columbia University*.—In the Physical Review of June, 1929, one of us (D.P.M.) reported changes in wave-length of the molybdenum $K\alpha_1$ line scattered at 90° from graphite, beryllium and aluminum. These were interpreted as due to the transfer of the binding energy of K and L electrons in the scattering substances. Further investigation of this phenomenon with improved apparatus employing a background compensation method failed to disclose, in addition to the unmodified line, any of the lines previously reported. The line $MoK\alpha_1$ was scattered from paraffin and graphite at an average angle of 90° and beryllium 154°. The experimental conditions for producing the scattered radiation were as nearly as possible like those of the earlier work. The measurements were made by means of ionization apparatus as before. However, the sensitivity and stability of the new measuring apparatus was sufficient to have disclosed such lines if their intensity exceeded 10 percent of the unmodified $MoK\alpha_1$ line scattered from paraffin and graphite. The result is in complete accord with similar experimental work already reported by J. A. Bearden and N. S. Gingrich. Unmodified scattering by beryllium was definitely observed although quite weak. No "anti-Stokes" line was observed as previously reported. Such a line should have appeared if its intensity was 50 percent of the unmodified $MoK\alpha_1$ line.

21. Scattering of x-rays in the neighborhood of 90 degrees. G. E. M. JAUNCEY AND G. G. HARVEY, *Washington University, St. Louis*.—X-rays from a tungsten target tube excited at 90 and 125 kilovolts were scattered by paraffin. The x-rays were filtered through aluminum so as to produce some degree of homogeneity, and the distribution of intensity amongst the wave-lengths still present was determined by an absorption method. The intensity of the x-rays scattered at the above angles by a thin slab of paraffin was calculated for each wave-length present in the primary beam, using the formulas of Dirac and Jauncey. Each wave-length was assumed to be changed on scattering by the Compton value and the proportion of the intensity of each wave-length which was absorbed in the methyl iodide in the ionization chamber was calculated. The total intensity absorbed in the ionization chamber was then found by graphical integration. In the experiment, the ratios of the intensities scattered at

75° and 120° to the intensity scattered at 97°30' were determined. These ratios were compared with the two theoretical ratios. The agreement is much better with Dirac's than with Jauncey's formula. At the wave-lengths used Dirac's formula is not sufficiently different from the formula of Klein and Nishina for this experiment to discriminate between them.

22. Scattering of x-rays by gases. E. O. WOLLAN, *University of Chicago*.—Measurements of the scattering of x-rays by gases are in progress using a molybdenum target, with Soller slits and matched filters of ZrO_2 and SrO . This arrangement makes possible the use of more homogeneous radiation and more definitely defined scattering angles than have hitherto been reported. The intensity of scattering of hydrogen at 90° has been used as a standard with which the scattering of other gases has been compared. Due to the small intensity of scattering from hydrogen, oxygen was used as a secondary standard, with which direct comparisons of intensity with other gases was made. Measurements of the intensity of scattering from argon at angles from 10° to 90° were obtained, and put on an absolute scale by comparison with oxygen. The scattering per electron for argon was considerably greater than for hydrogen and oxygen over the whole range of angles. This indicates a strong concentration of electrons near the center of the argon atoms.

23. Electron distribution in argon, and the existence of zero point energy. ARTHUR H. COMPTON, *The University of Chicago*.—Data on the scattering of x-rays by argon, reported by Wollan are analyzed by the method recently described by the writer (*Phys. Rev.* **35**, 925 (1930)) The resulting electron distribution curve (U curve) shows a maximum electron density at about 0.10Å from the center of the atom. The data of James and Firth (*Proc. Roy. Soc. A* **114**, 181 (1927)) on rock salt at 0°K give a maximum electron density of chlorine atoms at about 0.19Å from the center, for 900°K at about 0.58Å. The difference between the latter two values is due to the thermal motion of the atoms in the crystal. Similarly, the large difference between the radius of maximum electron density in the atoms of argon gas and of chlorine in rock salt at 0°K must mean motion of the chlorine ions in the crystal lattice. The amplitude of this motion is of the order of magnitude predicted on the quantum theory of zero point energy. This confirms the conclusion of James Waller and Hartree, who however based their conclusion on a theoretical rather than an experimental electron distribution for argon and chlorine.

24. Absorption of x-rays in gases. W. W. COLVERT, *University of Chicago*. (*Introduced by A. H. Compton*.)—X-ray spectral lines reflected from a platinum surfaced mirror and by a calcite crystal have been used for absorption measurements with neon, sulphur dioxide, chlorine and argon. The double reflection gives a more nearly homogeneous beam, since the mirror greatly reduces the higher orders of the shorter wave-lengths. The results are summarized in the following table.

Mass absorption coefficients

	0.496Å	0.561Å	0.631Å	0.710Å	1.389Å	1.539Å	2.288Å
Ne	.84	1.20	1.69	2.50	16.0	23.4	75.5
Al	1.96	2.71	3.82	5.32	37.3	50.7	149.6
SO_2	1.92	2.67	3.60	5.55	38.5	51.8	162.6
S(Calc)	3.40	4.64	6.89	9.96	66.4	88.4	284.0
Cl	4.14	5.76	8.18	11.52	76.9	102.7	315.0
A	5.06	6.89	9.80	13.0	85.7	114.0	339.4

25. The absorption of the $K\alpha$ line of carbon in various gases. ELMER DERSHEM AND MARCEL SCHEIN, *University of Chicago*.—The mass absorption coefficients of a number of gases for the $K\alpha$ line of carbon ($\lambda=44.6\text{Å}$) have been measured with the aid of a specially designed x-ray vacuum spectrograph in which a ruled grating was used to isolate the $K\alpha$ line. A photographic method was used and the densities of the photographic images obtained with and without gas in the chamber were compared by means of a photoelectric photometer. Pre-

liminary values of the mass absorption coefficients (μ/ρ) of the gases used are as follows He 3050; CO₂ 4750; N₂ 3950; O₂ 5800; Ne 11500; SO₂ 13000. Work on these and other gases is being continued and the above values may be slightly revised but are believed to be quite accurate.

26. The absorption coefficient of γ -rays from radium C and the effect of the rays on films. CHARLES S. BARRETT AND ROY A. GEZELIUS, *Naval Research Laboratory, Washington, D.C.*—The curve of film density vs. exposure is of the same type for γ -rays as for x-rays. The use of commercial screens of calcium tungstate reduce the exposures required in radiography with γ -rays to about 0.6 those required without screens; lead foil effects a reduction to about 0.75. The rapid increase in effectiveness of calcium tungstate screens with increasing hardness of rays in the x-ray region does not continue into the region of hard γ -rays. Recoil electrons from an aluminum sheet (optimum thickness about 2 mm) placed on the radium side of a film are not as effective for the above purpose as the electrons (chiefly photoelectrons) from lead foil. The linear absorption coefficient μ of γ -rays in iron was determined by densitometer measurements on films exposed under conditions similar to those of radiography, with precautions taken against scattered rays reaching the films from the rear. With blocks 30 cm square and 5–15 cm thick as absorbers and with films directly behind them, placed 45 cm from 250 millicuries of radon, $\mu = 0.30 \text{ cm}^{-1}$. This is in agreement with previous ionization measurements made under conditions where comparable amounts of scattered rays were present. A quantitative technique for γ -ray radiography has been worked out and is being published elsewhere.

27. A simple derivation of the formula for the half-width of the Debye-Scherrer lines. N. RASHEVSKY, *Westinghouse Research Laboratories, East Pittsburgh, Pa.*—In 1918 P. Scherrer published without proof the following expression for the half-width of the Debye-Scherrer lines:

$$h = 2(\ln 2/\pi)^{1/2} (\lambda/l \cos \theta) = 0.94(\lambda/l \cos \theta)$$

λ being the wave-length of the x-ray beam, l the size of the crystallites and θ the glancing angle. Seljakow and v. Laue independently gave later on rather elaborate analytical derivations of the above formula, their results differing from Scherrer's and from each others only in the value of the numerical factor (Seljakow—0.92; v. Laue—0.9). In the present paper a very simple and short derivation of the above formula is given, showing particularly clearly the physical cause of the broadening of the lines, and giving for the numerical factor the value 0.89.

28. The structure of some groups XO₃. W. H. ZACHARIASEN, *University of Chicago* (Introduced by H. G. Gale).—Through determinations of the crystal lattices of KBrO₃, KClO₃, NaClO₃ and Na₂SO₃ the size and the shape of the groups (BrO₃)⁻¹, (ClO₃)⁻¹ and (SO₃)⁻² were examined. These 3 groups show the same type of structure. This special type is also found for the groups (AsO₃)⁻³ and (SbO₃)⁻³ in the crystal lattices of As₂O₃ and Sb₂O₃ as determined by Bozorth. The structure type of the above 5 groups is distinctly different from the one of the groups (BO₃)⁻², (CO₃)⁻² and (NO₃)⁻¹. The cation is displaced an amount Δ out of the plane of the three oxygens, and this displacement can be expressed by: $\Delta = a/12(6)^{1/2}$, where a is the oxygen to oxygen distance in the equilateral triangle. Due to the existing relation between Δ and a , we can describe our type of groups as tetrahedral groups with one tetrahedral corner removed. Common for all groups of this type is that the cation has got only 2 electrons in the outer shell. The asymmetry which characterizes the configuration around the cation may be explained as due to deformation in the outer shell of the cation, where the charge distribution is very diffuse.

29. The building of atoms as related to nuclear abundance and stability. W. D. HARKINS, *University of Chicago*.—Recent investigations emphasize the importance of the rule that the elements of even atomic number are much more abundant than those of odd number. This and other evidence indicate that the most stable nuclei are those whose charge is represented by an even number. An even more important rule is that the most stable nuclei are those which

contain an even number of negative electrons. If the atomic species are divided into four classes according to the evenness or oddness of the number of nuclear electrons and protons, the most stable species are found to belong to Class I, for which these numbers, and the atomic number also, are even. The nuclear spin of all of the species of this class which have been investigated have been found to be zero. The nuclei of complex atoms in general seem to exhibit such relations as to indicate that with the possible exception of the alpha particle, they are built in steps. The particles which seem most likely to take part in increasing the mass of a nucleus are: the alpha-particle, the proton, the electron, the half alpha-particle ($\frac{1}{2}\alpha$)⁺, and possibly the neutron, although the last of these may not exist since the ratio of negative to positive electrons in a neutron is unity, which is abnormally high for a complex nucleus. The increase of mass by the addition of an electron may be negative on account of the packing effect.

30. Time lag in the formation of the latent image. LESTER I. ZIMMERMAN, *St. Louis University*. (Introduced by F. E. Poindexter).—Series of constant energy exposures were made on Hammer Extra-Fast plates at high and low light intensities by means of flashes of light from a rotating mirror for a range of mirror speeds. The time of illumination of the emulsion grain in each flash varied from 10^{-6} to 5×10^{-8} seconds. It was found that there was a gradual diminution of image density with decreasing time of flash until a critical flash interval was reached, after which the density-flash curve fell rapidly. The breaking point of the graph for high intensities was at a time of flash of approximately 1×10^{-7} seconds while that for the low intensity was 3×10^{-7} seconds. Assuming that the breaking over of the density-flash graphs is real, and not due to some undetermined characteristic of the apparatus, the conclusion is indicated that the formation of the latent image is a resonance process.

31. A study of the latent image at low intensities. FRANKLIN E. POINDEXTER AND LOUIS E. JAMES, *St. Louis University*.—Hammer Extra-Fast plates were exposed to light of very low intensities—the times for normal exposures ranging from thirty to two hundred and forty minutes. Two sources of light were used on each plate. A series of exposures was made with each source separately, a series of each on top of the other and, finally, a series was made when both lights were shining on the plate. It was found that the densities for the simultaneous exposures were in all cases greater than those formed by putting the image due to one source on top of the other. The difference between these densities, however, decreases with increasing intensities of the light sources. The results show that the failure of the reciprocity law is very appreciable even for fast plates at low intensities.

32. The band spectra of scandium-, yttrium-, and lanthanum monoxides. WILLIAM F. MEGGERS AND JOHN A. WHEELER, *Bureau of Standards*.—New data on wave-lengths and relative intensities of band heads in these three molecular spectra have been obtained and have been classified in a number of band systems resulting from transitions between various vibration levels of initial and final electronic states. For ScO 137 band heads are observed; these belong to 5 systems, the 0, 0 transitions of which are at I, 4857.79 and 4858.09A; II, 6017.07A; III, 6036.17A; IV, 6064.31A; V, 6079.30A. The YO spectrum closely resembles that of ScO; 126 band heads were observed; these are assigned to 5 systems with 0, 0 transitions at I, 4817.38 and 4818.20A; II, 5939.08A; III, 5972.04A; IV, 6096.78A; V, 6132.06A. In the LaO spectrum, more than 300 band heads have been measured; they appear to belong to 9 different systems. Our analysis of the LaO bands agrees in the main with that given by Jevons (*Proc. Phys. Soc. London* 41, 520 (1929)). All of the bands in these spectra are degraded to red except two groups of LaO which are degraded to violet.

33. Regularities in the second spectrum of xenon. C. J. HUMPHREYS, T. L. DEBRUIN AND W. F. MEGGERS, *Bureau of Standards*.—A new description of the spectrum of ionized xenon (Xe_{II}) has been completed; it gives wave-length and intensity data for about 1600 lines between the limits 2230A and 8716A. The ground doublet ($^2P_{1/2,1/2}$) in this spectrum has been identified among lines observed in the Schumann region by Abbink and Dorgelo (*Zeits. f. Physik* 47, 221 (1928)); the levels are separated by 10540 wave-numbers. This spectral term has been connected with others which combine so as to give lines in the visible Xe_{II} spectrum,

and the absolute values of the terms have been fixed by extrapolating series-forming terms to their limits. The ionization potential is found from these spectroscopic data to be 21.1 volts.

34. Hyperfine structure patterns. S. GOUDSMIT AND R. A. FISHER, *University of Michigan*.—Hyperfine structure separations obey the interval rule very accurately. This enables one to construct simple graphs which represent all possible line patterns for given quantum numbers. Such graphs are useful in the interpretation of hyperfine multiplets especially in cases where not all components are resolved. They were successfully applied to preliminary measurements of Bi II hyperfine structure, recently obtained by us. Application to the partly resolved hyperfine multiplets of Mn I (H. E. White and R. Ritschl, *Phys. Rev.* **35**, 1146 (1930)) gives results which differ considerably from those obtained by White.

35. The transfer of energy between molecules during collisions: quenching of mercury resonance radiation by admixed thallium vapor. O. S. DUFFENDACK, *John Simon Guggenheim Memorial Fellow, University of Michigan*.—The quenching of mercury resonance radiation $\lambda 2537$ by admixed thallium vapor was measured. At 0.8 mm mercury vapor pressure and 750°C the radius of the excited mercury atom has an apparent value 30 times greater than the normal kinetic theory radius. Previous measurements on quenching by permanent gases give a maximum radius 3 times normal. The addition of helium to the Hg-Tl mixture at 750°C permits the measurement of the quenching at 0.001 mm mercury vapor pressure and gives a radius of the excited mercury atom little greater than normal. When N_2 is substituted for He, the radius is somewhat greater. The differences are attributed to differences in the concentration of excited mercury atoms in the $^3\text{P}_1$ and $^3\text{P}_0$ states. The presence of metastable $^3\text{P}_0$ atoms makes the value of the average life of the excited atom uncertain.

The experiments indicate the possibility of isolating the effects of the $^3\text{P}_1$ state, in which case a radius very little greater than normal is probable: a result in agreement with estimates made from the quantum-mechanical theory of Kallmann and London (*Zeits. f. Phys. Chem.* **B2**, 207 (1929)). This investigation was carried out under the direction of Professor J. Franck at Göttingen.

36. The energy of dissociation of mercury molecules. J. G. WINANS, *University of Wisconsin*.—The absorption spectrum and the electrodeless discharge spectrum of mercury vapor between wave-lengths 2200 and 1550 were photographed with a fluorite vacuum spectrograph. In the absorption spectrum, three apparently continuous bands were observed with maxima at 1849, 1807, and 1685. With increasing pressure the 1849 band broadened symmetrically until it overlapped the 1807 band. With further pressure increase the 1849 band broadened toward longer wave-lengths but retained a sharp short wave limit coinciding with the short wave limit of the 1807 band. In the electrodeless discharge excited by a low voltage Tesla coil, the bands at 1849 and 1685 were emitted, but not the one at 1807. Assuming that this failure of 1807 indicated that molecules which absorb 1807 are dissociated, potential energy curves for Hg_2 can be constructed to explain this. These same curves explain also the peculiar limitation of the 1849 band at the 1807 band. From these curves the energy of dissociation of Hg_2 is found as 0.20 volts. It is necessary to ascribe the 1807 band to an electron transition from a molecular energy level to an atomic energy level. This constitutes a new type of photochemical dissociation. Similar explanations have been made for the band spectra of zinc and cadmium. (*Phil. Mag.* **7**, 555 (1929).)

37. A spectroscopic study of the decomposition of organic vapors by the electrodeless discharge. DAVID M. GANS AND WILLIAM D. HARKINS, *Department of Chemistry, University of Chicago*.—When subjected to the electrodeless discharge, the vapors of organic compounds at pressures of several tenths of a millimeter of mercury are rapidly decomposed into monatomic and diatomic, neutral and charged fragments, with emission of light. Thus, for benzene, acetylene, and naphthalene, the spectrum reveals the presence of H and C atoms, C^+ ions, and C_2 and CH molecules. With aniline, the spectrum shows, in addition, the violet cyanogen bands, the β bands of NH, and the second positive (N_2) and first negative (N_2^+) groups of nitrogen. The spectrum for phenol contains the water vapor bands, due to OH, and the third

positive group of carbon, due to CO, as well as the decomposition spectrum typical of benzene. These very reactive fragments unite with each other to form brown to black solids of high molecular weight. Sufficiently unsaturated hydrocarbons are completely transformed into insoluble solids as rapidly as vapor enters the flask. Saturated hydrocarbons, like *n*-heptane, form little solid, since hydrogen is liberated, which raises the pressure and tends to extinguish the discharge. Besides dark solids, substituted benzene derivatives generally also give gaseous products, as water for phenol, ammonia or lower amines for aniline, and hydrogen chloride for chlorobenzene. Further work is in progress.

38. A continuous fluorescence emission spectrum which accompanies a change of color and the Raman spectrum. WILLIAM D. HARKINS AND H. E. BOWERS, *University of Chicago*.—In the study of the Raman spectrum of certain liquids a continuous emission spectrum has been found to appear, together with the Raman line spectrum, in each case in which the liquid becomes colored by the action of the radiation from the mercury arc light. The continuous spectrum was always absent when no such change of color occurred. The continuous spectrum was given by eight organic bromine derivatives of the paraffin series and by a solution of ammonia in methyl alcohol. The continuous spectrum is found between 3900 and 5200Å, and between 5500 and 5800Å.

39. Further study of the absorption of infrared radiation by water vapor. E. K. PLYLER AND W. W. SLEATOR, *University of Michigan*.—By making use of Echelette gratings, a Moll thermal relay and the spectrometer constructed by Meyer and previously described, the authors have re-examined with increased resolution the absorption bands of water vapor whose centers lie near 1.38μ , 1.87μ , 2.66μ , 3.17μ and 6.26μ . The new study has greatly increased the number of measured lines. Especially, near 6.26μ and 3.17μ the number has been more than doubled. The new lines are mostly weak ones, but the work has resulted in better determinations of the wave-lengths of many strong lines which now appear as sharp single effects freed from the former confusion due to overlapping. The center of the harmonic of the great band near 6.26μ is seen to be better placed at 3.168μ than as it was formerly at 3.11μ . It also appears that the band has no absorption at the center, and is of the doublet type like the fundamental.

40. Progressive relationships in the near infrared absorption spectra of the halogen derivatives of benzene. F. S. BRACKETT AND UNER LIDDEL, *Smithsonian Institution and Bureau of Chemistry and Soils, Washington, D.C.*—Automatic records of the near infrared absorption spectra of benzene and its halogen derivatives at an average resolution of 12Å to the slit-width are offered. These spectra have been analyzed with respect to the second overtone of that fundamental vibration of benzene occurring in the region of 3.25μ , which probably approximates a linear oscillation of hydrogen with respect to carbon. In the progression benzene 8772 cm^{-1} , iodo-benzene 8780 cm^{-1} , brom-benzene 8787 cm^{-1} , and chlor-benzene 8800 cm^{-1} , a progressive shift to shorter wave-lengths of this second overtone occurring in benzene at the frequency 8772 cm^{-1} is observed. An explanation is offered based on the further reduction of electron density about the carbon centers resulting from the substitution for a single hydrogen of an increasingly electro-negative halogen in each case. Further shifts to shorter wave-lengths were predicted for the higher halogen derivatives. Spectra are offered of the three di-chlor, 1, 2, 4, and 1, 3, 5 tri-chlor, penta-chlor, and para- dibrom-benzenes, which in a general way substantiate these predictions. The general idea of relative decrease in saturation as correlated with increase of frequency is borne out. In the case of benzene, satellites are observed at frequencies occurring at multiples of 162 cm^{-1} . The presence of such a low frequency mode is consistent with the fine structure observed in the visible bands of benzene vapor.

41. Absorption bands of hydrogen halides in the liquid state. E. O. SALANT AND W. WEST, *Washington Square College, New York University*.—The (0, 2) bands of HCl, HBr and HI liquids and the (0, 3) of liquid HI, measured with quartz prism spectrometer, thermopile and galvanometer, show no rotational structure, centers of HCl and HBr bands being displaced to longer waves as compared with corresponding gas bands. The frequencies, with gas-liquid

displacements given in parentheses are, in cm^{-1} : HCl 5543 (125), HBr 4850 (180), HI 4262 and 6262. HI absorption, particularly, is strongly intensified in the liquid. With these values and the Raman lines (Salant and Sandow, *Phys. Rev.* **32**, 214 (1930)), the vibration frequencies and anharmonic coefficients of the vibrational terms are calculated for the liquefied hydrogen halides (the constants for the gaseous molecules, in parentheses, are from Birge, *International Critical Tables*, Vol. V):— ω_e : HCl 2800 (2991), HBr 2587 (2647), HI 2262; $x_e\omega_e$: HCl 8.5 (54), HBr 54 (44), HI 44. Differences between spectra of vapors and liquids are discussed. The frequency shifts of the hydrogen halides must be attributed not to a Lorentz-Lorentz force, but to some other, quantum mechanical interactions of the molecules (Breit and Salant, *Phys. Rev.* **36**, 871 (1930)).

42. Some effects of intense audio-frequency sound. NEWTON GAINES, *University of Texas*—Audible sound of great intensity is produced by magnetostrictive vibration of a nickel tube, two 250-watt radiotron tubes being employed in the apparatus. This sound is used to produce phenomena hitherto obtainable only with piezoelectric crystals vibrating at thirty or forty times the frequency and also entirely new phenomena. The nickel tube itself is vibrated so strongly as to rupture eventually at the middle. A five centimeter mound forms on the surface when the rod oscillates beneath water; this mound is *not* the result of radiation pressure. An air bubble released under water in the neighborhood of the vibrating rod becomes white, and under certain conditions moves against a strong stream of water. Carbon deposited on the sides of the nickel tube goes into colloidal solution when the tube is vibrated under water. The reaction of sonic radiation upon the radiator is demonstrated. Striations in a Kundt tube that are parallel to its axis are produced. Larvae are killed immediately by the sound; colon bacteria are killed, dying off in accordance with a simple logarithmic law. The irradiation of seed by the intense sound changes the rate of growth of the seedlings produced, usually retarding the growth but in certain cases accelerating it as much as 25 percent.

43. Supersonic interferometers. ELIAS KLEIN AND W. D. HERSHBERGER, *Naval Research Laboratory, Bellevue, D.C.*—The methods of applying high frequency sounds to small scale measurements are discussed. An interferometer was constructed and used to measure the velocity of sound in gases, liquids, and solids at frequencies ranging from about 10 to 700 kc. Three types of sources were tried, viz: quartz and rochelle salt crystals and magnetostrictive rods. The determination of the velocity of sound in solids are based upon (1) optimum transmission of sound through a partition whose thickness is an integral number of half wavelengths; (2) relative displacement of the nodal planes in a given liquid due to the immersion of the solid slab in the acoustical path. In the same manner, a small quantity of an unknown liquid is placed in a parallel walled cell and the latter is immersed in a liquid of known acoustic properties. Or, the variation in the velocity of sound with concentration of solution may thus be determined. Reactance and effective resistance of the interferometer (with a liquid medium) as a function of the reflector distance from the sound source were investigated. Approximate values of the impedance, power factor and watts dissipated in the instrument were thus computed. The use of the interferometer as a device for measuring supersonic frequencies is explained.

44. Sound absorption determined by transmission measurements. F. R. WATSON, *University of Illinois*.—A. H. Davis, (*Phil. Mag.* **50**, 75 (1925); **2**, 543 (1926)) has developed a formula for transmission of sound, $-I'/I = kW/as$, where I is the intensity of the sound incident on a partition, I' is the transmitted intensity, k is the coefficient of transmission, W , the area of the partition and as , the absorption of the surfaces in the receiving room. By suitable measurement of the ratio I'/I , it is thus possible to determine the absorption as . Preliminary tests by means of electrical instruments for the generation and reception of sound have given promising results, thus giving an instrumental substitute for the determination of the time of reverberation by the ear, as required by Sabine's method.

45. The rotating fluid in the relativity theory. EDWARD L. AKELEY, *Purdue University*.—The Einstein equations associated with the quadratic form

$$Adx_0^2 + 2Cdx_0dx_1 + Bdx_1^2 + J(dw^2 + dv^2)$$

where A , B , C and J are functions of u and v only, have been treated by a method which is a generalization of Weyl's theory of the axially symmetric field. The following transformation was used

$$\begin{aligned} A &= e^{d+s} \cos \psi & C &= e^d \sin \psi \\ B &= -e^{d-s} \cos \psi & J &= -e^2. \end{aligned}$$

The theory of the rotating fluid was developed in this way. A power series expansion of the type $d = d_0 + d_1\rho + d_2\rho^2$ was used, where $d_2 = d_{20} + (\omega^2/\rho)d_{12}$; $d_3 = d_{30} + d_{22}(\omega^2/\rho) + d_{14}(\omega^4/\rho^2)$. ρ and ω represent respectively the density and the angular velocity of the fluid, and d_i represents the coefficient of $\rho^{i\omega}$ in a double power series expansion in ω and ρ . The first approximation corresponds to the Newtonian theory. It is shown that there is a one to one correspondence between the figures of equilibrium in the two theories, and that the first approximation of the Einstein solution can be obtained from the Newtonian one. The second approximation predicts effects not included in the Newtonian theory. The field corresponding to that of the MacLaurin ellipsoid is developed to a second approximation. The relation of this treatment to the work of others is discussed.

46. Some physical properties of nitrogen. W. EDWARDS DEMING AND LOLA E. SHUPE, *Bureau of Chemistry and Soils, U. S. Department of Agriculture, Washington, D.C.*—The compressibility data on nitrogen obtained by Bartlett and coworkers are extrapolated to cover the range -70 to 600° up to 1200 atmospheres. A sensitive graphical scheme has been devised for obtaining $(dv/dp)_T$, $(dv/dT)_p$, $(d^2v/dT^2)_p$ at any point. It depends on the fact that the derivatives of $\alpha \equiv RT/p - v$ or $\Delta \equiv v(pv/RT - 1)$ enter as correction terms to the derivatives of v , just as α and Δ enter as corrections to v itself. Specific volume, density, coefficients of expansion $(-p/v)(dv/dp)_T$ and $(1/v)(dv/dT)_p$, fugacity, C_p , C_v , $C_p - C_v$, μ are calculated for the various temperatures and pressures. The calculations of C_p agree within 0.2 cal./mole deg. with the experiments of Mackey and Krase (*J. Ind. and Eng. Chem.* October, 1930) who worked to 700 and 800 atm. from 30 to 150° . The agreement is probably within the experimental error, but the trends of the two sets suggest that a real difference may exist. C_p decreases below 0°C at pressures up to 100 atm.; at higher pressures it increases. Experiment shows that along an isotherm $C_p = C_p^* + bp^2 + cp_3 + \dots$, the first power of p being absent. It is found that C_p increases fairly uniformly from 10 to 100 atm. along isotherms between 20° and 200° .

47. The specific heat of methane. P. C. LUDOLPH, *University of Illinois.* (Introduced by Jakob Kunz.)—The specific heat of methane has been calculated for the tetrahedral model advanced by Dennison and for the symmetrical pyramid as worked out by Guillemin. The curve for the values obtained from the tetrahedral model has the same shape (linear) as the experimental curve but falls below it (as much as 5 cal./mole at 873°K). The values for the pyramidal model are still lower (9 cal./mole at 873°K). Another curve was obtained for the tetrahedron by redistributing the dimensions of the oscillators so as to get the largest possible values for the specific heat with the given frequencies. This curve is again linear but it still falls below the experimental curve. Some of the discrepancy may be due to an error in the experimental values which would tend to make this curve too high. It may be stated that the specific heat calculations of methane favor the tetrahedral structure.

48. Joule-Thomson effect in helium. J. R. ROEBUCK AND H. OSTERBERG, *University of Wisconsin.*—After completing the work with air (*Proc. Am. Acad.* 64, 287 (1930)), the apparatus required extensive modification for use with helium. The effect of small proportions of air as an impurity was measured first, and as this proved very interesting the measurements were extended to the whole range of mixtures, all at the bath temperature 51.68°C , and inlet pressure 201 atm. The isenthalpic curve for pure helium is a straight line of negative slope, rising about 12°C per 200 atm. drop. As small quantities of air are added the curves do not change observably till possibly 10 percent air. With further increase in air the curves shift more and more rapidly over to about 28°C drop for pure air. Simultaneously the straight line for pure helium shifts over to the line, strongly concave toward the pressure axis, for pure air. The surprising result is the very small effect of the first addition of air and the increasing effect

of the equal later additions. Its pleasant aspect is that it effectually removes any worry as to the corruption of the helium data by air impurity. The isenthalpic curves for pure helium have been taken between the temperatures -100°C and $+100^{\circ}\text{C}$. They are all straight lines of negative slope, and over this range the small erratic variation in the values of the slope exceeds any systematic variation. This value of μ is -0.060°C per atm.

49. A convenient laboratory source of hydrogen. G. W. SARGENT AND WHEELER P. DAVEY, *School of Chemistry and Physics, The Pennsylvania State College*.—Certain lines of research require considerable quantities of a reducing gas at rather infrequent intervals. In such cases the use of tanked or electrolytic hydrogen becomes unduly expensive. We are using a 1 to 3 mixture of nitrogen and hydrogen obtained by cracking NH_3 . By slightly raising the outlet end of a 150 pound tank of liquid NH_3 , gaseous NH_3 can be boiled off at room temperature, metered through an ordinary dry gas meter and cracked. We find it best to crack the gas in a nickel tube about $1/4$ inch in diameter and about 12 feet long, coiled to fit inside an alundum tube which is heated to 1000°C by a nichrome winding. Slight traces of uncracked NH_3 are removed by passing the gas over about six feet of P_2O_5 . The gas meter helps determine how much liquid NH_3 is left in the tank. A mercury relief valve by-passes any excess NH_3 into running tap water. A similar valve by-passes any excess H_2 into a pipe leading outdoors. These relief valves prevent dangerous pressures in the hot nickel coil. The apparatus is cheap and compact and gives a large storage capacity of H_2 in the form of liquid NH_3 .

50. The deposition of dust on walls. W. J. HOOPER, *Battle Creek College*.—An apparent uncertainty exists in literature dealing with the cause for the peculiar deposition of dust on plaster and lath walls wherein the course of the laths and rafters behind the plaster is outlined in dust, popularly called "lath marks." Conclusive experimental proof of a thermal cause is given which is in agreement with the general theory of the behavior of small particles suspended in an atmosphere in which a temperature gradient exists.

51. Particle size of the disperse phase of nitrocotton solutions. WHEELER P. DAVEY, H. B. DE VORE, *The Pennsylvania State College and E. I. duPont de Nemours and Co.*—It is the purpose of this paper to report measurements made in 1927 on the particle size of nitrocotton in lacquer solutions, using the water-spreading method. (Davey, *Science* 1926, Eighth Colloid Symposium, 1930). Solutions of a given batch of nitrocotton in a mixture of ethyl acetate and ethyl alcohol would not spread satisfactorily on water at concentrations greater than 0.001 gm per cc. Measurements were taken down to concentrations of 7.8×10^{-6} gm per cc. The corresponding particle diameters were 3.69×10^{-7} cm and 1.54×10^{-7} cm. Over a considerable range the graph of particle diameter against logarithm of concentration is a straight line. Particle diameters at the lowest dilution are equal to about 20 atomic diameters of carbon, i.e. a maximum of about 140 nitrated glucose groups on the assumption of $2/3$ complete nitration.

52. On the determination of principal stresses from crossed Nicol observations. R. V. BAUD, *Westinghouse Research Laboratories, East Pittsburgh, Pa.* (Introduced by N. Rashevsky).—The information obtained from crossed Nicol observations, combined with the differential equations expressing equilibrium requirements, is sufficient to obtain on basis of a graphical integration, the two principal stresses separately at all points of a "two-dimensional" model. When orthogonal curvilinear coordinates are employed, the differential equations contain the curvatures of the principal stress direction lines. Filon's method consists of expressing the curvatures by certain angles ψ , which he takes from the map of isoclinic lines. The author proposes that an additional map with lines $\psi = \text{constant}$ be drawn, which procedure has certain advantages. When the paths of integration have one or more inflections, Filon's method is not entirely satisfactory. As an alternative, it is suggested to express the curvatures by the gradients $\partial\phi/\partial s$, or to measure the curvature by a curvature scale. A new method is suggested further, which consists in the use of polar coordinates. Crossed Nicol observations and "polar integration" combined appear to be the only existing method of studying stress distribution in rotating models. Even for static conditions preference will eventually be given to the "polar integration" in cases where the models have circular contours.

53. The effect of pressures up to 20,000 atmospheres upon some optical properties. THOS. C. POULTER, *Iowa Wesleyan College*.—This is a preliminary report and some of the data are of a qualitative nature. The rotatory power of a water solution of three sugars has been studied as effected by pressure. A rotatory power of ice VI has also been observed. The effect of pressure on the index of refraction of glass and of a paraffin oil has been studied.

54. On the change of the spectral composition of quasi-monochromatic radiation caused by scattering. OTTO HALPERN, *New York University*. (*Introduced by Richard T. Cox*.) It is shown that according to both the classical and quantum theories, there should appear in the scattered light from an ordinary quasi-monochromatic source frequencies corresponding to the proper frequencies of the scattering system and with an intensity of the same order of magnitude as that of the light scattered with unchanged frequency. The effect described affords a method of determining the spectral intensity of a line at an appreciable distance from its center of gravity. Reference is made to certain changes in hardness in the scattering of x-rays.

THE PHYSICAL REVIEW

EFFECTS OF CATHODE-RAY DIFFUSION ON INTENSITIES IN X-RAY SPECTRA

By D. L. WEBSTER, H. CLARK, AND W. W. HANSEN
STANFORD UNIVERSITY

(Received December 5, 1930)

ABSTRACT

Rediffusion of cathode rays.—The available evidence is reviewed and conclusions formulated on the rediffusion constants and distribution functions needed for the calculation of effects on x-ray emission intensities.

Thin-target x-ray intensities.—A previous paper gave the intensity of the *K* lines from very thin Ag supported on Be, as a function of voltage, in terms of the intensity at twice the excitation voltage as a standard. In the same terms after correction for two opposing effects, diffusion of cathode rays within the thin target and rediffusion from the beryllium, the corrected values differ from the originals by not over 2 percent. Possible sources of error are reviewed, and it is concluded that none can increase this percentage very greatly. This answers a criticism on the theoretical significance of these data.

Comparison with theories.—Present wave-mechanics theories involve approximations not valid at low voltages, but subject to this qualification Bethe's theory compares very favorably with these data. The best classical-mechanics theory is Thomas's. Empirically, the intensity = $\text{const.} \times U^{-0.8} \log U$, where $U = (\text{tube voltage})/(\text{excitation voltage})$.

Thick-target effects.—For line intensities percentage corrections for rediffusion, again taking the intensities at $U=2$ as standard, are more than twice those for thin targets at all voltages in the above range, and are of opposite sign. On continuous spectrum intensities averaged over all directions, these calculations confirm Kramers' suggestion, that most of the non-linear term in the intensity formula is due to rediffusion.

THE effects of diffusion of cathode rays on the intensities in x-ray spectra have become important recently, on account of improvements in research technique. Such improvements, in themselves, do not necessarily increase the effects of diffusion, but as the sources of larger errors of interpretation are eliminated, diffusion comes next in line for treatment. The larger errors, in this case, occur in the study of intensities as functions of cathode-ray energy, and come from two sources. One is the variety of speeds with which the cathode rays strike the atoms, even though they all enter the anode at one speed. The other is the difficulty of separating the parts of the measured radiation coming from atoms ionized by cathode-ray impact and by x-ray absorption. Both these sources of error have now been reduced to negligible

amounts, by the use of targets so thin that the cathode rays penetrate them without serious loss of speed, and that x-rays penetrate them without appreciable absorption. Thus the largest errors remaining may well be those due to cathode-ray diffusion.

In a recent paper¹ on measurements of x-rays from thin targets, we estimated these errors tentatively as "a few percent"; and since the deviations of all the available theories from our data exceeded this amount, the exact calculation of the corrections for these errors was postponed until further data were available. Still more recently, however, Wisshak² has questioned our estimate, stating his belief that the correction would prove to be so great as to reverse completely the relations between our data and the leading theories of impact ionization. Evidently the status of these theories depends on the order of magnitude of these corrections. Therefore a calculation of them, at least with sufficient accuracy to make sure of the relation of the data to the theories, becomes imperative.

It is therefore the purpose of this paper to report the results of such a calculation, and incidentally we shall include some by-products, of interest in the interpretation of other data on x-rays and cathode rays.

THE LAWS OF REDIFFUSION

The effects to be calculated arose from two types of diffusion of the cathode rays, one type occurring within the thin targets themselves, and the other in a block of beryllium used to support the thin targets and to conduct away the heat produced by the cathode rays. Diffusion within a thin target, making the paths of the cathode rays deviate from straight lines normal to the surfaces, causes a slight increase in the number of atoms struck by an average cathode ray. Diffusion in the beryllium must be considered in order to take account of the small percentage of the cathode rays which deviate so far as to be "rediffused," that is to return to the surface of the block and thus to make second impacts on the thin target. The effect of diffusion within the thin target is readily calculated from well-known laws, but to calculate the rediffusion effect we must first examine the available evidence and formulate as well as possible the laws of the phenomena concerned.

The rediffusion constant. First of all, we must find the best value for beryllium, of the "rediffusion constant" p , or fraction of the incident cathode rays that are rediffused. Since none of the data we have found in the literature refer directly to beryllium, we must get the value for it from the data, through the law relating p to the atomic number Z .

To measure p , one must measure the current carried by the rediffused electrons, but not include any of the slow secondary electrons leaving the metal at the same time. The theoretical reason for separating these two classes is that their causes for leaving the metal are different: rediffusion and ejection by the cathode rays, respectively. The practical reason, for the

¹ D. L. Webster, H. Clark, R. M. Yeatman, and W. W. Hansen, *Proc. Nat. Acad. Sci.* **14**, 679 (1928).

² F. Wisshak, *Ann. d. Physik* **5**, 507 (1930).

present purpose, is that the secondary electrons are too slow to produce x-rays as hard as those used in most intensity measurements.

Data on p , for various primary-ray energies, have been obtained by several investigators: Becker,³ at 35 kv.; Schmidt,⁴ with beta rays of about 800 kv.; Schonland,⁵ at 10 to 100 kv.; and Stehberger⁶ at 2 to 12 kv. The term "rediffusion constant," and its symbol p , do not mean the same quantity in all these papers. In Schonland's it refers to incidence along the normal, in Stehberger's at 50° from it, in Schmidt's and Becker's, at least as recomputed by Lenard⁷ and quoted by Stehberger, to incidence "im Normalfall," that is with the cathode rays already completely diffused before they strike the metal. For present purposes, the most important case is that of incidence along the normal, so we shall adopt the definition for that case.

One of the most striking conflicts of values is between those of Becker as recomputed and quoted (Al 0.28, Au 0.68) and those of Schonland (0.13 and 0.50 respectively). A part of this conflict is due to the difference in definition, since Lenard finds for Al along the normal the value 0.23, and this reduces the discrepancy considerably. Another part, however, is probably due to the theory underlying the recomputation, which involved the assumption of sudden absorption of cathode rays by individual atoms. Since this assumption has later been disproved,⁸ we may remove this part of the discrepancy by going back to Becker's original values. Thus we obtain Table I.

TABLE I. *Rediffusion constants for incidence along the normal.*

Metal	Al	Cu	"Blattmetall"	Ag	Au
Becker	0.172	—	0.407	0.433	0.496 to 0.56
Schonland	0.13	0.29	—	0.39	0.50

Considering the general improvements in cathode-ray technique between Becker's work in 1905 and Schonland's in 1925, we must indeed congratulate Becker on the smallness of the discrepancy, even though we shall use Schonland's values of p .

A more serious question is presented by Stehberger's data. His values of p at 50° incidence on Al are from 2.5 to 5.5 times Schonland's at normal incidence. This ratio seems far too great. Furthermore, Schonland found p independent of primary voltage, whereas Stehberger found it to decrease rapidly with increasing voltage. To be sure, their ranges of voltage barely overlap; but Schonland gives theoretical reasons for believing that p should be constant, and an important question is, whether Stehberger's data make Schonland's theory unreliable.

⁸ W. Bothe "Handbuch der Physik" ed. 1927, Vol. XXIV, Chap. 1, See especially Sec. 25.

The answer to this question appears to us to lie in the method of separation of secondary electrons from rediffused. Both observers found a considerable fraction of the electrons to have energies below 10 or 20 equivalent volts; both adopted a voltage basis for the separation, Stehberger drawing the line at 36 volts and Schonland at 200; and both agreed that any such basis was somewhat arbitrary, and might be incorrect.

On this point, we may use a line of reasoning similar to that of Bothe,⁸ about the distribution of velocities among cathode rays transmitted through metal films. Here the Thomson-Whiddington law of retardation makes it impossible for many of the rays to emerge with very small energy, simply because the range of a cathode ray of small energy is so short. For example, if an electron has been retarded until its kinetic energy is only 10 percent of that at incidence, it has only 1 percent of its range still before it, and the chances are very much against that short section of its range intersecting the surface. The same reasoning applies to rediffusion. Many cathode rays rediffuse with half their initial energy or more, so there is no question of any grave difficulty for a cathode ray to return to the surface with a long range still before it, and it is therefore highly improbable that any large fraction of the rediffusion will be in the last 1 percent of the range.

Drawing the line between secondary and rediffused electrons at 36 volts, however, with a primary voltage of 8 or 12 kv., Stehberger found over 30 percent of his "rediffused" electrons to have less than 10 percent of their initial energy. Evidently in view of these considerations of range, there is good ground for belief that these were not rediffused, but secondary.

Furthermore, the distribution of energy among secondary electrons, as calculated by Bothe,⁹ should be nearly independent of the primary energy; but their number should decrease rapidly with increasing primary energy, as in fact Stehberger found it did. Thus it may well be that Stehberger's data are not inconsistent, after all, with Schonland's data, or with his theory of the constancy of the rediffusion constant. And so long as we are not concerned with secondary electrons in the x-ray problems at hand, we shall use the values of p obtained at the higher voltages, where secondary electrons were less abundant and the probable error from them was therefore smaller.

Incidentally, if we had adopted the alternative of accepting Stehberger's values of p at low voltages and Schonland's at high, with a graded compromise for the intermediate region, the corrections to the x-ray data would not have been as greatly affected as the values of p , since the influence of the derivative of p with voltage would have largely offset that of the increase in the values of p . The chief difference would have been in the complexity of the problem.

For the thin-target problem, we shall need the rediffusion constant of beryllium, the material of the block supporting the thin targets in some of our own experiments. Since Schonland finds for atomic number $Z=29$, $p=0.29$, and for $Z=13$, $p=0.13$, a reasonable guess for $Z=4$ is $p=0.04$. But for a

⁹ W. Bothe, reference 8, Section 42.

more careful estimate, we shall use an equation from Wentzel's¹⁰ theory, which predicts that

$$p = b_1 \left(\frac{Z^2 \rho}{A \alpha_0} \right) + b_2 \left(\frac{Z^2 \rho}{A \alpha_0} \right)^2 \quad (1)$$

where b_1 and b_2 are constants, Z and A are atomic number and weight, and α_0/ρ is Lenard's "pure" mass absorption coefficient. Since this theory depends on the hypothesis of absorption, now disproved, this equation must be considered on a semi-empirical basis; but at that, since Lenard found α_0/ρ practically constant for light elements, for which also $A = 2Z$, we may extrapolate to low atomic numbers by assuming that

$$p = p_1 Z + p_2 Z^2. \quad (2)$$

This fits all of Schonland's data pretty well, with $p_1 = 0.011$ and $p_2 = -6.0 \times 10^{-5}$, and for Be it predicts $p = 0.043$.

The rediffusion energy distribution. The next problem is to find the best formula for the distribution of the rediffused electrons on a scale of kinetic energy. The data available are far from complete or accurate, but fortunately the answers to the x-ray problems at hand are changed so little by relatively great changes in this distribution function that even a very rough approximation will prove sufficient.

First let us consider some theoretical evidence. Schonland explained the constancy of his rediffusion constants by noting that for cathode rays of all speeds, in any one element, the distance required for a probable deflection of one degree, and the distance required for a loss of kinetic energy of one percent, bear a constant ratio. Thus, although any two cathode rays of different speeds of incidence must have different ranges, the shapes of their paths may be geometrically similar, and the probabilities that they come back to the surface must be the same. Extending this reasoning, their probabilities of coming to the surface with any given fraction of their initial kinetic energy still left, must also be the same. Or in algebraic terms, calling this fraction W , and this probability $pF(W)dW$, with

$$\int_0^1 F(W)dW = 1, \quad (3)$$

$F(W)$ should be independent of V .

Another theoretical point about $F(W)$ is the one discussed above, about the scarcity of electrons of very low energy. Quantitatively, as one may readily prove from the Thomson-Whiddington law, this means that $F(0) = 0$, and that its first derivative is finite.

Turning now to the experimental evidence, we have some velocity spectra photographed by Wagner¹¹ for Al, Cu, Ag and Au at primary voltages from 16 to 40 kv. While an exact translation of the densities in these photographs into

¹⁰ G. Wentzel, Ann. d. Physik 70, 561 (1923).

¹¹ P. B. Wagner, Phys. Rev. 35, 98 (1930).

numbers of electrons is impossible, they do appear to give at least a qualitative confirmation to the theoretical deductions just stated. And without any exact translation, they prove some other points more definitely: first, $F(W)$ is a continuous function, without any sharp peaks; second, there are no electrons rediffused with full primary energy, so that $F(1) = 0$; third, reducing W from 1, $F(W)$ rises rapidly to a maximum and then declines, probably more slowly than it rose; and fourth, that the value W_0 , where the maximum occurs, is higher for heavy elements than for light. Taking the densities literally, as a rough approximation, W_0 for Al would be about 0.85, for Cu 0.90, and for Ag and Au 0.94.

Confirmatory evidence appears in the spectra of the x-rays produced by the rediffused electrons, investigated by Nicholas¹² with copper and Lorenz¹³ with tungsten. While this evidence is not so direct, it indicates the same general sort of preponderance of high energies as Wagner's photographs, and again with no notable change in $F(W)$ with V .

A third line of evidence is on \bar{W} , the mean of the values of W for all the rediffused electrons. This may be calculated from measurements by Wisshak² on the ratio of the power absorbed by the anode of a gas-filled tube to the whole power input. If it is permissible to neglect the power given to positive ions, this ratio is $(1 - p\bar{W})$. According to Wisshak, it is independent of V , from about 3 to 35 kv., having the value 0.8 for Co and Cu, and 0.6 for Mo and Ag. These data, with Schonland's p 's, would make $\bar{W} = 0.7$ for Co and Cu, and nearly 1 for Mo and Ag. The correction for positive-ion power would reduce these values of \bar{W} .

Finally, there is evidence from the total intensity of the x-rays from the back and stem of the target of a Coolidge tube. Assuming the V^2 law of total x-ray intensity, the ratio of this "stem-radiation" to the radiation from the whole target, including the focus, should be $p\bar{W}^2$. Coolidge,¹⁴ with one of his standard tungsten tubes, found this ratio to be 2/11, both with a 2-inch alternative spark gap and with a 10-inch; Ledoux-Lebard and Dauvillier¹⁵ found 20 percent; and Rump,¹⁶ on the basis of this latter figure and some measurements of his own, considered 20 percent correct for any voltage from 43 to 150 kv. at least. For tungsten at normal incidence, equation (2) would make $p = 0.48$, so that \bar{W}^2 would be about 0.4, and therefore \bar{W} probably about 0.6; but for these 45° targets, p must be somewhat greater and \bar{W}^2 correspondingly less. This estimate is lower than those given above, but it agrees in making quantities dependent on p and $F(W)$ independent of V , as required by theory.

All this evidence is still far from a quantitative formula for $F(W)$, but all that is really needed for present purposes is a rough approximation, in a reasonably convenient mathematical form. To satisfy this latter requirement

¹² W. W. Nicholas, *Phys. Rev.* **29**, 619 (1927).

¹⁵ P. Ledoux-Lebard and A. Dauvillier, "Physique des Rayons X" p. 45. (quoted by Rump).

¹⁶ W. Rump, *Zeits. f. Physik* **43**, 254 (1927).

we shall neglect that about the behavior of $F(W)$ at $W=0$, where we shall never need to use it. All other requirements are then satisfied by either of the following formulas:

$$\left. \begin{aligned} F_1(W) &= G(1 - W)e^{-g(1-W)}, \\ \text{with } G &= g^2/\{1 - (g + 1)e^{-g}\}; \end{aligned} \right\} \quad (4)$$

and

$$\left. \begin{aligned} F_2(W) &= Q(1 - W)W^q, \\ \text{with } Q &= (q + 1)(q + 2). \end{aligned} \right\} \quad (5)$$

Fig. 1. Graphs of $F_1(W)$ and $F_2(W)$ from equations (4) and (5) respectively.

TABLE II. Parameters of $F(W)$ in Fig. 1.

W_0	g	q	\bar{W}	\bar{W}^2
0.90	10	—	0.800	0.660
0.90	—	9	0.833	0.706
0.80	5	—	0.635	0.454
0.80	—	4	0.714	0.536
0.67	3	—	0.520	0.333
0.67	—	2	0.600	0.400
0.50	2	—	0.455	0.272
0.50	—	1	0.500	0.300

Graphs of these functions, for several values of each parameter, g or q , are shown in Fig. 1; and corresponding values of W_0 , \bar{W} and \bar{W}^2 , for use in selecting the best value of g or q , are listed in Table II.

Briefly, for heavy elements, the evidence on W_0 and \bar{W} seems to favor the higher values listed here for these parameters, and that from \bar{W}^2 the lower ones; for light elements, the values must be lower than for heavy. In view of this uncertainty, it is indeed fortunate that the quantities we must calculate for the comparison of x-ray data with theories change so slowly with these parameters that even such rough information as this will suffice to place them within probable limits of experimental error.

The directional distribution of rediffused cathode rays. In the problem of the effect of rediffusion on the intensity of x-rays from a thin target supported on a block of another metal, it is important to know the ratio of the average number of atoms in the thin target, struck by a rediffused ray on its way out, to the number struck by a primary ray on its way in. Since all the corrections for diffusion and rediffusion effects are reasonably small, we shall neglect small quantities of the second order, i.e. in this case, the effect of diffusion within the thin target itself on the ratio of these numbers of atoms. Thus we shall assume that for cathode rays rediffusing at the angle Θ from the normal, this ratio is simply $\sec \Theta$. The directional distribution need then be found only with enough accuracy to get a reasonably accurate estimate of the mean value of $\sec \Theta$, which we shall call S .

Rediffusion can happen only to cathode rays deflected through more than a right angle, and indeed considerably more unless the paths after deflection through a right angle are much longer than those before. Thus rediffusion comes fairly near to involving complete diffusion, and the assumption of complete diffusion should give a first approximation for S . With this assumption, the probability that any infinitesimal segment of the path of a ray will intersect the surface of the block would be proportional to the sine of the angle this segment makes with the surface, and so the number escaping in a given solid angle $d\Omega$ would be proportional to $\cos \Theta d\Omega$. This deduction was indeed verified, for beta rays transmitted through reasonably thick aluminum, by Kovarik and McKeehan.¹⁷ Assuming it to hold for rediffused cathode rays, a simple integration gives $S = 2$.

For a better approximation, still with normal incidence, but with incomplete diffusion, we may assume that at any point within the metal, the number of paths in a solid angle $d\Omega$ is a function $f(\Theta)d\Omega$. Then the number emerging in this solid angle will be proportional to $f(\Theta) \cos \Theta d\Omega$, and $f(\Theta)$ may be measured directly by catching the emergent rays from an area varying inversely as $\cos \Theta$.

It was in this way, but with incidence at 30° from the normal, that Kovarik and McKeehan verified the simple cosine law for transmitted rays. Their rediffused rays, however, showed a minimum in the direction backward toward the source. From a typical graph which they published, it seems prob-

¹⁷ A. F. Kovarik and L. W. McKeehan, Phys. Rev. 6, 426 (1915).

able that if the incidence had been along the normal, the rediffused rays would have been represented well enough for present purposes by the formula

$$f(\Theta) = \text{const.} \times (1 + a\Theta^2), \quad (6)$$

with $1 + a(\pi/2)^2 = 1.4$.

A simple integration then gives

$$S = 2 \cdot \frac{1 + 1.14a}{1 + 0.73a}. \quad (7)$$

If the diffusion had been complete, a would have been zero, making $S=2$, as above; with a as in equation (6), $S=2.11$. For present purposes, the difference is immaterial, and as the foil from which these data were taken was not thick enough for complete diffusion of its transmitted rays, the difference for a thick block may be even less. So in all probability S is somewhere between 2.0 and 2.1.

THE THIN-TARGET EFFECTS

We are now in a position to solve the problem of the effects of diffusion and rediffusion on the intensities of x-rays, and we shall consider first a thin target supported by a thick block. Since targets of this type are useful primarily for line spectra, the intensity will be considered to be that of a line, for example one belonging to a K series, of excitation potential V_K , and we shall write all functions of the tube potential V in terms of the ratio $U = V/V_K$. Letting X_0 stand for the thickness of the target, the intensity of the line, with neither diffusion nor rediffusion, is $X_0 i_0(U)$, where $i_0(U)$ is the intensity per unit length of path. Then with rediffusion, the intensity due to the rediffused rays alone will be called $X_0 r(U)$, and the total intensity will be called $X_0 j(U)$. Now with diffusion within the thin target, the paths of the cathode rays are no longer straight, and the mean length of path of an incident ray within the target is slightly greater than X_0 . As it is a function of voltage, we shall call it $X(U)$, and we shall replace X_0 in each of the above expressions by $X(U)$. Strictly speaking, this is not quite accurate for the rediffused rays, but as the error is a small quantity of the second order, we shall neglect it.

Calculation of the effect of rediffusion. With these definitions and the formulas on rediffusion deduced in the preceding section, it is evident that

$$r(U) = pS \int_{1/U}^1 F(W) i_0(UW) dW. \quad (8)$$

We do not know $i_0(UW)$ accurately, of course, until after $r(U)$ has been calculated. But as will be proved later, we may safely replace it here by either of two functions, used previously in empirical formulas for $i(U)$, and shown graphically in Fig. 2, along with some data. Strictly speaking, these data refer to the function $j(U) = X(U)i(U)/X(2)i(2)$, but X changes very little with U , so this is nearly $i(U)/i(2)$; thus an empirical formula for $j(U)$ will do well enough for $i(U)$, if we can use it with an unknown constant factor. One of the formulas thus obtained is

$$i_1(U) = k_1 \frac{1 - 1/U}{m_1 + U} \text{ if } U > 1, \text{ or } 0 \text{ if } U < 1, \quad (9)$$

with k_1 the unknown constant and m_1 about 3.0. The other¹⁸ is

$$i_2(U) = k_2 U^{-m_2} \log U \text{ if } U > 1, \text{ or } 0 \text{ if } U < 1, \quad (10)$$

with k_2 unknown and m_2 about 0.77.

Fig. 2. Uncorrected data and empirical formulas. Black circles, 280A Ag film; white circles, 170A film; black and white circles, data from these films practically coincident.

To see whether the departures of these formulas from i_0 are of any importance here, we have also calculated r with two other functions, departing farther from the corrected graph than either i_1 or i_2 , and in opposite directions. One of these functions, suggested by Davis' theory,¹⁹ is

$$i_D(U) = k_D \left(1 - \frac{1}{U} \right); \quad (11)$$

the other, from Rosseland's theory,²⁰ is

$$i_R(U) = k_R \left(\frac{1}{U} - \frac{1}{U^2} \right). \quad (12)$$

¹⁸ D. L. Webster and W. W. Hansen, Phys. Rev. 33, 535 (1929).

¹⁹ B. Davis, Phys. Rev. 11, 433 (1918).

²⁰ S. Rosseland, Phil. Mag. 45, 65 (1923).

The resulting values of r agree with those from i_1 and i_2 to better than half of one percent of i , for any value of U in the range covered. So i_1 and i_2 are well within the limits of accuracy needed for this purpose.

For $F(W)$ we may use either of the functions F_1 and F_2 obtained in the preceding section, Eqs. (4) and (5), and tests with the simple intensity functions i_R and i_D show that it makes no notable difference which F is used. For convenience in integration, however, we have used F_1 with i_1 , and F_2 with i_2 . Thus we obtained two formulas for r , namely

$$r_1(U) = pSk_1 \frac{G}{m_1 g U} [(m_1 + 1) y e^{-y} \{Ei y - Ei z\} - g e^{-g} \{Ei g - Ei(g/U)\} - m_1 \{1 - e^{-y}\}], \quad (13)$$

where $y = g(m_1 + U)/U$ and $z = g(m_1 + 1)/U$, and

$$r_2(U) = pSk_2 Q U^{-m_2} \left[\frac{\log U}{(q + 1 - m_2)(q + 2 - m_2)} - \frac{1 - U^{-q-1+m_2}}{(q + 1 - m_2)^2} + \frac{1 - U^{-q-2+m_2}}{(q + 2 - m_2)^2} \right]. \quad (14)$$

For comparison of x-ray data with theories, we should like to find the function

$$i_0(U) = i(U) - r(U); \quad (15)$$

but as we have already seen, the data give i , and therefore r also, only with an unknown constant coefficient. To eliminate this coefficient, in our first paper this subject,¹ we plotted the "reduced intensity"

$$j(U) = \frac{X(U)i(U)}{X(2)i(2)} \quad (16)$$

as an empirical function; and now likewise we can compare with theoretical predictions the function

$$j_0(U) = i_0(U)/i_0(2). \quad (17)$$

As an intermediate step, correcting for rediffusion only, we shall make use of the function

$$\begin{aligned} j_r(U) &= \frac{X(U)i_0(U)}{X(2)i_0(2)} = j(U) \cdot \frac{1 - \{r(U)/i(U)\}}{1 - \{r(2)/i(2)\}}, \\ &= j(U) \frac{1 + \{r(2)/i_0(2)\}}{1 + \{r(U)/i_0(U)\}}, \end{aligned} \quad (18)$$

and this coefficient of $j(U)$ will be called $c_r(U)$.

To compute c_r we need numerical values of pS and either g or q . It appeared above that p for beryllium was probably about 0.043, and S 2.0 to 2.1.

Thus pS is probably about 0.086 to 0.090, though it may well be outside these limits. So we shall tentatively use the rounder number, 0.090, and if a better value of either p or S is found later, new values for c_r may be found by changing $(c_r - 1)$ in proportion to pS .

For g and q , since there is considerable doubt as to the best values to assign to them, we have left room for later improvements in accuracy by making calculations with all the values used in Fig. 1 or Table II. The results are given in Table III.

TABLE III. Values of 100 $(c_r - 1)$.

W_0	g	q	$U=1.0$	1.5	2.0	2.5	3.0	3.5
0.90	10	—	+7.4	+2.2	0	-1.0	-1.6	-2.0
0.90	—	9	+7.9	+2.0	0	-0.8	-1.2	-1.5
0.80	5	—	+4.5	+1.9	0	-1.3	-2.0	-2.9
0.80	—	4	+5.6	+2.5	0	-1.3	-2.2	-2.8
0.67	3	—	+3.1	+1.6	0	-1.2	-2.2	-3.0
0.67	—	2	+3.7	+2.0	0	-1.4	-2.5	-3.3
0.50	2	—	+2.3	+1.4	0	-1.0	-2.0	-2.8
0.50	—	1	+2.5	+1.5	0	-1.3	-2.2	-3.0

The changes actually made in the reduced intensities, by the use of these corrections, are shown in Table IV, for values of U from 1 to 3.3 the limits of the data in Fig. 1. Here, for simplicity, we have averaged the corrections for all of the values of g and q from Table III, that have any reasonable chance of applying to such a light element as beryllium, that is, for $W_0 = 0.80, 0.67$ and 0.50. And to give a rough indication of the probable error due to the uncertainty in these parameters, we are tabulating with each averaged correction the mean of the deviations from it, given by the six values of g or q .

TABLE IV. Reduced intensities, corrected for rediffusion.

U	1.0	1.5	2.0	2.5	3.0	3.3
Average of 100 $(c_r - 1)$	+3.6	+1.8	0	-1.3	-2.2	-2.7
$j(U)$ from empirical graph	0	+0.727	+1	+1.117	+1.148	+1.144
Average of corrections	0	+0.013	0	-0.014	-0.025	-0.031
Mean deviation of corrections	0	0.002	0	0.001	0.002	0.002
Ave. corrected intensity $j_r(U)$	0	+0.740	+1	+1.103	+1.123	+1.113

From this table it is evident that it makes no appreciable difference what value of g or q we use, within the range covered here; and even if the distribution of kinetic energy is not exactly like any of these functions $F(W)$, one could probably represent it pretty accurately by some linear combination of them, and even such a change would make no notable change in the corrections to be applied to $j(U)$.

Calculation of the effect of diffusion within the thin target. To calculate the reduced intensity $j_0(U)$, of Eq. (17), corrected for both rediffusion and

diffusion, we must not only correct the factor $i(U)/i(2)$ in $j(U)$ for rediffusion, but also the factor $X(U)/X(2)$ for diffusion. The basis for this correction is a formula given by Bothe²¹ "zum praktischen Gebrauch," namely

$$\lambda = \frac{8.0}{V} \cdot \frac{V + 511}{V + 1022} \cdot Z \left(\frac{\rho x}{A} \right)^{1/2}. \quad (19)$$

Here λ is the most probable deflection of a cathode ray by multiple scattering in a thickness x of an element of atomic number Z , atomic weight A and density ρ ; and λ must be expressed in radians, V in kilovolts, x in microns and ρ in gm/cc.

Letting Θ represent the deflection of any individual cathode ray at the depth x , the contribution of a layer dx to the mean path X will be the mean value for all cathode rays, of $\sec \Theta dx$. For a thin target, therefore, since $\sec \Theta$ is nearly enough $(1 + \frac{1}{2}\Theta^2)$, and the mean value of Θ^2 is $2\lambda^2$, we have

$$X(U) = \int_0^{X_0} (1 + \lambda^2) dx = X_0(1 + \frac{1}{2}\lambda_0^2), \quad (20)$$

where λ_0 is the value given by equation (19) for λ at $x = X_0$.

The correction factor for diffusion, analogous to $c_r(U)$ for rediffusion, is now obtained from Eqs. (16), (17) and (18), as

$$c_d(U) = X(2)/X(U), \quad (21)$$

so that

$$j_0(U) = j(U)c_r(U)c_d(U). \quad (22)$$

As an illustration, and also for more definite use in the next section, the effect of diffusion in one of our own Ag targets is shown in Table V.

TABLE V. *Effect of diffusion in a 280A Ag target.*

U	=	1.0	1.5	2.0	2.5	3.0	3.5
$X(U)/X_0$	=	1.076	1.034	1.019	1.013	1.009	1.006
$100(c_d - 1)$	=	-5.2	-1.4	0	+0.6	+1.0	+1.3

Results. Combining the corrections for diffusion and rediffusion, as applied to our data on thin silver, we obtain the reduced intensities in Table VI. Here as in Table IV, the values of $j(U)$, for the round-number values of U used in the computations, were read from the empirical graph in our previous paper, and the values of $j_0(U)$ were computed from them.

TABLE VI. *Reduced intensities, corrected for diffusion and rediffusion.*

U	=	1.0	1.5	2.0	2.5	3.0	3.3
$j(U)$	=	0	0.727	1	1.117	1.148	1.144
$100(c_r c_d - 1)$	=	-1.8	+0.4	0	-0.7	-1.2	-1.4
$j_0(U)$	=	0	0.730	1	1.109	1.134	1.128

²¹ Bothe, reference 8, Section 9.

For the other values of U at which data are given in Fig. 2, we have got the correction factors by interpolation, using Table VI for the 280A target, and a similar table for the 170A, differing only in the smaller correction for diffusion. The results, with the theoretical graphs with which they are to be compared, are shown in Fig. 3.

With regard to the empirical intensity functions, i_1 and i_2 of eqs. (9) and (10) resp., these corrections are so small that they come within the limits of error of i_1 , but for i_2 it is best to change m_2 from 0.77 to 0.80.

Fig. 3. Corrected data and theoretical graphs.

Reliability of these corrections. In a recent paper on thick-target x-ray measurements, Wisshak² reported data differing radically from our thin-target data in their relations to the theories. To compare our data with his he calculated a thick-target intensity function from our thin-target function $i_1(U)$, of Eq. (9), by the same formula that Rosseland had applied to his own theoretical function. The relation between this new thick-target function for Ag and Rosseland's was therefore much like that between the corresponding thin-target functions, shown in Figs. 2 and 3, i.e. the empirical graph was below Rosseland's at low voltages and above at high. Wisshak's empirical graph for the average of Cr and Cu, on the contrary, crossed Rosseland's theoretical graph in the opposite direction, at an angle of the same order of magnitude. Therefore Wisshak concluded, not only that there was a serious discrepancy between Rosseland's theory and his data, but also that the still larger difference between our graph and his must have been due to rediffusion in our target.

The present calculations, however, do not alter the relation between our graph and Wisshak's by anything like the amount indicated by this conclusion. In fact, to bring our graph into agreement with Rosseland's would require the correction, at $U=3$ for example, to be about 10 times as large as our calculations indicate, and for agreement with Wisshak's graph this factor would have to be nearer to 20. This raises the question: Can any of the uncertainties in the quantities or functions we have used be such as to make possible an increase of this order in our corrections?

Any change of g or q , in either direction, would reduce the corrections. Any other change in the energy distribution, keeping within the requirements of the evidence reviewed above, could hardly be such as to render impossible a good approximation by some linear combination of the functions we have used, and this would keep the corrections much as calculated here. A change in the parameter a , of the directional distribution, even to $a = \infty$, which would be so extreme as to make the probability of normal emergence zero, would still introduce only a factor of about 1.5. A change in p , keeping it independent of V , would certainly be limited by the fact that p for Be must be considerably less than for Al, and thus it could not go beyond a factor of 2 or 3. And finally, if p were assumed not independent of V , it could only decrease with increasing V , and this would reduce the correction. Altogether, therefore, any great increase in these corrections appears highly improbable. Evidently we must look elsewhere for the cause of the disagreement between our conclusions and Wisshak's, and in view of the great difficulties in the interpretation of thick-target data, it is our opinion that the cause is probably there.

This conclusion is of especial importance for the major question, which of the theoretical graphs in Fig. 3 is the best; but there is also the question, whether any of them is exact, so it may be well to note here some additional points about the accuracy of these data, not related to these corrections. Three possible sources of systematic error were mentioned in our first paper on these data. One was rediffusion (we had not realized the importance of diffusion within the thin target); another was the presence of some fluorescence radiation, never more than 0.2 percent and therefore negligible; the third was an unexplained darkening of the focal spot during use. This has since been explained, through the kindness of Dauvillier, who pointed out to us by letter an investigation of his,²² proving such darkening to be due to carbon, which in our case could have come from the carbonization of adsorbed grease vapor by cathode rays (not by heat, because the block was oil-cooled and the power input was low). If this carbon were thick enough to retard the cathode rays appreciably, it might cause serious errors, especially at low voltages. Fortunately, however, after finishing the measurements shown in Fig. 2, we made a very careful study of the intensity function in the first 2 kilovolts above V_K . Here we found effects exactly such as one would predict for a 280A silver target assuming that it retarded the cathode-rays at 25 kv. by about 200

²² A. Dauvillier, Journ. d. Physique 8, 1 (1927).

volts, as predicted by the Thomson-Whiddington law, and that an infinitely thin target would give an intensity starting from zero at $U=1$, with a finite derivative. These measurements will be reported in more detail later, along with others with improved apparatus. For the present, the important point is, that if there had been any appreciable retardation in the carbon, it would almost surely have been evident here. So there can hardly have been any serious error from that source.

A similar possibility is that of a deposit of tungsten. But this is ruled out, not only by the above test, but also by the absence of the tungsten K lines at 80 kv.

There may of course be sources of systematic error still unsuspected, and there are the erratic errors, whose magnitude can be judged by the departures of the points from the empirical graph in Fig. 3. But for the present, we shall assume that Fig. 3 is accurate enough to serve as a basis for conclusions about the theories now at hand.

COMPARISON WITH THEORIES

Of the theoretical graphs in Fig. 3, those for Davis and Rosseland are plotted from Eqs. (11) and (12) respectively, and that for Thomas²⁴ from

$$i_T(U) = k_T \frac{1 - 1/U + (2/3)m_T(1 - 1/U^2)}{1 + U + m_T}, \quad (23)$$

where the parameter m_T is the ratio of the kinetic energy of an atomic electron in a Bohr orbit to its ionization energy.

While these theories based on classical mechanics give definite formulas, the wave mechanics, so far as we know, has been applied only through approximations that become invalid at voltages near the ionization voltage. On this basis Bethe²³ gives a formula, in which the dependence of intensity on U may be expressed by

$$i_B(U) = k_B U^{-1} \log(4U/B) \quad (24)$$

where BeV_K is a quantity of energy, "of the order of magnitude of the ionization energy," eV_K .

Comparing this function with Wisshak's data, which cover about the same range of U as ours, Bethe states that it is probably unsatisfactory for this range, "because the rise of x-ray intensity with increasing excess of the bombardment energy over the ionization energy must be even steeper than in the Thomson [or Rosseland] theory, whereas experimentally it is somewhat more level." Comparing the theories with our experimental graph, however, we should exactly reverse this last clause. In view of the approximations in Bethe's theory, it must of course become invalid as U is reduced toward unity, but in most of this range it apparently agrees with the thin-target data better than with the thick.

²³ H. Bethe, Ann. d. Physik 5, 325 (1930).

²⁴ L. H. Thomas, Proc. Camb. Phil. Soc. 23, 829 (1927).

In the absence of any theoretically calculated value of B , beyond the order-of-magnitude estimate quoted above, we may treat it tentatively as an empirical parameter, and choose a value such as to make the equation fit the data as far down the scale of U as possible. Since i must be zero at $U=1$, this is $B=4$. We have therefore plotted a graph on this basis in Fig. 3, but in view of the arbitrary character of this assumption, we cannot call it exactly a graph for Bethe's theory, and so we are not giving it any name.

A suggestion as to the direction in which a true graph for Bethe's theory might differ from this one is given by his calculation of the effective cross-section of a hydrogen atom for inelastic collisions (including excitation as well as ionization). Here there is a quantity b , analogous to B . At high voltages, b is constant at 0.638; but inspection of the equations from which it is obtained shows that with reduction of voltage it must begin to increase. If B behaves likewise, the true graph for Bethe's theory may run somewhat steeper than the nameless graph of Fig. 3, and thus perhaps agree even better with our experimental graph.

Another interesting aspect of Bethe's equation is its agreement in mathematical form with i_2 , at least if m_2 is set equal to 1, as well as B to 4. This function i_2 was suggested first by a study of an empirical relationship between line and continuous spectra; and there some of the data indicated that $m_2=1$. Thus perhaps Bethe's theory may suggest theoretical connections, to match the empirical one between these spectra.

THICK-TARGET EFFECTS

Effect of rediffusion on line intensities. In a thick target, the effect of rediffusion, removing some of the cathode rays from the target before they have made their quotas of impacts, is to diminish the intensity of the x-rays. Let $I_0(U)$ be the intensity of the rays that would be emitted in a K -series line if there was no such loss, and $I(U)$ the actual intensity. Then the loss,

$$I_0(U) - I(U) = R(U), \quad (25)$$

is equal to the intensity of the rays that the rediffused electrons would emit if they struck another target of the same element and did not rediffuse from it. Thus

$$R(U) = p \int_{1/U}^1 F(W) I_0(UW) dW. \quad (26)$$

To calculate $R(U)$ we shall proceed much as with the analogous equation, (8), for $r(U)$. The chief difference in the two cases is that the sign of the correction for rediffusion here is opposite to what it was there, because the effect is a loss of impacts rather than a gain.

For I_0 in this integrand, we shall use either of two simple empirical formulas. One²⁵ of these is

$$I_1(U) = K_1(U - 1)^n, \quad (27)$$

²⁵ D. L. Webster and H. Clark, Proc. Nat. Acad. Sci. 3, 181 (1917); A. Jonsson, Zeits. f. Physik 43, 845 (1927); S. K. Allison, Phys. Rev. 30, 245 (1927).

where n is between 1.3 and 2.1, and K_1 is a constant. The other²⁶ is

$$I_2(U) = K_2(U^2 - 1), \quad (28)$$

where K_2 also is constant.

Neither of these formulas is very accurate, but in view of other corrections, less definitely known than the one for rediffusion, we shall go no farther with this case than to find the order of magnitude of this correction. And for that, we may use either function, simplifying matters still further by letting n = either 1 or 2, although I_1 with $n=1$ is very far from correct.

The constants K_1 and K_2 are not so little known as those of the thin-target functions, but there is enough uncertainty here also to make it better for most purposes to use a "reduced intensity," which we shall call

$$J(U) = I(U)/I(2). \quad (29)$$

The corrected reduced intensity is now

$$J_0(U) = J(U) \cdot \frac{1 + \{R(U)/I(U)\}}{1 + \{R(2)/I(2)\}} = J(U) \cdot \frac{1 - \{R(2)/I_0(2)\}}{1 - \{R(U)/I_0(U)\}}, \quad (30)$$

and this correction factor for $J(U)$ will be called $C(U)$.

Values of $C(U)$, corresponding to the $c_r(U)$ of Table III, are shown in Table VII.

TABLE VII. Values of $100 (C(U) - 1)$ for Ag, $p=0.39$ and $W_0=0.90$.

$U =$	1.0	1.5	2.0	2.5	3.0	3.5
$I_1, n=1, g=10$	-23.8	-7.2	0.0	+3.3	+5.0	+6.1
$I_1, n=1, g=9$	-26.0	-7.4	0.0	+3.0	+4.5	+5.5
$I_2, g=10$	-21.5	-5.9	0.0	+2.3	+3.4	+4.1
$I_2, g=9$	-23.7	-6.1	0.0	+2.2	+3.2	+3.8
$I_1, n=2, g=10$	-17.0	-6.0	0.0	+3.1	+4.9	+6.1
$I_1, n=2, g=9$	-19.0	-6.6	0.0	+3.2	+5.0	+6.2
Averages	-21.8	-6.5	0.0	+2.8	+4.3	+5.3
100 (c_r-1) from Table 4	3.6	1.8	0.0	-1.3	-2.2	-2.7
$(C-1)/(c_r-1)$	-6.1	-3.6	-2.6	-2.2	-2.0	-2.0

From this table it is evident that the rediffusion correction factors for thick-target line intensities are about 2 to 4 times as far from unity as those for thin. This raises anew the question of the cause of the disagreement between our conclusions and Wisshak's,² about the status of the theories of ionization by impact. In Wisshak's interpretation of his data, the allowance for rediffusion consisted in substituting for the measured tube current, the current computed from the voltage and the heat in the target. But as the ratio of these currents was found to be constant, the difference affects only the constant coefficient K , in $I(U)$, and does not affect $J(U)$ at all. So it appears to us that the correction factor $C(U)$ would be useful here. And just as the cor-

²⁶ Simplified from a formula used by G. Kettmann, *Zeits. f. Physik* **18**, 359 (1923); and E. C. Unnewehr, *Phys. Rev.* **22**, 529 (1923).

rection c_r for thin targets shifted our graph toward Wisshak's, this opposite correction C shifts his graph toward ours. Nevertheless, both corrections together move the graphs only about a seventh as far as is necessary to bring them into agreement. Evidently there is some other cause for the difference.

The most obvious suggestion is that there is a real difference between the elements used here by Wisshak and by us, namely between his average of Cr and Cu and our Ag. Another possibility is that the other uncertain factors in the interpretation of thick-target data are responsible for the discrepancy. So it is significant, though ambiguous, that recent data of ours (not yet published) on thick targets of Ag with corrections for target absorption by Kulenkampff's method and for fluorescence radiation by ours,²⁷ give a far better agreement with the function calculated by Wisshak from our thin-target formula for Ag than do his data on Cr and Cu.

To put this statement into a more quantitative form, we may express all these intensity functions with enough accuracy in terms of the function $I_1(U)$, of Eq. (27), namely $K_1(U-1)^n$. Wisshak's graphs for Cr and Cu make n between 1.3 and 1.4, and his function calculated from our thin Ag makes n about 1.85. Our data on thick Ag make n about 1.65 before correction for re-diffusion, and about 1.73 after. The remainder from 1.73 to 1.85 is in the direction one would expect from Kulenkampff's²⁸ comparison of his continuous-spectrum intensities for thin Al with the intensities calculated from his thick Al by a method the inverse of that which Wisshak used here. So this discrepancy may be ascribed tentatively to the errors in the Thomson-Whiddington law of retardation of the cathode rays, which has been used, for lack of anything more accurate, in all such calculations. The net result, then, is that the apparent discrepancy between the thick and thin-target data may well be no greater than can be expected from the uncertainties in the relations between them.

Details of these comparisons would be beyond the scope of this paper, however, and will therefore be reserved for later consideration, in connection with more data. In the meantime, the values of n given here for thick Ag must be regarded as somewhat provisional, as we are making still further improvements in our apparatus, but they are fairly good up to about 100 kv ($4 V_K$); and for rays corrected only for target absorption, an exponent 1.6 will serve moderately well up to 180 kv.

Continuous spectra. Turning from the line spectra of thick targets to the continuous, we are rid of the complications of fluorescence, but we run into another complication, arising from the fact that the intensity emitted by a single atom (or a thin target) is not the same in all directions, as proved by Kaye,²⁹ Duane,³⁰ Kulenkampff²⁸ and Nicholas.³¹ As it concerns us here, this means that the diffusion of the cathode rays within a thick target will

²⁷ D. L. Webster, *Proc. Nat. Acad. Sci.* **14**, 330 (1928).

²⁸ H. Kulenkampff, *Ann. d. Physik* **87**, 597 (1928).

²⁹ G. W. C. Kaye, *Proc. Camb. Phil. Soc.* **15**, 269 (1909).

³⁰ W. Duane, *Proc. Nat. Acad. Sci.* **15**, 805 (1929).

³¹ W. W. Nicholas, *Bureau of Standards Jour. Res.* **2**, 837 (1929).

tend to annul the directional differences that would have occurred without it. This effect has been discussed by Kulenkampff and Nicholas, who have shown that it is practically complete except near the high-frequency limit of the spectrum, and that the directional effects near the high-frequency limit are such as one might expect from the data on thin targets. Having no new contribution to make on this point, we may treat the effect of rediffusion alone by neglecting the directional effects and comparing theoretical predictions, not with intensities in any particular direction, but with the average, so far as it is known, for all directions.

This treatment of the rediffusion effect amounts practically to putting on a somewhat more nearly quantitative basis an idea advanced by Kramers³² in a paper on his theory of the continuous spectrum. First neglecting rediffusion as well as all directional effects, Kramers found for the thick-target intensity in a range $d\nu$.

$$I_0(V, \nu) d\nu = K_0 Z(\nu_0 - \nu) d\nu = K_0 Z \nu_0 u, \quad (31)$$

where K_0 is a constant, $\nu_0 = eV/h$, and $u = (\nu_0 - \nu)/\nu_0$. Observed intensities are not far from obeying this formula, but they are given more accurately by adding a non-linear term,³³ so that the empirical formula is something like

$$I(V, \nu) = K' Z \nu_0 [u + BZ(1 - e^{-Au})], \quad (32)$$

where A is a function of Z , ν and ν_0 , and B of ν and ν_0 , though perhaps not of Z , and both A and B change only slowly. K' will be defined more explicitly below. Kramers explained the presence of a non-linear term of this general sort, as an effect of rediffusion.

A calculation of I , based on Kramers' theoretical intensity I_0 and the rediffusion formulas used in the first part of this paper, gives, when $F_1(W)$ is used,

$$I_1(V, \nu) = K_0 Z \nu_0 [(1 - p)u + p\{(1 - \overline{W})(1 - e^{-\sigma u}) - ue^{-\sigma u}\}], \quad (33)$$

at least if $e^{-\sigma} \ll 1$, and when $F_2(W)$ is used,

$$I_2(V, \nu) = K_0 Z \nu_0 [(1 - p)u + p\{(1 - \overline{W})(1 - v^{q+3}) - uv^{q+2}\}], \quad (34)$$

where $v = 1 - u$.

Each of these functions is much like the empirical function of Eq. (32), in that the larger term, $(1 - p)u$, is proportional to u , while the smaller, non-linear, term increases from zero at $u = 0$, more or less like $(1 - e^{-Au})$. Furthermore the ratio of these terms, as a function of Z , contains $p/(1 - p)$, which is not far from proportional to Z , like the corresponding ratio in Eq. (32).

With regard to the dependence of the linear term on Z , it is usually said to be simply proportional to Z , with K' in Eq. (32) constant. The best evidence on this point, however, comes from the data of Wagner and Kulen-

³² H. A. Kramers, *Phil. Mag.* **46**, 836 (1923).

³³ D. L. Webster, *Phys. Rev.* **9**, 220 (1917); E. Wagner and H. Kulenkampff, *Phys. Zeits.* **23**, 503 (1922); D. L. Webster and A. E. Hennings, *Phys. Rev.* **21**, 312 (1923); W. W. Nicholas, *Phys. Rev.* **29**, 619 (1927).

kampff,³⁴ who made an approximate allowance for rediffusion by defining intensity, not as x-ray energy per incident cathode ray, but per unit current as measured by heat in the target. It is in these terms only, that the K' of Eq. (32) is approximately constant. To convert to the intensity definition used here, we must let

$$K' = K(1 - p\overline{W}), \quad (35)$$

with K constant. This new factor $(1 - p\overline{W})$, is not far from the $(1 - p)$ of Eqs. (33) and (34).

Likewise on integrating to get the total intensity, unresolved, we find

$$E_1 = E_2 = \frac{1}{2}K_0 Z\nu_0^2(1 - p\overline{W^2}), \quad (36)$$

and from Eq. (32), neglecting the second term,

$$E = \frac{1}{2}K'Z\nu_0^2 = \frac{1}{2}KZ\nu_0^2(1 - p\overline{W}), \quad (37)$$

agreeing fairly well with E_1 or E_2 .

Thus these formulas describe the main facts of thick-target continuous spectra to a first approximation, confirming Kramers' qualitative predictions. We cannot expect great accuracy here, because the basic formula for $I_0(V, \nu)$ was derived by the Thomson-Whiddington law from a theoretical thin-target formula which agrees only approximately with Kulenkampff's data, and so $I_0(V, \nu)$ itself may be as good as it is, only because of a cancellation of errors. An approximate verification of these thick-target formulas is therefore as much as one can expect.

EXPERIMENTAL EVIDENCE FOR ELECTRON VELOCITIES AS THE CAUSE OF COMPTON LINE BREADTH WITH THE MULTICRYSTAL SPECTROGRAPH

BY JESSE W. M. DuMOND AND HARRY A. KIRKPATRICK
CALIFORNIA INSTITUTE OF TECHNOLOGY, PASADENA

(Received December 1, 1930)

ABSTRACT

The main purpose of this research was to test the correctness of the assumption that the initial velocities of electrons in the scattering body cause the observed breadth of the Compton shifted line. The test consists in observing the natural breadths of the Compton line for different scattering angles and primary wave-lengths and comparing these with the functional dependence of breadth on scattering angle and primary wave-length deduced theoretically on the basis of the assumption under test. It is shown in this paper that if electron velocities are the cause of the breadth then this breadth should increase with the scattering angle according to the approximate formula $\Delta\lambda = K \cos \frac{1}{2} \theta$ where $\Delta\lambda$ is the breadth, θ the scattering angle and K a constant depending on the primary wave-length and the scattering substance. For the same scattering angle and substance the breadth should be proportional to the primary wave-length.

The experimental test was made with the multicrystal spectrograph of fifty units herein briefly described. Three scattering angles were used, $63\frac{1}{2}^\circ$, 90° , 156° , *the inhomogeneity in each case being less than one degree*. The spurious breadth due to this inhomogeneity is negligible compared to the observed breadths. Three very clear cut spectrograms are reproduced representing MoK radiation scattered from graphite together with microphotometer curves taken from them. The increase of shifted line breadth with scattering angle is clearly visible and compares favorably with the theoretical prediction. The increase of line breadth with increasing primary wave-length comparing the breadths of shifted α_1 and shifted β_1 lines seems just detectable. The unshifted lines are very sharp, the α doublet being clearly resolved. Incidentally the cause of the heavy background so frequently observed on Compton effect spectrograms has been found to be non-selective scattering at the crystals and a great reduction of background and improvement in contrast has been effected by the use of baffles to diminish this effect.

The observed shift of the Compton line supports Compton's formula $\delta\lambda = (h/mc)(1 - \cos\theta)$ where $h/mc = 24.2\text{X.U.}$

The shifted line breadths are greater than those reported by Gingrich and Bear-den and possibly Ross but seem to be in general accord with previous breadths obtained at this laboratory and with those of H. M. Sharp and of E. L. Nutting. The reason for these discrepancies is unknown. The possibility of double or higher multiplicities of scattering is being investigated. (See note added in proof at the end of this article.)

PURPOSE OF THE INVESTIGATION

NEARLY all investigators have observed that the Compton shifted line is broader than either the unshifted line or the primary line. Jauncey,¹ Wentzel² and DuMond³ have each attributed the observed breadth of the

¹ Jauncey, Phys. Rev. **25**, 314-322 (1925); 723-736 (1925).

² Wentzel, Zeits. f. Physik **43**, 188 (1927); **43**, 779-787 (1927).

³ DuMond, Phys. Rev. **33**, 643-658 (1929).

Compton line to the velocities possessed initially by the electrons in the scattering body. DuMond³, and almost simultaneously, Chandrasekhar⁴ have applied the above assumption to the conduction electrons in the interatomic spaces of the crystal lattice in the case of electrically conducting scatterers and the former has shown that the results compared with his observed Compton line structures seem to support favorably the new Fermi, Pauli, Dirac, Sommerfeld statistics for such conduction electrons. It is important to test the correctness of the assumption that the velocities (or more accurately the momenta) of electrons bound in atoms or in the interatomic spaces of the crystal lattice are responsible for Compton line broadening.

We have attempted to test this assumption by observing the dependence of Compton line breadths on the scattering angle in the case of MoK radiation scattered by graphite and comparing this with the theoretical functional dependence to be expected if the assumption be correct that electron velocities cause the breadth. The theoretical considerations will be dealt with first.

PART I. THEORETICAL

GENERAL NON-MATHEMATICAL DISCUSSION

Before passing to the analytical argument we venture to offer a verbal discussion of the cause of Compton line-breadth regarded as a Doppler effect of the random-moving electrons scattering the radiations in order to serve as a guide to the reader through the cold formality of the analysis. The use of the words "Doppler effect" we insist shall not be naïvely interpreted as committing us to any *mechanism* (classical, undulatory or otherwise) to "explain" the wave-length modification associated with scattering of radiation by a moving scattering agent. It is now an old story that the Doppler effect from a moving scatterer can be equally well derived on either the extreme undulatory hypothesis or the extreme corpuscular hypothesis—the latter derivation requiring only the quantum application of the laws of conservation of momentum and energy to the elementary scattering process. *Furthermore the interpretation of the broadening of the Compton line as a Doppler effect of the motion of weakly bound electrons here presented is a perfectly valid first approximation to the quantum mechanical treatment of the effect as given by Wentzel, Gordon and others.* The condition for such validity is that the binding energy of the electron shall be small compared to the energy imparted to the electron in the scattering process. This condition is fulfilled in the present case.

When x-radiation is scattered by the electrons in a scattering body the total effect of the motion of the electrons may be thought of as a superposition of two "Doppler effects"—one caused by the initial motion of the electrons, the other caused by the motion imparted to the electrons by the radiation in the scattering process. The first Doppler effect can in the case of random electron motions have either a positive or a negative sign, depending on whether the electron's initial velocity before scattering has a component directed toward or away from the vector expressing the change in momentum suffered by the

⁴ Chandrasekhar, Royal Soc. Proc. A125, 231-237 (1929).

radiation in the scattering process. The second Doppler effect can have only one sign (corresponding to an increase in scattered wave-length over incident wave-length) because the momentum imparted to the electron in the scattering process must always be opposite in direction to the vector change in momentum of the radiation. Both Doppler shifts will vanish for zero scattering angle and be a maximum for a scattering angle of 180° .

The first Doppler shift having either positive or negative sign accounts for the broadening of the Compton modified line. The second Doppler shift accounts for the justly famous shift of the Compton line toward longer wave-lengths.

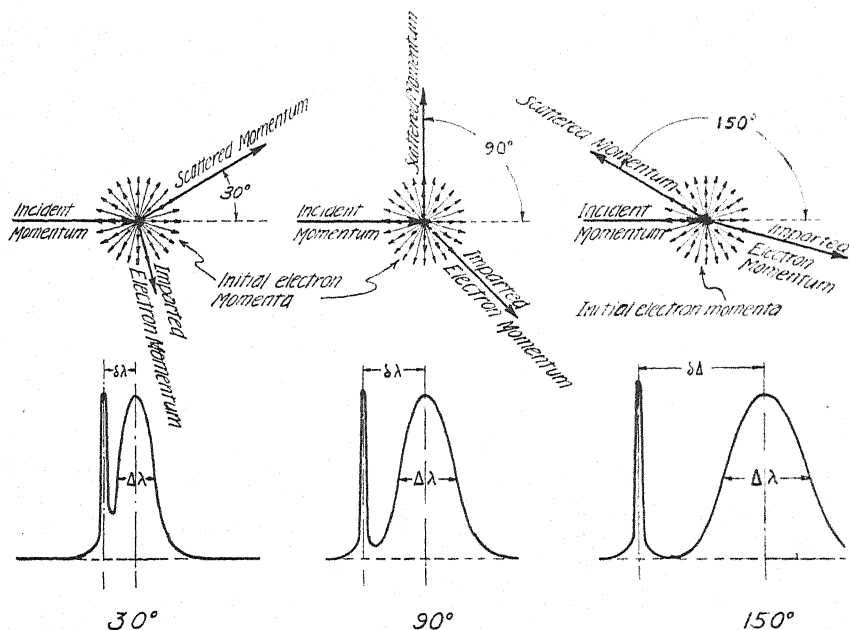

Fig. 1. Schematic illustration of Compton scattering by randomly directed moving electrons for three scattering angles together with idealized spectra of the resulting scattered radiation for each case. The constancy of the initial momentum and the increase in the momentum imparted to the electron with increasing scattering angle is shown. In this diagram the randomly directed initial momenta are *much exaggerated* relative to the imparted momentum.

Let us define the relative breadth $\Delta\lambda_r$ as the breadth at any scattering angle divided by the breadth at 180° scattering angle (maximum breadth). Let us also define the relative shift $\delta\lambda_r$ in an entirely analogous way. The relative breadth and the relative shift will be shown to be given by⁵

⁵ It is interesting to note that the relative shift is the *square* of the relative breadth. This is because the *shift* increases with the scattering angle due to *two* causes, (1st because the Doppler effect from *any* moving scatterer increases with the scattering angle, 2nd because the velocity of the moving scatterer itself increases with the scattering angle in the case of the Compton shift) while the *breadth* increases with the scattering angle due to only the first of these causes alone, the velocity of the scattering electron accountable for the breadth being independent of the scattering angle.

$$\text{Breadth } \Delta\lambda_r = \sin \frac{1}{2}\theta \text{ approximately}$$

$$\text{Shift } \delta\lambda_r = \sin^2 \frac{1}{2}\theta$$

Fig. 1 shows diagrammatically the vectors of light momentum, random initial electron momentum and momentum imparted by the scattering process to the electron for three scattering angles together with an idealized Compton shifted line spectrum for each case. In Fig. 2 the relative breadth and relative

Fig. 2. Relative breadth and relative shift computed for molybdenum *K* radiation using Eqs. (10) and (8). The relative breadth is the quotient of the breadth at any scattering angle by the maximum breadth which occurs at 180°. The relative shift is similarly defined.

shift are plotted as functions of the scattering angle. In this case the more accurate formula derived below has been used for the computations of relative breadth.

ANALYTICAL SOLUTION

Case of one free scattering electron only. The solution of this case in the form of Eq. (5) was obtained by de Broglie in his "Ondes et Mouvements Fascicule" 1, pp. 94-95. The primary radiation is taken as travelling in the positive *x*-direction. θ is the angle of scattering; ν_1 is the initial frequency; $\beta_1 c$ the speed of the electron before scattering, a_1, b_1, c_1 , the direction cosines of its velocity and $a_1 = \cos \theta_1$ so that θ_1 is the angle between the initial electron momentum and the initial light momentum. ν_2 is the frequency of the scattered quantum and its direction of propagation has the direction cosines p, q, r , making angle ϕ with the initial velocity of the electron and angle θ with *OX*. Fig. 3 shows the relations of the various vectors and angles. Evidently

$$\cos \phi = a_1 p + b_1 q + c_1 r$$

$$p = \cos \theta.$$

The recoiling electron has a final speed $\beta_2 c$ in the direction defined by the cosines a_2, b_2, c_2 .

The following four equations express the conservation of energy and of the

three rectangular components of momentum before and after the scattering process.

$$h\nu_1 + m_0c^2/(1 - \beta_1^2)^{1/2} = h\nu_2 + m_0c^2/(1 - \beta_2^2)^{1/2} \quad (1)$$

$$h\nu_1/c + (m_0\beta_1c/(1 - \beta_1^2)^{1/2})a_1 = (h\nu_2/c)p + (m_0\beta_2c/(1 - \beta_2^2)^{1/2})a_2 \quad (2)$$

$$(m_0\beta_1c/(1 - \beta_1^2)^{1/2})b_1 = (h\nu_2/c)q + (m_0\beta_2c/(1 - \beta_2^2)^{1/2})b_2 \quad (3)$$

$$(m_0\beta_1c/(1 - \beta_1^2)^{1/2})c_1 = (h\nu_2/c)r + (m_0\beta_2c/(1 - \beta_2^2)^{1/2})c_2 \quad (4)$$

Eliminating a_2 , b_2 , c_2 and β_2 and letting $\alpha = h\nu_1/m_0c^2$ we obtain on solving for the change in wave-length,

$$\lambda_2 - \lambda_1 = \frac{\beta_1(\cos \theta_1 - \cos \phi)}{1 - \beta_1 \cos \theta_1} \lambda_1 + \frac{2\alpha \lambda_1 \sin^2 \frac{1}{2}\theta}{1 - \beta_1 \cos \theta_1} \quad (5)$$

where the second term accounts for the simple Compton shift and the first term represents the modification caused by the electron's initial speed β_1 .

Fig. 3. Illustrating the various angles and vectors involved in Compton scattering by an electron possessing initial momentum. The initial electron momentum is exaggerated. The vectors are shown radiating from a sphere at the origin on which the angles between vectors appear as arcs of great circles. This sphere is shown merely to aid in visualizing the diagram in three dimensions.

As we are particularly interested in the *breadth* of the shifted line we define a wave-length coordinate, $l = \lambda_2 - \lambda_1 - 2\alpha\lambda_1 \sin^2 \frac{1}{2}\theta$ so chosen that l has its origin at the "center" of the shifted line (shifted position for scattering by free *initially stationary* electrons) and measures the wave-length deviation given by the first term of the right hand member of Eq. (5). Then

$$l = \frac{\lambda_c \cos \theta_1 - \lambda_1 \cos \phi}{1 - \beta_1 \cos \theta_1} \beta_1 \quad (6)$$

in which λ_c is the Compton shifted wave-length for the simple case of an initially stationary electron

$$\lambda_c = \lambda_1 + 2\alpha\lambda_1 \sin^2 \frac{1}{2}\theta.$$

Equation (6) can be much simplified by describing the direction of the initial electron momentum in terms of a new angle Ψ measured from a reference axis⁶ taken in the direction of the change in momentum which the radiation would suffer for the simple Compton case of a stationary electron scattering radiation at the angle θ .

In Fig. 4 let OA be the direction of the incident quantum, OB the direction of the scattered quantum, OC the direction of the electron's initial velocity. Make the vector OA equal in length to λ_c , the vector OB equal in length to

Fig. 4. Illustrating the definition of the "natural" reference axis and of the angle ψ . It should be emphasized that λ_c is the simple Compton shifted wave-length for the case where vector C vanishes ($\beta_1=0$) and that therefore λ_c is constant for a given primary wave-length and scattering angle and the direction of the natural reference axis is a constant. Note that λ_c is taken along the *incident* direction and λ_1 along the *scattered* direction. This inversion is caused by the fact that the momenta are inversely as the wave-lengths.

λ_1 and the vector OC equal in length to β_1 . We define a new wave-length λ^* represented to the same scale by the distance AB . Now note that the numerator of Eq. (6) can be represented in terms of the vectors of Fig. 4 (designated by their termini) as the difference of two scalar products

$$C \cdot A - C \cdot B$$

or what is equivalent $C \cdot (A - B)$

The vector whose length is λ^* is precisely $(A-B)$ hence if Ψ is the angle between OC and AB we rewrite Eq. (6) as follows

$$l = \frac{\cos \psi}{1 - \beta_1 \cos \theta_1} 2\beta_1 \lambda^* \quad (7)$$

where

$$2\lambda^* = (\lambda_c^2 + \lambda_1^2 - 2\lambda_c \lambda_1 \cos \theta)^{1/2}. \quad (8)$$

The denominator is nearly unity in most practical cases. Thus it is evident that the wave-length deviation l from the simple Compton shift caused by a scattering electron having an initial velocity βc (instead of zero velocity) is proportional to the projection $\beta_1 \cos \Psi$ of the electron's initial velocity along the direction of the vector representing the change in momentum which the radiation would suffer if scattered by an initially stationary electron through the scattering angle θ .⁶

This latter direction is a stationary axis in space independent of the direction of the electrons' initial motion and the projection on it in question can be either positive or negative, i.e. $\cos \Psi$ may have either sign. Thus the extreme values of l are given (if β^2 is considered negligible compared to unity) by the inequality

$$-2\beta_1 \lambda^* + 2\beta_1^2 \lambda^* \cos \frac{1}{2}(\pi - \theta) \leq l \leq 2\beta_1 \lambda^* + 2\beta_1^2 \lambda^* \cos \frac{1}{2}(\pi - \theta) \quad (9)$$

or if the first power of β be considered negligible compared to unity

$$-\beta_1 \lambda^* \leq l \leq 2\beta_1 \lambda^* \quad (9.1)$$

In either case therefore l can vary over the wave-length range

$$\Delta \lambda = 4\beta_1 \lambda^* \quad (10)$$

for electrons of constant initial speed β_1 and all possible directions of motion.

Case of ensemble of electrons of speed βc and random direction. Since the velocities are uniformly distributed as to direction over the surface of a sphere the probability of scattering by an electron whose velocity makes an angle Ψ to $\Psi + d\Psi$ with the above defined natural reference axis⁷ is

$$P(\psi)d\psi = \frac{1}{2} \sin \psi d\psi. \quad (11)$$

The probability $P(l)$ of a given deviation l from the Compton shift is then to be obtained from Eqs. (7) (11) and the derivative of (7), by eliminating Ψ and $d\Psi$.⁷ This gives

⁶ The vector change in light momentum for scattering at angle θ by an *initially stationary electron* constitutes the natural and appropriate reference axis for the problem of scattering at angle θ by moving electrons.

⁷ This operation is much simplified if the denominator in Eq. (7) be first set equal to unity. This amounts to neglecting β in comparison to unity. θ_1 is a complicated function of the colatitude ψ and the azimuth ϕ . Taking the above defined natural reference axis as polar axis and the plane of the scattering angle as reference plane we have

$$\cos \theta_1 = \cos \psi \cos \frac{1}{2}(\pi - \theta) + \sin \psi \sin \frac{1}{2}(\pi - \theta) \cos \phi$$

$$P(l)dl = (4\beta\lambda^*)^{-1}dl \text{ (approximately)} \quad (12)$$

The relative error committed in this formula is of the order of β . For $\lambda^* = 740$ X.U. $l = 25$ X.U. the error committed is about 3 percent. For narrower parts of the line structure it is even much less. From Eq. (11), since

Fig. 5. Spectral distribution curve of originally monochromatic radiation after scattering through angle θ by an ensemble of electrons of initial speeds βc and random directions.

the right hand member is independent of l , it is evident that all deviations l are equally probable within the limits placed by inequality (9). Outside these limits the probability is nihil. Thus (see Fig. 5) a good approximation to the line structure contributed by the randomly directed ensemble of electrons of speeds between β and $\beta + d\beta$ is a rectangular spectral distribution of breadth $4\beta\lambda^*$ and of area proportional to the population of the speed class β to $\beta + d\beta$. (This distribution is not quite centered on the Compton shifted position but as can be seen by reference to inequality (9) is displaced toward longer wavelengths by a slight amount $2\beta_1^2\lambda^* \cos \frac{1}{2}(\pi - \theta)$. This shift is wholly inappreciable however for values of β of importance in the experimental case).

Fig. 6. Illustrating the relation between spectral intensity distribution in the Compton line (left) and population of electron speed states (right). Each elementary rectangle on the left is equal in area to a rectangle on the right while the spectral breadth $4\beta\lambda^*$ of each rectangle on the left is proportional to the abscissa β of the rectangle on the right.

Case of ensemble of electrons with random directions and any speed distribution, $\Phi(\beta)$. The line structure in this case is to be thought of as built up out of an assemblage of rectangles of infinitesimal height each having its

dimensions determined in the same way as the rectangle of Fig. 5. For convenience in adding spectral intensities the rectangles must of course be piled on top of each other in order of decreasing breadth, that is to say decreasing values of β . Referring to Fig. 6 the curve $\Phi(\beta)$ on the right represents the populations of the states or speed ranges β to $\beta + d\beta$ required by the dynamics of the electrons in the solid scattering body while the curve on the left represents the resulting Compton line structure. The elementary rectangular area $2ldy$ in the left hand curve is to be kept proportional to the elementary rectangular area $\Phi(\beta)d\beta$ in the right hand curve. If the constant of proportionality is k we can express the differential equation of the line structure curve in terms of the speed distribution function thus

$$-2ldy = k\Phi(\beta)d\beta \quad (13)$$

since the half breadth of each rectangle is $l = 2\beta\lambda^*$ we can replace $d\beta$ by $dl/2\lambda^*$ and β by $l/2\lambda^*$. Dividing Eq. (13) by $-2l$ and integrating from $y=0, l=\infty$ to $y=y, l=l$ we obtain the equation of the line structure curve for continuous functions which vanish as $l \rightarrow \infty$

$$y = -k \int_{l=\infty}^{l=l} l^{-1} \Phi(l/2\lambda^*) dl. \quad (14)$$

Definition of line "breadth." For the purpose of the present investigation we are especially interested in the spectral "breadth" of curves such as shown in Fig. 6 and defined by Eq. (14) and in particular we wish to study the dependence of the breadth on the scattering angle θ . There is no ambiguity

Fig. 7. Illustrating terminology of line breadths.

about the breadth of a rectangular spectral distribution such as is shown in Fig. 5 but real Compton lines resemble more nearly Fig. 6, the scattering electrons being without doubt distributed over a wide range of speeds. We shall speak of the "breadth" $\Delta\lambda$, e.g. $\Delta\lambda_{1/2}$, $\Delta\lambda_{1/4}$ meaning the spectral breadth measured across the line structure at a specified proportion of its height. Thus we mean by $\phi\lambda_{1/2}$ the spectral breadth of the line measured at a point half way up from the background to the peak. See Fig. 7.

Dependence of line breadth on scattering angle. Consider what happens

to the Compton line as the scattering angle is varied, keeping the primary wave-length and the material of the scatterer (and therefore $\Phi(\beta)$) always the same. Under these conditions the only quantity that suffers change is λ^* and referring to Fig. 6 it is evident that all the elementary rectangles of breadth $4\beta\lambda^*$ going to make up the line structure will be horizontally extended or contracted in the same proportion. The breadth just defined above, $\Delta\lambda_h$, will always measure the spectral breadth of the rectangle contributed by one and the same class of electrons of speeds between β and $\beta+d\beta$.

Now λ^* defined in Eq. (8) can most easily be visualized graphically. In Fig. 8 we construct triangles for the values of the scattering angle $\theta = 0^\circ, 22.5^\circ,$

Fig. 8. Graphical construction for λ^* .

$45^\circ, 67.5^\circ, 90^\circ, 112.5^\circ, 135^\circ, 157.5^\circ, 180^\circ$ and make the sides adjacent to θ equal respectively to λ_1 and λ_c where $\lambda_c = \lambda_1 + (h/mc)(1 - \cos \theta)$. The third side of this triangle is $2\lambda^*$. Since λ_c and λ_1 are nearly equal an approximation to λ^* is

$$\lambda^* = \lambda_1 \sin \frac{1}{2}\theta \text{ (approximately)}$$

Hence it follows that the *relative breadth* $\Delta\lambda_r$ as we have already asserted without proof is

$$\Delta\lambda_r = \frac{\Delta\lambda_h}{\Delta\lambda_{h, \max}} = \frac{4\beta\lambda^*}{4\beta\lambda_{\max}^*} = \sin \frac{1}{2}\theta \text{ (approximately).}$$

The reader is referred to Fig. 2 which shows the dependence of relative breadth on scattering angle along with the relative shift. The accurate formula for λ^* , Equation (8), has been used in plotting this curve.

RECAPITULATION OF ASSUMPTIONS

The theory here outlined assumes

1. Conservation of momentum and energy in elementary processes.
2. Electron binding energy negligible compared to energy transferred to electron in scattering process.
3. The initial electron velocity small compared to the velocity of light.

4. Probability of scattering by a given class of electrons proportional to population of the class.

Assumption 1 is in accord with quantum as well as classical mechanics.

Assumptions 2 and 3 are most applicable to precisely those cases of interest for the Compton effect from radiation of about the hardness of MoK radiation. Assumption 4 is probably valid for most of the scattering electrons.⁸

PART II. EXPERIMENTAL

IMPORTANCE OF HOMOGENEITY OF SCATTERING ANGLE

Because the wave-length shift of the Compton modified line depends on the scattering angle the breadth of that line is increased if the scattering angle is not sharply defined in the experimental set up. This spurious breadth due to inhomogeneity of scattering angle was thought by many physicists to be the sole cause of the observed diffuseness of the Compton modified line. At

Fig. 9. Illustrating the spurious breadth introduced by a given inhomogeneity of scattering angle at different scattering angles.

only one scattering angle ($\theta = 180^\circ$) a considerable angle inhomogeneity produces very little spurious breadth because the shift has an analytic maximum there. See Fig. 9. Hence several experimenters⁹ have studied the breadth of the modified line at large angles of scattering and concluded that a natural breadth exists. There is some disagreement as to its size however.

For our present purpose it is not possible to resort to the convenient device of working at scattering angles near 180° thereby escaping from the necessity of maintaining a very homogeneous scattering angle. Since we are to examine the dependence of modified line breadth on scattering angle it is necessary to work at a number of angles other than 180° and to maintain these angles very homogeneous in each case. As all who have worked in this field are aware, the requirement of homogeneity of scattering angle is antagonistic to the equally pressing requirement of a large solid angle of radiation

⁸ See Compton's "X-Rays and Electrons," page 291.

from the source incident upon the scatterer to give sufficient energy in reasonable exposure times. Unfortunately there are no x-ray lenses to collect x-radiation and render it parallel.

To circumvent these difficulties the authors have constructed the multi-crystal spectrograph. This instrument has been described in detail elsewhere¹⁰ and will be touched on but briefly here.

DESCRIPTION OF MULTICRYSTAL SPECTROGRAPH

The instrument consists of fifty small cylindrical units each a Seemann type spectrograph in itself placed vertically on the arc of a horizontal circle of about a half meter radius. Let us call this circle the "major circle" of the instrument. Each unit contains a brass wedge standing at about 0.1 mm

Fig. 10. Geometry of "focussing" and of homogeneity of scattering angle in the multi-crystal spectrograph. θ_1 , θ_2 and θ_3 show actual positions of $K\alpha$ line in the first second and third orders respectively. The scattering body is shown set to give homogeneous scattering for the first order.

distance from the cleavage face of a small slip of calcite. The units are orientated so that each calcite will reflect the $K\alpha$ doublet of Mo to exactly the same point on a photographic film coinciding with an arc of the major circle on the opposite side from the bank of crystal units. The geometry of the instrument is such that if one such wave-length coincides or focusses at one point on the circularly curved negative all other wave-lengths and orders will

¹⁰ DuMond and Kirkpatrick. Review of Scient. Insts. 1, 88 (1930). The principal improvement made in this instrument since the above article was written consists in the addition of fifty individual adjusting levers for the crystals as well as fifty permanently attached mirrors.

also focus at other points on the negative. In Fig. 10 a wave-length λ_1 is shown focussed from all fifty crystals at the point θ_1 . The crystal reflecting planes if produced would all intersect at the point β on the major circle. The incoming radiation, if it were not reflected by the crystals to the point θ_1 , would converge in a point α_1 also on the major circle. α_1 and θ_1 are distant from β on opposite sides by an arc 2θ where θ is the Bragg angle for the wave-length in question. We utilize the fact that the directions of incoming rays are concurrent at α_1 . A second circle is described so as to pass through both the focal spot of the x-ray tube and through α_1 . The scattering body is shaped to coincide with this circle as shown in Fig. 10. Thus the scattering angle is

Fig. 11. Geometrical dispositions of x-ray tube, scatterer and spectrograph for the three scattering angles studied.

very nearly homogeneous over all parts of the scatterer. Fig. 11 shows the positions of scatterer, tube and spectrograph for the three angles of scattering which have so far been studied. The principal sources of inhomogeneity of scattering angle are the size of the focal spot of the x-ray tube and the thickness of the scattering body. The use of 50 crystals instead of one permits the tube to be placed much farther away from the scatterer without necessitating unreasonable exposure times and thus permits a great reduction in the inhomogeneity of scattering angle due to the two above mentioned causes.

PRECAUTIONS AS TO PLANENESS OF CRYSTALS AND FOCUSING

At first sight the instrument just described seems fantastically difficult to construct and adjust. As a matter of fact however once a set of fifty good

crystals had been obtained and tested for planeness and a satisfactory orientation method was worked out the task of adjusting them to focus accurately took only about two months. We have been pleasantly surprised to find that the crystals have remained in good adjustment for a period up to the present of about three months.

One of the most exacting and difficult requirements was to get good slips of calcite plane over their entire length. *In studying the Compton effect it is absolutely essential that the crystals be plane over the entire length used in reflecting x-rays.* This is because the scattering body constitutes an *extended source* so that the *entire length* of the crystal reflects x-rays to *each point* on the film. Thus a twisted crystal will give blurred diffused spectral lines with an extended source whereas the same crystal would give sharp but inclined or bent lines with a point source. See Fig. 12. Our first care was therefore to insure that all crystals should be "plane." This we tested by means of primary radia-

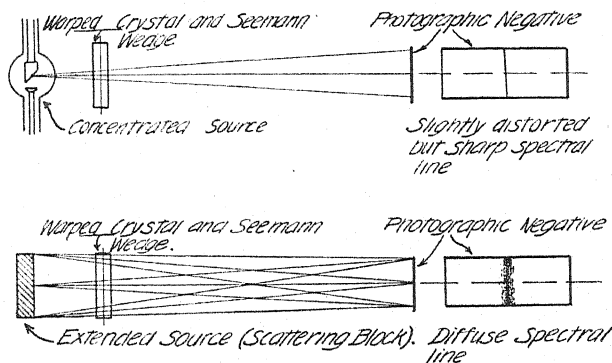

Fig. 12. Illustrating how a warped crystal gives a sharp line with a point source but a blurred line with an extended source.

tion from an x-ray tube placed a short distance from the front of the spectrograph. As the tube was much nearer the crystal than was the negative and had a rather small focal spot only a small portion of the length of the crystal was used in forming the lines on the negative. By moving the x-ray tube up and down parallel to the wedge of the Seemann spectrograph any region in the height of the crystal could be used to reflect spectral lines to the negative. Our practise was to compare in this way the position of lines reflected from four points along the height of the crystal with the lines as reflected from the midpoint of the crystal. Crystals that failed to reflect lines to the same point to within less than half the breadth of a line (or about half an x-unit on our spectrograms) were discarded. The backs of the crystals had to be ground to fit into their holders before such tests had any significance and on account of the numerous discards this constituted one of the most tedious features of the experiment. We take a pardonable pride therefore in calling attention to the great sharpness of the unshifted lines we have obtained. This sharpness bears witness to the planeness and perfection of each and every one of the fifty crystals used as well as to the accuracy with which they are focussed.

The focussing of the crystals was accomplished photographically. After fifty good crystals mounted in the cylindrical Seemann units in the spectrograph had been obtained, one of these near the center was permanently clamped in a predetermined orientation so as to reflect the $\text{MoK}\alpha$ lines in a convenient position on the film. This was called the reference crystal. The other forty-nine units were first roughly orientated by means of a fluorescent screen so as to reflect their lines at the same point on the film to within a few millimeters. Direct radiation was used, the Mo tube being mounted in a lead box in front of the spectrograph on a large wooden sector turning on a pin directly under the point α_1 . Divisions marked on the circular edge of this sector made it possible at a moment's notice to align the tube with any desired crystal. A lead shield was used to isolate all but the crystal under test. The

Fig. 13. Plan and elevation of multicrystal spectrograph.

fine adjustment of the crystals by photography consisted in taking a photograph of the $K\alpha$ lines with the reference crystal and then without disturbing the negative taking the $K\alpha$ lines with the crystal to be adjusted. Shields were used in front of the negative so that the reference lines appeared in the middle of the height of the negative while the lines from the crystal under test appeared just above and below. When the focussing of a crystal was acceptable its lines joined those of the reference crystal forming continuous lines across the negative with no perceptible break or jog at the two junction points. Forty-five seconds sufficed to give a good exposure. A complete set of forty-nine such pairs of exposures was made testing the state of adjustment of all crystals against the reference crystal. These exposures appearing on ten pieces of film were all developed, fixed and dried at one time in an especially designed holder, thus economizing enormously on the time over what would be required for separate development. Each crystal was then orientated

through the angle demanded by the error in adjustment indicated in the photographs. This could be done with considerable accuracy, thanks to a small gilded plane mirror permanently mounted on top of each crystal holder. The reflection of a scale 3 meters distant from the mirror was observed with a telescope as a means of measuring the angles through which the crystal must be turned to correct the error indicated on the photographs. After making the indicated orientation adjustments a second set of forty-nine pairs of comparison photographs was taken. A few of the crystals were already found to be in perfectly acceptable focus with respect to the reference lines. These were eliminated from the remainder of the work by dropping small brass covers over their adjusting screws. The cycle was then repeated and each time more and more crystals came into acceptable adjustment until after eleven cycles all had been satisfactorily adjusted.

The fine orientation of the crystals is accomplished by means of a small steel lever, one for each crystal unit, which can be clamped at one end to the projecting shank of the crystal holder. The other end of this lever is given a slight sidewise motion to right or left by two conical headed screws pressing on opposite sides of two conical holes in which they enter loosely. Fig. 13 shows a complete plan and elevation of the entire spectrograph.

PART III. RESULTS

BREADTH NOT DUE TO POOR RESOLUTION OR INSTRUMENTAL DEFECTS

The unshifted lines on the Compton effect exposures play the role of a control on the resolution of the spectrograph. Some workers in this field are under the impression that even the unshifted lines in scattered radiation are broader than the primary lines. Such however is not the case as can be plainly seen on our three spectrograms reproduced in Fig. 14. It is quite evident from an inspection of Fig. 14 that the unshifted lines are very much narrower than the broad diffuse distribution of the Compton modified radiation. It therefore cannot be claimed that the observed breadth of the modified line is caused either by poor resolution, poor focussing of crystals, or any other defect in the spectrograph since this latter quite evidently *gives on the same negative very sharp lines*. The $K\alpha$ doublet in the unshifted position is completely resolved.

No intensifying screens have been used in the exposures with the multi-crystal spectrograph. This eliminates any possible blurring due to poor contact between the intensifying screen and the negative and any falsification of relative intensity that such screens might cause.

X-RAY INTENSITIES AND EXPOSURE TIMES

An ordinary molybdenum target Coolidge water-cooled x-ray tube placed in a lead housing was used as the source of primary radiation. The radiation passed out of the lead housing through a hole of the right size and shape to give a beam which would just illuminate the whole scatterer with about a centimeter to spare all around. The tube was run at from 20 to 25 m.a. and 50 k.v. continuously 24 hours a day. The exposure times were respectively

360 hours, 223 hours and 897 hours for the scattering angles 63° , 90° , and 156° . The long exposures were necessitated by the great distance from the

Molybdenum K Radiation Scattered from Graphite

Fig. 14. Spectra of molybdenum K radiation scattered at three very homogeneous scattering angles from graphite, taken with the multicrystal spectrograph. Note sharpness of unshifted lines and increasing breadth of shifted lines as the scattering angle increases.

tube to the scatterer. In the case of the 156° exposure the tube was 120 cm from the far end of the scatterer and 70 cm from the near end. The large distance however gives a huge improvement in homogeneity of scattering angle.

HOMOGENEITY OF SCATTERING ANGLE

The greatest inhomogeneity of scattering angle in any case is one degree. The inhomogeneities are indicated in Fig. 14. These inhomogeneities could not possibly produce the observed shifted-line breadth but would on the contrary give a breadth of about the same order of magnitude as the width of the narrower unshifted lines.

To insure this homogeneity of the scattering angle the positions of tube and scatterer were accurately located by means of a radius arm capable of describing the circle on which they and the point α_1 must lie. This radius arm carries a plumb-bob at its outer end which can be lowered into close proximity with the curving scatterer and the point α_1 . The x-ray focal spot is aligned

Fig. 15. General view of experimental set-up. Note the radius arm for locating the tube and scatterer, also the baffle plates to reduce background.

with this plumb-bob by sighting from two directions with auxiliary plumb-lines. By measuring the angle through which this radius rod must turn in passing from α_1 to the x-ray focal spot the angle of scattering can be and was measured with more than adequate accuracy. In the general view Fig. 15 of the experimental set-up this radius arm is clearly visible.

MODIFIED LINE BREADTH INCREASES WITH SCATTERING ANGLE

Even a cursory glance at the spectra of Fig. 14 shows that the modified line breadth increases with increasing scattering angle. In order to test this quantitatively we have made microphotometric analyses of these spectra. A few of the microphotometer curves are reproduced in Fig. 16, and in Fig. 17 the theoretical curve of relative breadth is plotted for comparison with the points corresponding to observed breadths. The adjustment to the theoretical curve is made for the grand average of the points corresponding to the *largest scattering angle, the other points falling where they will*. The agreement is seen to be as good as the reproducibility of the breadth measurements.

In measuring the breadth of the shifted β_1 line the effect of β_2 is probably

negligible. In the case of the $\alpha_1\alpha_2$ doublet, however, the shifted radiation due to these two components is confounded in one broad band. It is necessary to decompose this into two similar bands 4 X.U. apart and having the relative intensities 2:1 required by the known ratio of intensities of $\alpha_1:\alpha_2$. This decomposition is done by means of the following device: Referring to Fig. 18

Fig. 16. Microphotometer curves of the spectra shown in Fig. 14. Five such curves (fifteen in all) were obtained for each scattering angle by running the microphotometer slit across the lines in different regions of their height. The three curves here shown are fairly typical of the entire set.

let $F(x)$ be the function representing the observed line structure. Let $f(x)$ be the curve representing the contribution to $F(x)$ made by the α_1 line. Then the contribution made by the α_2 line will evidently be $\frac{1}{2}f(x-\delta)$ where $\delta=4$ X.U., the known wave-length separation of α_1 and α_2 . We have then that

$$F(x) = f(x) + \frac{1}{2}f(x - \delta)$$

where $F(x)$ is experimentally given and $f(x)$ is to be found. From the experimentally known function $F(x)$ subtract the known function $\frac{1}{2}F(x-\delta)$

$$F(x) - \frac{1}{2}F(x-\delta) = f(x) + \frac{1}{2}f(x-\delta) - \frac{1}{2}f(x-\delta) - \frac{1}{4}f(x-2\delta).$$

To this in turn add the known function $\frac{1}{4}F(x-2\delta)$

$$F(x) - \frac{1}{2}F(x-\delta) + \frac{1}{4}F(x-2\delta) = f(x) - \frac{1}{4}f(x-2\delta) + \frac{1}{4}f(x-2\delta) + \frac{1}{8}f(x-3\delta).$$

Evidently if this process be continued indefinitely we shall have

$$F(x) - \frac{1}{2}F(x-\delta) + \frac{1}{4}F(x-2\delta) \text{ etc.} = f(x)$$

because the last term neglected will vanish both due to its rapidly decreasing coefficient and due to the diminution in $f(x-n\delta)$ as n becomes large.

Fig. 17. Measured relative breadths of shifted lines compared with theoretical prediction based on initial electron velocity as the cause of breadth. The full line is the theoretical curve.

Fig. 18. Illustrating the method of decomposing line structure curves from the $K\alpha$ doublet.

In practise the decomposition can be very rapidly effected graphically by the following procedure. Construct the curve $F(x)$ representing the observed shape of the Compton line to scale and erect equally spaced vertical ordinates

with the spacing δ . The value of the ordinate F_4 say is corrected by subtracting from it half the value of F_3 , its first neighbor to the left, then adding a quarter of F_2 , subtracting an eighth of F_1 , etc., etc., until the amounts to be added to or subtracted from F_4 become negligible. All the ordinates are treated in this same way. By actual trial on curves of the type of the Compton line structure this method has been found to work very well. It is of course an easy matter to check the work by adding the two components obtained in the decomposition process and comparing the sum with the original curve.

In Table I the observed breadths of α_{12c} and β_{1c} at half maximum height are recorded for the three scattering angles studied. Measurements on five microphotometer curves taken across the spectral lines in different regions of their height are recorded for each scattering angle. The tabulated breadths of α_{1c} were obtained graphically by the decomposition method described above.

MODIFIED LINE BREADTH INCREASES WITH PRIMARY WAVE-LENGTH

Attention is called to the fact that in Table I the average breadths of α_{1c} are systematically higher than the average breadths of β_{1c} . We do not feel that the precision of our breadth measurements justifies more than a claim to a qualitative agreement with theory in this respect. It is interesting to note however that in each case the longer primary wave-length gives the broader shifted line and that the breadths are in about the same proportion as the wave-length in agreement with the formulae

$$\Delta\lambda = 4\beta\lambda^*$$

$$\lambda^* = (\lambda_1^2 + \lambda_c^2 - 2\lambda_1\lambda_c \cos \theta)^{1/2}$$

$$\lambda_c = \lambda_1 + \frac{h}{mc}(1 - \cos \theta)$$

CAUSE AND ELIMINATION OF HEAVY BACKGROUND

It has been noted by many observers that the background intensity relative to the line intensity in the spectra of scattered radiation is much stronger

than in the case of the primary radiation. Many explanations have been offered for this, all of which probably contributed to the effect in some small measure. We believe that we now have unquestionable evidence however that the great bulk of this enhanced background effect is due to non-selective scattering at the crystals and crystal wedges. General, amorphous, or non-selective x-ray scattering by the crystal in a spectrograph is due to scattering of the modified Compton type. Such scattering is incoherent and hence non-selective as to wave-lengths. It is also non-specular, i.e. the conditions of equality of incidence and reflection angles is not imposed. This means that a given point on the negative can receive radiation of all wave-lengths by this scattering process from all parts of the scattering body. This same point on the negative can by spectrally selective Bragg reflection only receive one wave-length scattered from one very small portion of the scattering body. Hence, though the modified scattering may be small, it is greatly favored by the fact that it is integrated over a wide range of continuous spectrum and over a broad solid angle as large as the scatterer can subtend. With these considerations in mind we have tried the effect of introducing a set of baffle plates in front of the spectrograph in such a way as to greatly limit the solid angle of radiation which can be collected at the crystal and wedge. With these baffles in place each crystal can only "see" a very small segment of the scatterer about three centimeters long at most whereas without the baffles each crystal was exposed to scattered radiation from a large part of the entire 55 cm length of the scatterer. The baffles leave plenty of room for the formation of the entire shifted and unshifted K spectrum however which only covers a range of about three degrees. These baffles can plainly be seen in the general view Fig. 15. See also Fig. 10.

The result of introducing the baffles was most striking. Whereas without the baffles the back-ground fogging of our negatives was so strong as to nearly obscure the unshifted and shifted lines, rendering the negatives quite hopeless for reproduction *this background was entirely suppressed as soon as the baffles were introduced*. We feel certain therefore that the non-specular, non-selective scattering at the crystal faces and wedges is responsible for the heavy background.

MEASUREMENTS OF SHIFT

As a check on the Compton formula for the shift, $\delta\lambda = (h/mc) (1 - \cos \theta)$ we have plotted in Fig. 16 the positions predicted for the shifted lines by the above formula assuming $h/mc = 24.2$ X.U. as computed from present accepted values of these constants. The agreement is good and seems to eliminate the possibility of a 9 percent deviation from this value reported recently by other observers.¹¹

CRITICAL DISCUSSION OF RESULTS

The line breadths which we have observed and reported in this paper are not in accord with the observations of two other observers, namely J. A.

¹¹ Davis and Mitchell, Phys. Rev. 32, 331 (1928).

Bearden¹² and N. S. Gingrich¹³ both of whom have studied the breadth of the modified line at large scattering angles (to reduce the broadening from angular inhomogeneity) using the double crystal spectrometer. These experimenters obtain lines broader than the unshifted lines but still sufficiently narrow to show partial resolution in the case of the shifted $K\alpha$ doublet. P. A. Ross, using his ingenious balanced filter method, also seems to observe a partial resolution of this doublet. This method however does not give very distinct evidence as to the breadth of the shifted line. Ross' and Bearden's primary wave-lengths were somewhat shorter than those used in the present investigation and Ross' angles of scattering are smaller. Both these conditions would, if the theory presented in this paper is correct, tend to give these observers a somewhat narrower shifted line¹⁴ than that here reported. N. S. Gingrich however reports narrower lines than ours under conditions nearly identical to ours. Indeed his scattering angle is larger and is inhomogeneity of scattering angle about twenty times as great as ours. His modified $MoK\alpha$ radiation observed with the double crystal spectrometer appears as two sharply pointed peaks partially resolved at the base. We are completely at a loss to explain the discrepancy between our results and his. Examination of our photographic spectrograms (here reproduced Fig. 14) shows not the slightest suggestion of resolution of the shifted $K\alpha$ doublet although the resolution of our spectrometer as proved by our well resolved unshifted lines is amply sufficient for this purpose. The principal difference between Gingrich's conditions and ours was the use of the double crystal (high resolution) spectrometer in place of our multicrystal spectrometer, the use of much greater x-ray intensities incident on his scatterer than ours and the presence of much greater inhomogeneity of scattering angle in his case than in ours.

On the other hand however recent photographic results published by F. L. Nutting¹⁵ show a *broad* modified β_1 line in good agreement with our modified line breadths and much too broad to permit of resolution of two lines as close as $MoK\alpha_{1,2}$. Our present modified line breadths are also in good qualitative agreement with those obtained previously by DuMond¹⁶ for aluminum and beryllium scatterers with a photographic method at large scattering angles. (As the scatterers are different no more than qualitative agreement is to be looked for here). Finally our line breadths agree with those obtained photographically by Sharp¹⁷ under large and homogeneous scattering angles and with primary radiation and scattering substance substantially the same as ours.

We cannot understand why the photographic methods *used with adequate resolution* should yield broader modified lines than the double crystal spectrometer. Perhaps some hitherto unsuspected parameter affects modified line

¹² J. A. Bearden, Phys. Rev. **35**, 1427 (1930).

¹³ N. S. Gingrich, Phys. Rev. **36**, 1050 (1930).

¹⁵ F. L. Nutting, Phys. Rev. **36**, 1267 (1930).

¹⁶ DuMond, Phys. Rev. **33**, 643 (1929); DuMond, Proc. Natl. Acad. **14**, 875 (1928).

¹⁷ Sharp, Phys. Rev. **26**, 691 (1925).

breadth. Such parameters might be the x-ray intensity incident on the scatterer or the electrical potential of the scatterer. These seem highly unlikely.

We are now carefully investigating the possibility that multiple scattering may exaggerate our line breadths. Our method of doing this is to make an exposure at 156° with a scatterer cut up into small pieces with intervening properly orientated lead baffles which will almost entirely eliminate the possibility of multiple scattering. There are two reasons why we can almost certainly predict a negative result from this control experiment.

First, the scattered radiation from the entire scatterer at a point outside the direct beam but not far distant from the scatterer itself can be faintly seen on a fluorescent screen. At this point it is certainly less than one percent of the intensity of direct radiation incident on the scatterer. It seems then unlikely that the ratio of intensity of scattered radiation from the scatterer incident a second time on the scatterer to primary intensity should be more than one percent and this is too small to account for the discrepancy between our modified line breadth and that of Gingrich.

Second, our present modified line breadths are in agreement with those above mentioned of Sharp, Nutting and DuMond, each of which was obtained under conditions which should give if anything less double and multiple scattering than Gingrich had.

Absolute breadths of shifted lines. Our purpose in this article has been especially to test the *functional dependence* of the natural breadth of the shifted lines on scattering angle and primary wave-length and to compare this with the functional dependence to be expected if the initial velocities of the scattering electrons cause the breadth. We hope to present in the near future a careful study of the electron velocity distributions to be expected from the shapes of our line structure curves. We will state at the present time merely that the breadths of our lines do not seem inconsistent with the velocities to be expected in the carbon atom. A very considerable task of theoretical computation and reduction of our experimentally observed curves remains to be performed before we can definitely draw a favorable or unfavorable comparison between observation and theory on this point. Our observed breadths at half maximum recorded in this paper correspond to a class of electrons the ratio of whose velocities to the velocity of light is $\beta = 0.0076$. This is equivalent to about 15 volts.

In conclusion we wish to express our appreciation of Dr. Millikan's support of this research and of the patience and skill of Julius Pearson, our instrument maker, who developed the technique and did the tedious work of grinding and fitting the small calcite units into their holders.

NOTE ADDED TO PROOF: We have just developed a 900-hour exposure at 156° scattering angle with a graphite scatterer divided into fifty parts by lead baffles so orientated as to permit the entrance of the incident radiation and the exit of the scattered radiation, but arranged to prevent any multiple scattering by exchange of radiation from one unit to another. The units have smaller dimensions than the scatterer used by N. S. Gingrich. We believe therefore that our multiple scattering should be less than his. *The Compton line however on this exposure appears with the same breadth as the one reproduced in this paper.*

REVISED VALUES OF O I TERMS, NEBULAR AND CORONAL LINES OF OXYGEN

By J. J. HOPFIELD

DEPARTMENT OF PHYSICS, UNIVERSITY OF CALIFORNIA

(Received November 14, 1930)

ABSTRACT

The chief triplet of oxygen $\lambda 1302$ has been measured in the third order of a vacuum grating spectrum having a dispersion of 1.7 Å per mm.

On the basis of these measurements, the ground triplet term of oxygen $2s^2 2p^4 {}^3P_2$, 3P_1 , 3P_0 has the revised values 109837.1, 109679.17, 109610.52 giving the *ionization potential of oxygen* as 13.550 volts.

Nebulium lines have been produced in the laboratory for the first time. The two lines $\lambda 6300$ and $\lambda 6364$ have been remeasured, and their values, together with the new values of the ${}^3P_{012}$ term, are used to give more accurate values of the metastable levels of oxygen.

The coronal line $\lambda 6374.2$ is pointed out as being identical within limits of experimental error with the oxygen line $\lambda 6374.29$. This would indicate the presence of oxygen in the solar corona.

INTRODUCTION

RUNGE and Paschen¹ made the first classification of the spectrum of oxygen. On the basis of their analysis we have known of two types of multiplicity in the terms of this spectrum, namely, those now known as quintet multiplicity and triplet multiplicity. The next extension of our knowledge of this spectrum was the discovery of the ultraviolet triplet series by the author.² These series arise from the combinations of a new triplet ground term $2s^2 2p^4$, ${}^3P_{012}$ with some of the triplet and quintet terms already known.

At about this time the development of Hund's theory of complex spectra made it manifest that the electron configuration ($2s^2 2p^4$) of the normal oxygen atom gives rise not only to the $2s^2 2p^4 {}^3P_{012}$ term already found, but also to the $2s^2 2p^4 {}^1D_2$, $2s^2 2p^4 {}^1S_0$ terms as well. These latter terms became as important as the ${}^3P_{012}$ ground term, since they arise from the same electronic configuration.

The first important discovery in the search for these terms was that due to McLennan³ and his co-workers, who first reproduced the green auroral line $\lambda 5577$ in the laboratory and showed that it was due to oxygen. This was confirmed in a quite different manner by the author⁴ who found that its wave number was exactly the frequency difference of two strong oxygen lines $\lambda 1217$ and $\lambda 999$ which were unclassified at that time.

⁴ J. J. Hopfield, Phys. Rev. **29**, 923 (1927).

Bowen's⁵ discovery that the prominent nebular lines represent transitions between metastable terms of atoms or their ions suggested at once that the auroral line $\lambda 5577$ might arise in such a transition in neutral oxygen. This was actually found to be the case by McLennan, Sommer³ and others by the magnetic splitting of the line showing it to belong to the singlet system, and presumably to the transition $2s^2 2p^4 \ ^1D_2 - 2s^2 2p^4 \ ^1S_0$. The discovery that the two ultraviolet lines $\lambda 1217$ and $\lambda 9994$ involve a new and common term added another to the list of singlet terms. Too few of these terms were as yet known to form a Rydberg series, and no combinations of them with the known oxygen terms had been found.

Frerichs⁶ made a most important contribution to our knowledge of these terms when he found a sufficient number of them to form such a series and thus evaluated the limit of the series the $2s^2 2p^4 \ ^1D_2$ metastable term. This fixed the position of the singlet terms with reference to the known scheme of oxygen terms.

His evaluation of the $2s^2 2p^4 \ ^1D_2$ term, however, contains two sources of error, first the rather large error in the measurement of ultraviolet lines, and second, the error of fitting these lines into a none too accurate formula when relatively few lines of the series are known. The experimental errors cannot be obviated but they can be reduced by using more precise instruments. The second error, although it may be large, is an additive one and is of no consequence when one is dealing with lines of the same system. It becomes a serious difficulty when one is dealing with lines forming intersystem combinations when these systems of terms have been independently determined. If, however, such combinations are once identified and measured, this source of error immediately drops out and there is left only the experimental values to be improved. Happily, Paschen⁷ has now found such combinations in new lines on plates which I took of the oxygen spectrum while working in his laboratory and Sommer⁸ has also found them in the spectrum of the aurora. I have now remeasured these lines, fixing the terms more accurately, and I have also redetermined the value of the $2s^2 2p^4 \ ^3P_{012}$ ground term from new data. These improved values conjointly give a correction of 7.5 cm^{-1} to be added to all the singlet terms. It should be borne in mind that all the singlet terms are not fixed with the same accuracy by this correction. Fortunately, the $2s^2 2p^4 \ ^1D_2$ term is accurately fixed by these corrections, and also the $2s^2 2p^4 \ ^1S_0$ term which is linked to the former by the aurora line. Although the same correction has been added to the remaining singlet terms, they still contain the relatively large error of the original ultraviolet measurements. The remaining terms of the table given by Frerichs are already linked to the Paschen-Runge terms of oxygen and need no correction.

EXPERIMENTAL

(a) **Measurements of the $\lambda 1302$ triplet of oxygen.** The $\lambda 1302$ triplet of oxygen was photographed in the third order of a 3-meter vacuum grating spectrograph with iron lines of the first order as standards. The spectrograph was designed by the author and built in this laboratory. The dispersion in the third order is 1.7Å per mm. Fig. 1b shows these spectra. It is noticed from the figure that the oxygen lines are longer than the iron lines used for comparison. This, of course was due to an adjustable shutter before the plate that limited the comparison spectrum. It was rather fortunate for this purpose that such a shutter had been provided, because two of the lines $\lambda\lambda 1305-6$ are blended with weak iron lines. $\lambda 1302$ is quite free from iron lines. The unblended line $\lambda 1302$ was measured with the iron lines as standards, and a considerable number of iron lines were measured in each direction in order to calibrate the plate. The measurements were obtained from two plates, the one mentioned above and another in which the shutter was not used with the comparison spectrum. The other two lines, $\lambda\lambda 1305-6$, were measured at the portions showing below the iron spectrum. In this case the plate had not been disturbed from its previous setting in the comparator. $\lambda 1302$ was used as the reference line and the correction curve already determined for this plate from the iron spectrum was applied.

Since the light from the iron arc was shined through the discharge tube that generated the oxygen spectrum, it is quite certain that the same portion of the grating was illuminated in both cases. Whether the reflecting power of the grating for the regions $\lambda 1300$ and $\lambda 3900$ which are here superimposed remained relatively constant for both spectra was of course not determined and would remain as a source of error if the spectra were not exactly focussed. The focus was very sharp, however. The wave-length of these lines, as well as those of the comparison spectrum are given in Table I.

(b) **Nebular lines $\lambda\lambda 6300, 6364$, coronal line $\lambda 6374$.** Since the two oxygen lines $\lambda 6300$ and $\lambda 6364$ are the only "nebulium" lines yet produced in the laboratory, it seems worth while to relate under what laboratory conditions they appeared. The discharge tube was made of quartz. It was II-shaped, had an

internal diameter of about 8 mm and a total length of about 80 cm. It contained large nickel electrodes in the two legs. The horizontal part of the tube faced the slit of the spectrograph end-on. The whole tube was immersed in a bath of running water for cooling. Pure oxygen was obtained electrolytically. It was dried by passing it over phosphorus pentoxide. The gas was allowed to flow through the discharge tube continuously, being admitted by a torsion capillary valve of glass and pumped out by oil and mercury vapor pumps. The pressure in the discharge tube was not measured but it was estimated to be between 1 and 2 cm. A 5000 volt 5 kilowatt transformer was used without auxiliary inductance or capacity, and the current employed was between 1 and 1.2 amperes being regulated by a flowing water rheostat in series with the discharge tube. After the discharge tube was well cleaned by long running, the spectrum, a part of which is shown in Figure 1a, was photographed. The spectrograph used for making the picture was a Zeiss 3-prism instrument giving a dispersion of 29Å per mm at $\lambda 6300$. Neighboring oxygen lines were used as standards, and the Hartmann interpolation formula with a correction curve was used in measuring the plate. Visual observation of the appearance of the discharge might be of interest. When the tube was viewed end-on through the plane quartz window the discharge formed a red core down the axis of the tube, and this core became gradually more diffuse off the axis. When viewed with the spectroscope the green aurora line was very prominent, being about as strong as the neighboring green triplets. Besides the oxygen lines the only visible lines were $H\alpha$. Long exposure photographs also showed traces of the Angstrom CO bands.

The plate used was a panchromatic plate sensitized for infrared as well. The duration of exposure was twelve hours, although two hours' exposure was sufficient to give the "nebulium" oxygen lines.

Table II gives the wave-lengths of the nebular lines and the previously unidentified coronal line $\lambda 6374$.

TABLE II. *Nebular lines and coronal line of oxygen.*

* Altered values of terms: § numerical error corrected.

Tables I and II give excellent agreement of the spacing $2s^22p^4\ ^3P_2 - 2s^22p^4\ ^3P_1$ ground terms. This confirms also the identification of the lines $\lambda 6300$ and $\lambda 6364$ with even greater precision than that given by Paschen. The accuracy of the measurement of these two nebular lines as produced in

oxygen together with the more accurate evaluation of the $2s^2 2p^4 \ ^3P_{012}$ ground term justifies the revision of the term values given in Table III.

It is rather remarkable that these nebular lines can be produced in the laboratory when the conditions for their production are extremely low pressures according to Bowen. The pressures in the nebulae are undoubtedly very small, but the pressure in the discharge tube was, as already mentioned, relatively high.

The wave-length of the red coronal line $\lambda 6374.2$, as given by Campbell and Moore,⁹ seems to be identical with the unclassified oxygen line $\lambda 6374.29$ which is shown as a strong line on the plate, Figure 1a. This line is not entirely new, as Kayser records it in his "Tabelle der Hauptlinien—" as $\lambda 6373$ and due to oxygen. Frerichs has it in his list of unclassified lines as $\lambda 6374.292$. This coincidence in the wave-lengths of the oxygen and the coronal line and also the fact that the line occurs in an isolated position in the oxygen spectrum when only lines of O I were present would seem to indicate their identity, and is strong evidence of the presence of oxygen in the sun's corona. Really to prove the identity of these two lines a more accurate determination of the line in the corona is necessary.

Since this line is one of the brightest in the coronal spectrum, being second only to $\lambda 5303$ of the corona, the terms in oxygen which give rise to it become of great interest. The most promising lead in their identification would be a study of the Zeeman pattern of this line. This, so far as I know, has not yet been made.

This investigation has been greatly assisted by the grant of a fellowship by the John Simon Guggenheim Memorial Foundation that allowed the author the privilege of a year's study in Germany. I am also greatly indebted to Professor F. Paschen, President of the Physikalisch-technische Reichsanstalt, for putting every facility of his excellent spectroscopic laboratory at my disposal.

EVIDENCE FOR A BE ISOTOPE OF MASS 8 AND FINE STRUCTURE MEASUREMENTS IN THE BeH BANDS

BY WILLIAM W. WATSON AND ALLAN E. PARKER
SLOANE PHYSICS LABORATORY, YALE UNIVERSITY

(Received December 2, 1930)

ABSTRACT

An intense spectrogram of the $\lambda 4991$ BeH band has been obtained in the third order of a 21-foot concave grating with a dispersion of 1.286Å per mm. Every P and R line of the (0, 0) band in the strong interval $K''=6$ to 20 is accompanied by a very weak line in the position calculated for Be^8H , except where a strong line of another branch prevents measurement. The relative intensities of the Be^9H and Be^8H lines are about 1:2000. Discussion shows this to be a reliable indication of the presence of a small amount of a beryllium isotope of mass 8.

This BeH band system is composed solely of the $\Delta v=0$ sequence, with the band origins forming a head at the (4, 4) band, thus accounting for band origins on both sides of the (0, 0) origin in this same sequence. The doubling of the branches at the origin is observed, the relative intensities of the components being in complete agreement with those predicted for case b doublet states. The system represents a ${}^2\Pi \rightarrow {}^2\Sigma$ transition with $A=1.97\text{ cm}^{-1}$ for the ${}^2\Pi$ state. Peculiar Λ -type doubling relations and the reverse bending of the branches for high K values are discussed.

INTRODUCTION

ALTHOUGH any table showing the α -particle plus proton and electron content of known nuclei¹ leads to the prediction that the nucleus of mass 8 should be found as an isotope of beryllium, the mass spectrograph has failed to reveal it. This has led Atkinson and Houtermans² in their theoretical consideration of the possibility of the building-up of the elements in the stars by the penetration of protons into the nuclei to postulate that the Be^8 nucleus is unstable, disintegrating into two α -particles. But it is not certain that nuclei which are integral multiples of α -particle units are necessarily composed solely of α -particles.³ However, Lord Rayleigh has pointed out⁴ specimens of the mineral beryl have been found to contain an unexplained amount of helium. If this helium originated from Be^8 , it would indicate that this Be isotope "has existed within geological times, and subsequent to the formation of the mineral." And since nothing is really known about its instability, some Be^8 may very well still exist in Be minerals, as existing temperature conditions would not cause its disintegration. If so, the band spectrum method of isotope study should detect its presence.

Band systems due to the diatomic molecules BeO, BeF, and BeH have

⁴ Lord Rayleigh, Nature 123, 607 (1929).

been obtained in emission from an arc. The arc is not a good source for the detection of faint isotope lines,⁵ but the satisfactory production of these spectra in absorption would seem difficult because of the high temperatures necessarily involved. Of the emission spectra that of BeH at $\lambda 4991$ is the best for this investigation because it can be obtained with very great intensity at high dispersion, and because the bands have the open structure characteristic of hydrides. This band system has been previously examined by one of us,⁶ and a preliminary investigation⁷ of one of these spectrograms for possible Be⁹H lines revealed a number of very weak lines in the calculated positions. It seemed likely that more intense spectrograms at still higher dispersion would give additional and more definite information on the question of the isotopic origin of these faint lines.

EXPERIMENTAL PROCEDURE

The source of radiation was a 110-volt dc arc between beryllium electrodes in a hydrogen atmosphere at about 6 cm pressure. The arc current was held at about 5 amperes. With this reduced hydrogen pressure the Be arc runs much

Fig. 1. Reproductions of the $\lambda 4991$ BeH bands. *a.* Short exposure. Shows the relative arrangement of the *P*, *Q*, and *R* branches and the formation of a vibrational head. *b.* The 10-hour exposure measured for isotope effect. The doubling of the first *P* branch lines is evident.

steadier and the BeH bands are emitted much stronger than when atmospheric pressure of hydrogen is used. Because of the heat developed, it was found necessary to interrupt the exposure at frequent intervals.

The spectrum was photographed on Eastman panchromatic plates in the third order of a 21-foot concave grating in a stigmatic mounting, the dispersion being $1.286\text{\AA}/\text{mm}$. For the most intense spectrograms the total elapsed time was 10 hours, but of this we estimate slightly more than 4 hours to be actual exposure time. In Fig. 1b, which is a reproduction of this spectrogram, the great intensity of the principal branches is evident.

⁵ A. S. King and R. T. Birge, *Astrophys. J.* **72**, 19 (1930) discuss this point in detail in connection with their discovery of C^{13} in the spectra of C_2 , CO, and CN.

ISOTOPE EFFECT

In computing the isotope shift of the possible weak lines originating in Be⁸H the procedure is as follows. Assuming the masses of the two isotopes to be exactly 9 and 8, and taking the mass of hydrogen as 1, the usual isotopic coefficient $\rho = [(1/8+1)/(1/9+1)]^{1/2} = 1.00625$. If the values of these Be nuclear weights are computed by interpolating between Li and B on the known packing-fraction curve⁸ one obtains 9.013 and 8.013. These masses, together with $H=1.008$, give a value for ρ identical with that just mentioned. We have, then, $\rho-1=0.00625$, $\rho^2-1=0.01250$, $\rho^3-1=0.0187$, and $\rho^4-1=0.0256$.

The vibrational isotope shift is given by

$$\Delta\nu^v = (\rho - 1) [\omega_e'(v' + \tfrac{1}{2}) - \omega_e''(v'' + \tfrac{1}{2})] \\ - (\rho^2 - 1) [\omega_e'x'(v' + \tfrac{1}{2})^2 - \omega_e''x''(v'' + \tfrac{1}{2})^2]$$

which, as we shall concern ourselves only with the *P* and *R* branches of the (0,0) band, becomes

$$\tfrac{1}{2}(\rho - 1)(\omega_e' - \omega_e'') - \tfrac{1}{4}(\rho^2 - 1)(\omega_e'x' - \omega_e''x'').$$

Since the bands in this BeH system compose the $\Delta v=0$ sequence only, the values of the vibration frequencies ω_e' and ω_e'' cannot be exactly determined. However, it is certain that these quantities are almost equal for these bands,⁶ and that therefore their difference will be small. Hence the constants $\omega_e' = 2053 \text{ cm}^{-1}$ and $\omega_e'' = 2025 \text{ cm}^{-1}$ computed in the earlier work from the rotational data for the (0, 0) band will suffice in their place. These, together with the $\omega_e'x' - \omega_e''x''$ difference given in reference 6, placed in this vibrational isotope effect equation gives $\Delta\nu^v = +0.11 \text{ cm}^{-1}$.

The rotational isotope effect has been computed after the accurate manner recommended by Birge,⁹ using the coefficients of the rotational energy term from reference 6. Even the sixth powered term in the rotational energy with a mass factor $\rho^6 - 1$ becomes appreciable in this case for $K > 15$, and is equal to 0.05 cm^{-1} at $K = 20$. Since the Be⁸ isotope is lighter than the main Be⁹, the the rotational isotope effect is + (towards higher frequency) in the *R* branch and - (towards lower frequency) in the *P* branch. The vibrational contribution of 0.11 cm^{-1} is then to be added to the rotational shift for the *R* branch lines and subtracted from this shift for the *P* branch lines.

Calculations of the expected positions of Be⁸H lines have thus been made for all of the stronger *P*- and *R*-branch lines of the (0, 0) band. Measurement of the plate reveals a very weak line at the calculated point for every *P* and *R* line in the interval $K'' = 6$ to 20 except where an overlapping or adjacent strong line of another series makes measurement impossible. Table I gives the comparison of the calculated and observed displacements of these weak lines from the corresponding Be⁹H lines. The average discrepancy between the calculated and observed shifts is 0.04 cm^{-1} in the *P* branch and 0.05 cm^{-1} in

⁸ F. W. Aston, Proc. Roy. Soc. 115, 487 (1927).

⁹ R. T. Birge, Trans. Faraday Soc. Dec. 1929.

the *R* branch, which is of the order of magnitude of the possible electronic isotope shift.

The relative intensities of these weak and main-branch lines are rather difficult to obtain. Fig. 2 is a copy of a microphotometer trace of the *P*(17), *P*(18) line region taken with the 40:1 magnification ratio of a Koch-Goos registering microphotometer. Since the deflection for the strongly over-exposed main lines as against that for the background on the plate is no measure of the intensity of these lines, such a trace serves merely to indicate the character and relative positions of these very weak lines among their stronger neighbors. To get some idea of the correct relative intensities of these lines, spectrograms were taken of the bands under identical conditions for various

Fig. 2. Copy of microphotometer trace of the region of the BeH bands including the *P*(17) and *P*(18) lines showing the very weak lines attributed to Be⁸H.

very short times in order to determine the time of exposure which would give the Be⁹H lines with the same intensity as noted for the weak Be⁸H lines with the long exposure time. An exposure of but 15 seconds, which is approximately 1/1000 that of the 4 hour time for the main exposure, produced the *P*(17) and *P*(18) lines with about the same intensity as these Be⁸H lines. Comparison of the areas under a microphotometer trace of these 15 second lines and the 4 hour Be⁸H lines verified their approximate equality in intensity. Then making allowance for the fact that general background on the plate for the long exposure tends to increase the intensity of very weak lines, the conclusion is reached that the correct relative intensity of the Be⁸H and Be⁹H lines is more nearly 1:2000.

THE RELIABILITY OF THIS INDICATION OF A Be⁸ ISOTOPE

The most cogent argument against the conclusion that these measurements indicate that a small amount of a Be isotope of mass 8 really does exist would be that since there are such a large number of lines in this system, the agreements with the computed Be⁸H positions may be all just chance coincidences with lines of bands representing transitions between higher vibrational levels. Impurity lines such as H₂ can be ruled out, because there are no indications of them on the portions of our plates beyond the extremes of this band system. Now in the discussion of the fine structure in these bands given below, it is shown that vibrational states as high as (9, 9) are probably present. Since the lines in question are of very low intensity they could belong

only to say the (8, 8) and (9, 9) bands. But the lines of the *P*-branches of these bands would have in the *P*-branch region examined a spacing more nearly like that of the (0, 0) band *R* branch—about 20 cm^{-1} as compared to about 14 cm^{-1} for the (0, 0) band *P* branch—because of the fact that the (0, 0) band order $B' > B''$ is just reversed. Just the opposite is true of the line spacings in the *R* branch. The sequence of weak Be^8H lines then could not possibly belong to any one branch of these weaker Be^9H bands. And the probability that if all of these weak lines belong to several different main band

Note: For every line between $K''=6$ and 20 missing in these sequences measurement is impossible because of overlapping stronger lines of other branches.

branches, the totality of agreements indicated in Table I could happen by chance is negligible. It should be emphasized again in this connection that the isotope line has been found for every *P* and *R* line of the (0, 0) band for *K* values from 6 to 20, the interval of maximum intensity, except where a stronger line of some other branch interfered with the measurement.

It would of course be desirable to check these conclusions by the finding of the Be^8 , Be^9 isotope effect in some other Be band system. With this in mind we have obtained an intense exposure of the BeO bands at high dispersion. The source was merely a 220-volt d.c. arc between Be metal electrodes in air. A Be^8O^{16} (1, 0) head should lie 10.34Å to the violet from the Be^9O^{16} (1, 0) head at $\lambda 4427.3$, while a Be^9O^{18} (0, 1) head should be found 7.40Å to the violet from the Be^9O^{16} (0, 1) head at $\lambda 5054.4$. These main heads are strongly developed on our plate, but unfortunately the regions on their violet sides are overrun with weak lines representing high rotation levels of the BeO bands in the adjacent sequences due to this form of excitation. Nevertheless the exact points for these calculated weak isotope heads are sufficiently clear, and not a trace of either of them is apparent. In view of the fact that O^{18} is definitely established with an abundance ratio of 1:1075 to O^{16} , our failure here merely means that such an arc is not the proper source for the detection of faint iso-

tope lines. It will apparently be necessary to develop some Be band system either in absorption or in the electric furnace in order to obtain further evidence of the Be⁸ isotope.

NEW FINE STRUCTURE MEASUREMENTS IN THE BeH BANDS

It is the object of this section to present some new details of the BeH system together with their probable interpretation. The earlier work⁶ led to the logical assumption that these bands are due to the transition ${}^2\Pi \rightarrow {}^2\Sigma$ with the ${}^2\Pi$ state approximately pure case *b*, because of the apparent lack of observable spin doubling of the lines near the band origins. All of the lines in the bands with the exception of the first R_1 line ($R_1(\frac{1}{2})$) are thus to be considered as the coalescence of the two members of a spin doublet having the same K' and K'' values but differing by one unit in J' and J'' values. In this event the quantum number J has no significance, and the lines are to be designated by their K'' values.

The higher resolution of our third order plates, however, reveals the expected doubling of the lines near the origins. These have only been measured for the P and Q branches of the main ($\frac{1}{2}, \frac{1}{2}$) band, all the first R -branch lines being so close to strong Q -branch lines as to make accurate measurement of

					38.19	

the doublet interval impossible. Table II gives these new data to $K''=7$ which should replace the corresponding part of Table I of ref. 6. This earlier table is then quite correct from $K''=7$ to 45, and is to be supplemented by the additional lines for $K''=45$ to 51 of Table III below. The doubling of the lines $P(2)$, $P(3)$, and $P(4)$ is clearly to be seen in Fig. 1c.

To evaluate the coupling constant A , measuring the interaction energy between L^* and S^* , it is only necessary to substitute our observed doublet intervals in the equation¹⁰

$$\Delta f(K) = [A\Lambda^2/K(K+1) + \gamma](K + \frac{1}{2})$$

given by Mulliken for case *b* states.¹¹ The mean value of A so obtained is

¹⁰ R. S. Mulliken, Reviews of Modern Physics 2, 60 (1930), Eq. (36), p. 108).

¹¹ As Mulliken has recently pointed out, (Reviews of Modern Physics 2, 507 (1930)) this equation is only adequate for a very limited range of A/B_v values close to $A=0$. These BeH bands happen to be the one good example of this situation.

1.97 cm⁻¹. Application of the Hill and Van Vleck formula yields practically the same result.¹²

Our observation of the relative intensities of the components in the *P*-branch doublets gives good confirmation of the assignment $F_1 > F_2$ for the order of the rotational energy levels in this $^2\Pi$ state with an A/B_v lying between 0 and +4.¹³ The high frequency component is always the stronger, as in the case of the $\text{CH}^2\Sigma \rightarrow ^2\Pi$ bands for the $^2\Pi$ state of which $A/B_v = +2$, whereas for the similar MgH , CaH , etc. bands the high-frequency component is the weaker, in fact much weaker for the lowest rotational levels than is predicted by the theory. For these BeH bands, however, the relative intensities are in very good agreement with the ratios computed with the aid of the intensity equations for case *b* doublet states developed by Mulliken¹⁴ from the Hönl and London and Sommerfeld and Hönl equations. These intensity ratios for the first three *P*-branch lines are:

Line	$P_1:P_2$ (calc.)	(obs.)
<i>P</i> (2)	1:0.56	1:0.51
<i>P</i> (3)	1:0.70	1:0.83
<i>P</i> (4)	1:0.77	1:0.74

The observed intensity ratios were obtained from a comparison of the areas under a microphotometer trace obtained with the Koch-Goos instrument. The larger discrepancy for the *P*(3) ratios is due to a photographic disturbance produced by an adjacent Fe line of the comparison spectrum.

The comparison of the observed doublet intervals in the first *P*- and *Q*-branch lines, together with combination differences, fix definitely the *K*-values of the lines of the *Q*-branch, and show that the relative numbering of the lines of the three branches in Table I of the previous work is correct. To evaluate the Λ -type doubling in the $^2\Pi$ state we form the differences

$$\frac{1}{2} \{ [R(K) - Q(K)] - [Q(K+1) - P(K+1)] \} \cong F_b'(K + \frac{1}{2}) - F_a'(K + \frac{1}{2}).$$

This doubling starts at $K=1$ with a very small negative value, goes through zero at $K=4$, and increases slowly with K to a value of approximately 10 cm⁻¹ at $K=42$. After this it begins to decrease with further increase in the rotational quantum number. For $K' > 5$, where the spin doubling becomes negligible, and for $K' \gtrsim 20$ the Λ -type doubling is proportional to $K'(K'+1)$, as predicted by Van Vleck¹⁵ for case *b* $^2\Pi$ states. The average value of the factor of proportionality is about 0.014. Now Van Vleck shows that with the assumption that the *L* vector precesses uniformly about the electric axis in the molecule, and for the case $L=1$, this proportionality factor would be of the order of magnitude $4B^2/\nu$. For BeH this quantity is $4(10.16)^2/2 \times 10^4 \cong 0.02$. If this same doubling law held for the highest rotational levels, the Λ -type dou-

¹² This value for *A* should replace the tentative value assigned in Fig. 15 of reference 11. Also the value of $B=7.82$ there given should be 10.16, the value of B_v'' given in reference 7

¹³ Cf. R. S. Mulliken, Phys. Rev. 32, 388 (1928).

¹⁴ R. S. Mulliken, Phys. Rev. 30, 785 (1927).

¹⁵ J. H. Van Vleck, Phys. Rev. 33, 467 (1929).

bling would be about 23 cm^{-1} at $K=40$, whereas actually it remains almost constant at 10 cm^{-1} from $K=35$ to 42 and then begins to decrease. This departure from the normal doubling law begins at about $K=20$ where the reversal in the direction of shading of the branches also becomes apparent.¹⁶ Both of these phenomena indicate a marked distortion of the molecule with increase in rotational energy and are evidence for an uncoupling of L from the internuclear axis.

On the long wave-length side of the origin of the $(0, 0)$ band (main Q -branch head) in Fig. 1 two weaker Q -branch heads are to be seen. This may at first seem puzzling, because with the $(0, 0)$ band Q -branch degrading initially toward the violet, successive Q -branches of this $\Delta v=0$ sequence should normally be found on the violet side of the $(0, 0)$ origin. The explanation of this unusual feature lies in the fact that in this band system the vibrational frequencies ω_v' and ω_v'' are almost equal (about 2053 cm^{-1} and 2025 cm^{-1} respectively). Hence the slight differences in the course of the vibrational energy as a function of v in the two states are sufficient to actually produce a change in the sign of the vibrational energy contribution to the radiated energy for $v'=v'' \geq 8$. That is, the successive Q -branch heads rapidly converge to zero separation at the $(4, 4)$ head at about 20064 cm^{-1} as shown in Fig. 1, and then return to lower frequencies. This would make the two weaker Q -branch heads on the red side of the main Q head probably the $(8, 8)$ and $(9, 9)$ Q -branches. The order $B_v' > B_v''$ also reverses at about the $(4, 4)$ band, since these quantities are given approximately by¹⁷

$$B_v' = 10.45 - 0.325v'; \quad B_v'' = 10.25 - 0.275v''.$$

Therefore the spacing of the lines in the weak R branches of the bands from $(4, 4)$ to $(9, 9)$ should become closer, comparable to that of the P branches in the strong $(0, 0)$ band, thus accounting for the lack of corresponding R -branch heads. Similarly, the weak P -branch for these higher vibrational bands should have a larger spacing more like the $(0, 0)$ R -branch. All of these P and R branches have not been examined in detail, but sufficient measurements have been made to indicate definitely that this is the correct explanation of the rather complex fine structure in this unusual band system.¹⁸

51	17.14		

¹⁶ Cf. reference 6 and W. W. Watson, Phys. Rev. **34**, 1013 (1929) for diagrams.

¹⁷ E. Bengtsson, Nature **123**, 529 (1929).

¹⁸ F. A. Jenkins, Phys. Rev. **31**, 539 (1928) has shown that the tail bands in the violet CN system are produced by this same phenomenon; i.e. of the bands in a sequence forming a head and returning into the region beyond the first band head in the sequence.

Finally, it is to be noted in Fig. 1 that the *R*-branch of the (0, 0) band, the lines of which at the origin start out with increasing spacings, actually forms a head, and several lines of the returning portion are observed on our strongest plate. Corresponding lines in the *Q* and *P* branches have also been measured. Table III giving these data supplements Table I of reference 6.

One would expect to find distortions such as those observed in these BeH bands due to large accretions of rotational energy of rather common occurrence in molecular spectra. Actually, however, similar phenomena have been reported only for some He₂ and H₂ levels¹⁹ and for the red CaH bands^{20,21}. Possibly the investigation of the rotational structure of molecular spectra lying in the Schumann region and representing predicted higher electronic levels reveal other examples of irregularities of the same nature.

AN APPLICATION OF THE RESONANCE RADIOMETER TO
THE REFLECTION SPECTRUM OF QUARTZBY J. D. HARDY AND S. SILVERMAN
JOHNS HOPKINS UNIVERSITY

(Received December 1, 1930)

ABSTRACT

The reflection spectrum of quartz has been previously studied by means of both the rock-salt prism spectrometer and the echelette grating spectrometer. Early investigators have shown that for crystalline quartz, with the reflecting surface perpendicular to the optic axis, there is a double reflection maximum, one lying at 8.4μ and the other at 8.9μ ; and that fused quartz exhibits a single maximum at 8.8μ . These regions have been studied under high dispersion by the authors using an echelette grating spectrometer. The high resolving power that was obtained was due to the sensitivity of the radiometric device, the resonance radiometer, which was first described by A. H. Pfund.¹ The complete theory of the instrument was developed by one of us.² By the use of this large resolving power and dispersion it has been possible to show that these spectra are considerably more complex than were found previously. The usefulness of magnesium oxide as a filter for excluding the higher orders of lower wavelengths has been tested with gratifying results.

INTRODUCTION

PREVIOUS investigators have studied the reflection spectra of quartz with particular attention to crystals cut perpendicular to their optic axes. Among the various investigators Rubens and Nichols,³ Coblentz,⁴ and Gorton⁵ employed a prism spectrometer; Wood and Trowbridge⁶ used an echelette grating. The results show some agreement as to the wave-lengths of the reflection maxima, which are located at 8.4μ and 8.9μ respectively, but there is an apparent marked difference in the depth of the minimum which separates the maxima. Closer examination of these dissimilar curves shows that they actually represent very approximately the same structure. The work done with the prism spectrometers shows the ratio of the reflecting power of the quartz surfaces to that of a silver surface, while the work done with the grating shows only the energy curve of the source after three reflections from quartz. This makes it difficult to compare directly the results of the grating with those of the prism. Also, it should be pointed out that as very few workers have restricted themselves to similar crystal forms or similar geometrical systems, it is necessary to be cautious in attempting any comparison of the various results. The conditions for observation in the present case are as

follows; the angle of incidence was measured to be very close to 30° ; the crystal surface was polished smooth and cut perpendicularly to the optic axis; the results are the ratios between the reflecting power of quartz surfaces and that of clean silver. It is thought that if these conditions are approximated it should be possible to use the positions of the reflection maxima and minimum for calibrating prism spectrometers in the 8μ region.

In the early part of this year, Professor A. H. Pfund made some observations on the reflection from crystalline quartz (not published) and found results differing markedly from those of Coblenz and others. He found, using a very narrow slit, a much lower minimum at 8.6 and some indication of unresolved fine structure. It was decided, therefore, to examine this spectrum with an apparatus whose sensitivity and resolving power would far surpass anything yet applied to this region. The diagram of the spectrometer is shown in Fig. 1.

Fig. 1. Spectrometer arrangement for observing the reflection spectra.

APPARATUS

The source of light, N_1 was a Nernst glower, run at 0.8 amp. from a storage battery. This light is interrupted periodically by the pendulum of the resonance radiometer; the period of which is adjusted to be equal to twice the optimum period of response of the first thermocouple. The light is then admitted to the spectrometer periodically with the time of admission exactly equal to the time of darkness, and the slit is alternately illuminated and darkened. Light from the Nernst glower is reflected from a concave mirror on to the first quartz plate R_1 which is covered with a layer of MgO . This plate acts as a filter and purifier. The beam is then reflected from a second plate of quartz R_2 to the first slit. This second plate is set in place with a strong spring so that it may be replaced exactly by a silvered surface. The beam then passes through the spectrometer and is focused upon the receiver of the first thermocouple. The grating used was a 5 inch, 1312.5 lines per inch echelette prepared at this University by Professor Wood, and ruled to throw its blaze, or maximum concentration, at 8.5μ . The thermocouple was a Bi-Sb · · Bi-Sn

splashed filament type, with a silver receiver which was covered with bismuth black. It was mounted behind a rock-salt window and evacuated to a non-conducting vacuum. The grating had a dispersion ratio of 570; i.e. at a scale distance of 3.2 meters, 1 mm represented 50Å. The calibration was done by means of the higher orders of the 5461 line of the mercury arc, and was accurate to 15Å. The slits of the apparatus were 0.07 mm wide, yielding an effective "slit-width" of 15Å. This width of slit is the most advantageous in this region both for resolution and intensity giving a resolving power of 80 percent of the theoretical value, or about 4000.

Inasmuch as the resonance radiometer has been recently described in detail, it will be necessary here to outline only its salient points.² The first thermocouple is connected to tuned vibration galvanometer 1, which is so constructed that it is highly underdamped with a half-period equal to the time of response of the thermocouple. Galvanometer 2 is identical with 1 except for a device permitting accurate tuning with 1. The two galvanometers and the pendulum are kept in as exact tune as possible. The amplifier light source is a tungsten filament bulb burned at about 3.6 amp. from a storage battery. It lies behind the first grid R_1 , and is focused on the concave mirror of galvanometer 1. This mirror then throws an image of R_1 coincident upon a second grid R_2 , which is identical with R_1 , except that it has a double spacing at the center. Then the beam of light which is transmitted by R_2 is broken into two halves, which are exactly out of phase as regards luminosity. As the mirror of galvanometer 1 rotates, the image of R_1 slides across R_2 , darkening one half whilst illuminating the other half. These two beams are then focused by means of a split lens upon a compensating thermocouple T_2 , which is in turn connected to the second galvanometer. There will then be two amplifying factors: First, the resonance amplification arising from the periodically interrupted beam falling upon S_1 . Secondly, the motion of G_1 causes the image of R_1 to oscillate across R_2 , so that the intensity of the light falling upon the junctions of T_2 varies periodically and sets G_2 in turn into a resonance vibration. This second factor may be varied by changing the intensity of S_2 . Throughout this experiment the total amplification was kept at about 4000, and deflections which could not be detected on an ordinary high-sensitivity galvanometer ranged as high as 30 centimeters on this instrument.

METHOD OF PROCEDURE

The actual readings were taken as follows: The spectrometer was set for a given wave-length, and the first quartz "purifying" plate was held over a brightly burning ribbon of magnesium. It was coated with a fine, white powder of magnesium oxide. The thickness of the coat was judged sufficient when the whole plate appeared uniform when held against a brilliant back ground. The plate was then placed carefully in its holder, and thereafter left undisturbed. The second quartz plate was put in, and the shutter was removed, allowing the second galvanometer to build up to a maximum. Three or four deflections on each side were noted, with an average deviation, at a scale distance of 1 meter, of about 1 percent. The second quartz plate was

removed, and replaced by a silver surface; the readings were then repeated. The direct ratio of the readings yields the relative reflecting power of quartz and silver. To get the absolute reflecting power, one must correct for the small deviation of the reflection coefficient of silver from that of a perfect reflector. However, this correction is smaller than the experimental error. Inasmuch as direct ratios are taken, it is unnecessary to take any account of water vapor or any other absorbant present in the air path. The magnesium oxide⁷ was used with the hope of cutting out the higher orders of lower wave-lengths; an ideal filter would be one which was opaque to 4μ , and perfectly transparent from 7.5 to 9.5μ . As a test for the usefulness of MgO , the first slit was covered by a piece of thin cover-glass, which transmitted fairly well up to 4μ , and which

Fig. 2. Reflection spectrum of crystalline quartz. Circles, Hardy and Silverman; crosses, Coblentz.

was opaque to 8μ . With the grating set for 8μ , and with two *silvered* plates in place, one covered with the oxide, no resonance deflection was detected. In passing, it might be noted that even with such a high amplifying factor, the zero unsteadiness was never greater than 2.0 cm in the daytime, and usually around 5 mm at night. Moreover, with an unsteadiness of 2 cm, it was possible to measure deflections of less than four centimeters to an accuracy of a millimeter. In general the deflections were of the order of ten or more centimeters so that the resultant ratios shown on the curves are judged to be accurate to about one percent. The curves shown are the results of several sets of observations which were found to agree among themselves exceedingly well.

⁷ A. H. Pfund, Phys. Rev. 36, 71 (1930).

The position of the grating was checked several times and the wavelengths plotted are accurate to 0.0015μ .

RESULTS

The spectrum of crystal quartz shows a rapidly increasing reflectivity at 8.1μ . Between 8.3 and 8.4 there is considerable fine structure, and a sharp maximum at 8.506μ . The minimum immediately following is triple, showing dips at 8.612 , 8.628 and 8.662μ respectively; and peaks at 8.617μ and 8.646μ .

Fig. 3. The reflection spectrum of fused quartz. Circles, Hardy and Silverman, squares, Coblentz.

There is a rise to a maximum at 8.931 , a small decline to 9.024 and a shorter rise to 9.125 . Following this last maximum the intensity falls off steadily. Dr. A. H. Pfund had previously found indications of the structure at 8.4μ , although he was not able to resolve it, and also of the dip at 8.9μ .

The spectrum of fused quartz is less regular, and nowhere shows any of the regular smoothness attributed to it in the literature.^{8,9} It rises from 16 percent

⁸ Schaefer and Matossi, "Das Ultrarote Spektrum," p. 317.

⁹ J. Lecompte, "La Spectre Infrarouge," p. 145.

at 7.870μ in a series of staggers to a set of sharp maxima and minima. Maxima appear at 8.832 , 8.865 , 8.893 , 8.913 and 8.942μ . The minimum at 8.904 is particularly sharp. The intensity on the long wave side again falls off in a step-wise fashion.

The resonance radiometer has shown itself to be quite practical in its application to work in infrared spectroscopy. Although it has the disadvantage that in its present form it is not practical to use it as a direct recording instrument, its freedom from unsteadiness and stray disturbances and its reliability in the matter of reproducing readings more than offset its faults.

In conclusion, the authors wish to express their appreciation to Professor A. H. Pfund of this University, whose aid and many suggestions have been invaluable.

RECOMBINATION IN MERCURY VAPOR

BY HAROLD W. WEBB* AND DAVID SINCLAIR

PHYSICS LABORATORIES, COLUMBIA UNIVERSITY, NEW YORK CITY

(Received December 6, 1930)

ABSTRACT

The afterglow in ionized mercury vapor was studied as a recombination phenomenon, to determine how its intensity varied with concentration of electrons and of positive ions, vapor pressure and the mean energy of the electrons, the last expressed as a temperature, T . The afterglow was observed in a region outside of the arc to which positive ions and electrons were carried by a stream of vapor, auxiliary electrodes being used to control the electron temperatures. The total number of electrons, N , was assumed closely equal to the number of positive ions. The intensity of the visible part of the afterglow radiation was shown to be closely proportional to the total intensity under the experimental conditions, and was therefore used as a measure of the rate of recombination. This intensity, I , was found to be proportional to the first power instead of to the square of the electron concentration, with possible exceptions at low concentrations and low electron temperatures. I varied with vapor pressure, increasing roughly as the fourth power of the pressure. With increase in electron temperature from 1300° to 5600°K , I decreased by a factor of 2500. From this rapid change in I it is concluded that the afterglow cannot be due to a simple recombination process, since work of other authors with caesium and helium has shown that I should then vary not more rapidly than the reciprocal of the temperature. The results were found to fit either of the following empirical equations: $I = \text{const } N^2/N_0$ or $I = \text{const } N^2/N_1$, where N_0 is the number of fast electrons having energies greater than a determined value and N_1 the number having a definite energy. The values of the critical energies corresponding to these two equations were found to be 1.15 volts and 1.35 volts, respectively.

The results suggest that the recombination in mercury vapor takes place in two stages, of which the second is responsible for the radiation of the series lines, and that the effect of the fast electrons is to reionize from the first stage.

Considerable difficulty was experienced during measurements as the result of changes in the contact potential of the exploring electrodes used for measuring electron temperatures and concentrations. These changes were apparently due to traces of oxygen.

THE recombination of ions and free electrons has been studied in various ways but the nature of the process is still very obscure. The results of these studies have been well summarized in several recent publications,¹ and only a few outstanding points need be reviewed here. Especially have the simple recombination of an ion and an electron accompanied by emission of radiation and the converse process of photoionization been investigated in detail. The most extensive quantitative experiments in this field have been

* The appointment of the senior author as Ernest Kempton Adams Fellow enabled him to secure the collaboration of Mr. Sinclair.

made by Mohler,² who found in caesium vapor and in helium continuous spectra extending from near the series limits to higher frequencies. These spectra are interpreted as due to the recombination of ions with electrons, in which process an electron falls into the lowest energy level of one of the series, the difference in frequency between that of the radiation observed, ν , and that corresponding to the series limit, ν_i , being due to the kinetic energy of the electron before impact, $mv^2/2$. The relation between these frequencies is given by $h\nu = h\nu_i + \frac{1}{2}mv^2$. In these experiments the mean energy of the electrons was about 0.3 volt. Mohler found that the intensity of the radiation varied as a function of the electron velocity, v , and determined the value of the coefficient of recombination; $\alpha = \text{const. } v/(\nu - \nu_i)v^2$, or α is proportional to $1/vv^2$. Theoretical studies³ of the process give α proportional to $1/v$, $1/vv$, or similar expressions in fair agreement with experiment. It is of particular interest to note that, in these experiments, the rate of recombination of electrons and positive ions was found to vary very slowly with the kinetic energy of the electrons, that is inversely as the first power of the velocity, in marked contrast with results to be described later.

Hayner⁴ has shown that the afterglow in mercury vapor is due to some process of the nature of recombination. In her experiments the voltage on a low-voltage arc in mercury vapor was abruptly cut off and the behavior of the radiation which persisted, called the "afterglow," studied in the post-arc period immediately thereafter. The cutting off of the arc voltage extinguished the spectral series lines practically instantaneously, but after a brief transition period of about 10^{-4} sec. the series lines reappeared gradually increasing in intensity, reaching a maximum in about 2×10^{-4} sec. and then gradually decreasing. The behavior of the ionized gas in the experimental tube in the post-arc period gave every evidence that the afterglow was the result of a recombination process involving electrons and positive ions. The dark transition period following the cut-off of the arc voltage was explained as due to the fact that the velocities of the electrons were too great to permit recombination. The subsequent gradual growth of the intensities of the series lines corresponded to the gradual decrease in these velocities due to impacts with neutral atoms, while the decrease following the maximum was the result of the disappearance of ions and electrons due to their recombination and to diffusion to the walls of the tube. The nature of the spectrum of the afterglow furnishes additional evidence that it is produced by a recombination process. In it the ratio of the intensities of the higher members of the spectral series to the intensities of the lower members is very much greater than in spectra resulting from direct impact excitation as are observed in the arc.

Kenty⁵ in a similar experiment in argon found like results. The mean energy of the electrons at the time when the afterglow was most intense in the

post-arc period was determined by the Langmuir probe method as 0.4 volt, confirming the explanation that the recombination in the arc period and in the dark transition period was prevented by the high speed of the electrons and that radiation from recombination only became observable after the electrons had lost most of their energy.

Measurements on gases highly ionized, subject to no impressed field, have in general shown that the distribution of velocities among the electrons is Maxwellian and that a definite "temperature" may be assigned to the distribution. The Langmuir probe method gives a means of determining this temperature and gives also data for computing the concentrations of ions and electrons. The fact that the electrons have such a distribution, or one nearly approaching it, makes it very difficult to reconcile Hayner's results with the theory that the observed afterglow was due to simple recombination of positive ions and electrons, in which the probability of electrons of given velocity recombining with positive ions depends only upon the concentration and velocity of those electrons and the concentration of the ions. For, as we have seen, the most effective electrons in recombination are the slow ones. Now the number of these in a Maxwellian distribution varies with the temperature approximately as $1/T^{3/2}$, the total number being kept constant. Now on liberal estimates the total change in the electron temperature from the transition period, when the intensity of the afterglow was too small to observe to the moment of maximum intensity, was in Hayner's experiment not greater than a ten-fold decrease; on the other hand the change in intensity during this time appears to have been of a different order of magnitude, estimated as at least a thousand-fold increase. The intensity could not therefore have varied as the number of electrons moving slowly enough to have high probability of recombination, unless the velocity distribution was not Maxwellian but one in which the slower electrons were relatively very much scarcer at the higher temperatures. There is every evidence that this was not the case. Considerations of this difficulty in interpreting these results lead to the experiments described in this paper, in which the intensity of the afterglow was studied as a function of electron temperature, concentrations of positive ions and electrons and vapor pressure.

APPARATUS AND METHOD

To avoid the difficulties of making precise determinations of electron temperatures and concentrations under the rapidly changing conditions in the "post-arc" period following the cut-off of an arc, the investigations of the afterglow were made in a region outside the arc to which the positive ions and electrons were carried by a stream of vapor. The apparatus used was similar to that described in an earlier paper.⁷ The essential parts of the experimental tube, drawn to scale, are shown in Fig. 1. The mercury in the pool below the cathode *K*, was heated by a furnace, *H*, and the vapor streamed rapidly past

⁶ Rayleigh, Proc. Roy. Soc. A108, 262 (1925).

⁷ Webb and Wang, Phys. Rev. 33, 329 (1929).

the cathode and the anode, *A*, into the branch tube through the gauze, *G*, past the observation point, *P*, and was condensed in the region marked *C*. The cathode was an internally heated nickel cylinder with oxide coating.* The gauze, *G*, was of nickel wire, 0.03 cm in diameter and 0.6 cm spacing. At *P*, in the center of the tube, was placed a vertical probe, consisting usually of a platinum wire 0.0025 cm diameter exposed for about 0.5 cm. Opposite the probe was a quartz window 1.2 cm in diameter attached by a graded seal. A side tube 0.7 cm in diameter and 7 cm long closed at the end extended out at right angles near *P*, and was used in estimating the vapor pressure in the tube at this point. The condenser, *C*, was cooled by a coil of lead tubing carrying circulating water. This coil could be adjusted as to length and position

Fig. 1. Diagram of experimental tube.

or replaced by air cooling to control the flow of mercury vapor in the tube. Premature condensation in the tube between the furnace and the condenser was prevented by secondary heaters.

The pumping tube, *T*, passed first to a McLeod gauge, then to a magnetically operated cut-off and finally to a mercury diffusion pump. During observations this pump was in constant operation.

The arc current was varied up to 10 amperes, with an average potential drop of about 8 volts. From below the anode was emitted the usual low-voltage arc radiation with the higher members of the series relatively weak in intensity, while beginning a little above the anode and extending throughout the branch tube and the condenser was the afterglow in which the higher members of the series were relatively much stronger. The intensity of the

* For this cathode we are indebted to Mr. L. J. Buttolph of the General Electric Vapor Lamp Co.

afterglow at the point P was measured by a specially constructed visual photometer sighted through the quartz window. The radiation thus measured was practically all contributed by the sharp triplet $\lambda\lambda 5461, 4358, 4047$, and the intensities of these lines were taken as a measure of the total radiation of the afterglow. To justify this assumption spectrograms of the glow at different electron temperatures were made and compared and it was found that at least up to the 11 D and 7 S members the ratios of the intensities of the above triplet to those of the higher members varied only slightly, not sufficiently to introduce serious error. Rayleigh⁶ reports considerable variation in these ratios with age of the afterglow, but presumably the conditions in the present investigation were not so widely varied as in his. Furthermore, as will be seen later, small errors resulting from this method of measuring the intensity of the afterglow would not have affected appreciably the nature of the results.

Simultaneously with the intensity measurements observations were taken with the probe to determine the corresponding concentration of the electrons and their temperature. It was assumed that the number of positive ions was practically equal to that of the electrons, which for concentrations of the order observed is probably closely true. The usual logarithm of current to probe vs. probe-voltage plot gave, after deducting the current due to the positive ions, a straight line for voltages below the space potential, the slope of which determined the electron temperature. The concentration of electrons was computed from the space potential, as determined by the break in the curve, and the probe dimensions in the usual way. It should be noted that under the conditions of this experiment the distribution of electron velocities could be followed only up to about 0.7 volt (in a few cases to 1.0 volt) owing to the masking by the positive ions of the electron currents to the probe at greater negative potentials. Therefore the presence of the fast electrons is indicated only by the fact that the Maxwellian distribution holds very closely for the slow electrons and we assume it to hold for higher speeds.

Considerable difficulty was experienced with the probe owing to changes in its contact difference of potential in the course of a measurement. This was evidenced by a gradual shift in the voltage corresponding to a given current to the probe. The curve taken with increasing voltage did not coincide with that for decreasing voltage. The direction and amount of the drift were not always the same but depended upon the material used for the probe, its size and the presence of small amounts of impurities in the tube. In general one to two minutes were required for any phase of the change. When, however, the currents to the probe were large the resultant heating caused more rapid changes. A complete discussion of the many tests made cannot be given here, but it may be noted that similar effects were found with platinum, tungsten, iron and carbon probes; a tungsten probe continuously heated to a temperature of about 1700° C was equally unsteady; a trace of sodium accidentally introduced into the tube resulted in a characteristic fluctuation.

It is probable that this drift was due to traces of oxygen in the tube. To test this an artificial leak was introduced near the cathode, as the result of

which the changes in the contact potential of the probe became very rapid, confirming this conclusion. It was further found that, although all metal parts were pre-outgassed and the tube baked at 500° C for many hours before introducing the mercury, considerable gas was evolved when the arc was running even after many hours of operation. Tests, made by closing the cut-off and measuring the rate of accumulation of gas in the gauge, indicated that there was a gas pressure in the stream of mercury vapor of about 10^{-7} mm at the times when marked drifting occurred. This drifting was never wholly eliminated, but, by continued baking and pumping, conditions were attained under which the drifting was sufficiently small to permit satisfactory measurements.

It is probable that many of the troubles experienced by other observers were due to this cause. The difficulty which Mohler and Boeckner⁸ found with a probe in caesium vapor is not surprising, especially the increased unsteadiness when approaching large values of the probe current. It was found also in our work, as in theirs, that a large probe gave less trouble, since it suffered less rise of temperature. Other authors have obtained curves deviating from the expected straight line, or curves which are interpreted as made up of several straight lines indicating several groups of electrons each having a different temperature. Some of these complexities may have been due to effects similar to those described here.

The vapor pressure in the tube at the point of observation depended upon the temperature of the lower furnace and upon the use and position of the cooling coils on the condenser. The magnitude of this pressure was determined approximately by measuring the temperature at which liquid mercury was in equilibrium with the vapor at the end of the small side tube opposite the point of observation.

The electron temperature at the point of observation, though it depended to some extent upon the vapor pressure and the velocity of the vapor streaming from the region of the arc, was usually controlled by the gauze *G*. A positive potential on *G*, with respect to the anode, accelerated the electrons in the vapor stream and increased the temperature of those passing through the gauze and down the tube. Temperatures ranging from 1000° to 6000° could be obtained. The application of the positive potential to the gauze also decreased the concentration of the ions and electrons, in some cases as much as 70 percent. The concentration could, however, be brought back to its original value by increasing the arc current.

RESULTS

In determining the relation between the intensity of the afterglow, *I*, and the electron temperature, *T*, the vapor pressure was held constant for each series of measurements. It was assumed that the only other variable was the concentration of the electrons, which was equal to that of the ions, and this was kept as nearly constant as possible by adjusting the arc current. As this

⁸ Mohler and Boeckner, B. S. J. of Res. 2, 489 (1929).

concentration could be held only approximately constant the relation between intensity and concentration, N , was determined by a series of measurements in which the vapor pressure and electron temperature were kept constant. The results of these determinations are shown in Figure 2, in which the intensity of the afterglow is plotted as a function of the electron concentration. Three typical curves are shown, the differences in the slopes having no significance. These curves show that the intensity is closely proportional to the first power of the electron concentration, and not to the square of this concentration as might be expected if ordinary recombination processes were in question. Therefore, before studying the relation between intensity and

Fig. 2. Intensity of afterglow vs. electron concentration; electron temperature and vapor pressure constant. Scales are arbitrary.

electron temperature the intensities observed were divided by the first power of the corresponding number of electrons. Furthermore throughout any set of measurements of the relation of I to T the variation in N was not large and since the variation of the intensity with electron temperature was very rapid, errors arising from small departures from the first power relation were well within the limits of measurement.

It is interesting to note that Mohler and Boeckner⁸ found a similar result with caesium. Contrary to expectation the intensity varied more nearly as the first power than as the square of the concentration of electrons, which was again equal to the number of positive ions. They noted, however, that at low currents the square law held. In the present experiment, also, there was indication that, for small concentrations especially at low electron temperatures, the square law more nearly described the results than the first power law. These results were however, not very dependable.

The relation between the intensity of the afterglow and the vapor pressure, the temperature of the electrons and the number of ions and electrons being held constant, was not precisely determined, owing to experimental difficulties. The results showed, however, a large increase in intensity with increase of vapor pressure. To a rough approximation the intensity varied as the fourth power of the vapor pressure within the limited pressure range observed, 0.06 to 0.10 mm. It is interesting to note that Mohler and Boeckner found in the recombination spectrum of caesium that the intensity increased surprisingly rapidly with vapor pressure, the rate of increase being comparable with that found in the present work.

Fig. 3. Intensity of afterglow as a function of electron temperature; vapor pressure and electron concentration constant. Curve a: $\log I$ vs. T (lower temperature scale). Curve b: $\log I$ vs. T (upper temperature scale). Curve c: $\log I/T^{1/2}$ vs. $1/T$. Curve d: $\log I/T^{3/2}$ vs. $1/T$.

The experimental results giving the relation between the intensity of the afterglow, I , and the electron temperature are shown in Figure 3. Curve (a) shows the results for a vapor pressure of 0.06 mm. The ordinates are the intensities, corrected for variations in N , plotted for convenience as $\log_{10} I$. The abscissas are electron temperatures in $^{\circ}\text{K}$. In these measurements N was of the order of 10^{11} per cc.

Curve (b) Figure 3, shows the results for another set of measurements at approximately the same vapor pressure. Owing to the fact that in this case no determinations of N were made, this curve has not been corrected to $N =$

constant. The variation of N over this curve may have been as great as three-fold. The intensity scale is furthermore not the same as in Curve (a), owing to the use of a different photometric standard. This curve shows, however, that at higher temperatures the variation of I with T follows roughly the same law as in the lower temperature range. The striking feature of these curves is the very large decrease in I with small relative increase in temperature. Curve (a) shows a decrease in I of about 400 times as T increases from 1300° to 3600°K . Including the data of Curve (b) we see a decrease in I of about 2500 times as T changes from 1300° to 5600° .

DISCUSSION

As pointed out earlier the rapid change of intensity, I , with electron temperature, T , observed in the afterglow cannot be explained by any simple process of recombination in which the decrease in the rate of recombination depends simply upon the increase in the average velocity of all the electrons. For, if the recombination is similar to that observed in caesium, with the coefficient of recombination approximately proportional to $1/v$ (v =electron velocity) and the electrons have a Maxwellian velocity distribution as seems to be the case, to a first approximation I should be proportional to the integral taken over all velocities of the number having a velocity v divided by v . This is equal to $\text{const } N^2/T^{3/2}$ where N is the total number of electrons, considered here as held constant. The total change in $1/T^{3/2}$ over the entire range of electron temperatures measured was not greater than 3, while I changed by a factor of nearly 2500, a different order of magnitude. Now, on the other hand, if we consider N_0 , the number of electrons having energies greater than some given value, E_0 , we see that this can be made to vary with the electron temperature as rapidly as we please, by proper choice of E_0 . We have

$$N_0 = N [\text{erf } (E_0/kT)^{1/2} + (2/\pi^{1/2})(E_0/kT)^{1/2} e^{-E_0/kT}]$$

in which expression, if E_0 is not too small, the second term containing the exponential factor is the controlling one. (In the present work neglecting the first term introduces only an inappreciable error.) Now the simplest empirical relation between I and T which fits the results was found to be $I = C_1 T^n e^{C_2/T}$, equation (1), where C_1 and C_2 are constants and n is small. Because of the large value of the exponent the exponential term was found to be the important factor in determining the form of the curve and the precision of the measurements was not sufficient to enable one to differentiate between small values of n . The agreement between experiment and equation (1) can be seen from Curve (c), Figure 3, in which the data of Curve (a) have been replotted, with ordinates $\log_{10}(I/T^{1/2})$ and abscissas $1/T$. The points fall well within the experimental error on the straight line, $\log_{10}(I/T^{1/2}) = \text{const}/T + \log_{10} C_1$. In this plot n was taken as $\frac{1}{2}$ for reasons to be given below. Other series of measurements, taken at vapor pressures ranging from 0.06 mm to 0.10 mm when plotted in the same way gave nearly equally good agreement with the equation.

Now if I be taken proportional to N , as was found to be approximately true, equation (1), after rearranging, becomes:

$$I = \text{const } N^2 \div [N(2/\pi^{1/2})(E_0/kT)^{1/2}e^{-E_0/kT}] = \text{const } N^2 \div N_0 \quad (2),$$

where k is Boltzmann's constant. Thus we may express our results very well in the simple form, that the intensity of the afterglow varies directly as the square of the total number of electrons and inversely as the number of electrons having energies greater than E_0 . If instead of N_0 , we consider the number, N_1 , of electrons having an energy equal to E_0 , we arrive at a similar result. N_1 varies as $(1/T^{3/2})e^{-E_0/kT}$, and if in equation (1) we put $n=3/2$, we obtain the result, $I = \text{const } N^2/N_1$. This results in a linear relation between $\log_{10}(I/T^{3/2})$ and $1/T$, as shown in Curve (d) Figure 3, in which the data of Curve (a) are expressed in these coordinates. We therefore find that we are in equally good agreement with experiment if in equation (2) we substitute N_1 for N_0 , which gives the result that the intensity is inversely proportional to the number of electrons having their energy equal to E_0 . The part played by the fast electrons is thus to prevent the afterglow, the effect of electron temperature on the intensity depending primarily upon the change in the number of such electrons. It should be remarked that this general conclusion does not rest solely on the close fit of the results with the relations given above but seems to be a necessary conclusion from the observed rapid change of I with T , so long as we assume that the effect of each electron on the process is a function of its energy and not of the mean energy of the whole group of electrons.

The value of E_0 as determined from the data of Curve (c) is 1.15 volt, from Curve (d) 1.35 volt. The values found from other series of measurements, when computed as in the case of Curve (c), range from 0.95 to 1.20 volt. The lowest value was obtained from a set of measurements covering only the lower temperatures and was probably affected by the fact that the intensities were often found to be less than those corresponding to the above equations when the electron temperature was below 1400° . Considering the precision of the measurements it seems probable that E_0 is a constant, independent of the vapor pressure and other conditions and that the best average of the values determined is 1.15 volt when computed assuming I to depend upon N_0 , and 1.35 volt if it depends upon N_1 . Furthermore, unless the efficiency of this preventative action of the fast electrons rises very rapidly as their energies approach the value E_0 from below, it seems that we must assume that E_0 is a minimum or a critical value for the energy of an electron which can so function and not an average value.

There has been found no evidence that metastable or excited atoms of the 2^3P states play any major part in the afterglow phenomenon.

Our results suggest that we are dealing with a process more complex than that of a simple recombination in which only a single electron and an ion take part, possibly a recombination process involving two electrons and an ion. The form of equation (2) suggests that this process is of the type illustrated by the following hypothetical picture, suggested by Mr. George Dean.

Assume that under the conditions in question complete recombination is accomplished in two stages, a first stage in which a slow electron falls into an outer level of the positive ion, and a second stage in which the electron makes a transition from this outer level to a lower level with the emission of series line radiation.* The first stage may be assumed to be accompanied by continuous radiation and to be governed by the laws similar to those governing the recombination observed in caesium and helium discussed above. Assume further that fast electrons having energies greater than a certain minimum value E_0 (or electrons having exactly the energy E_0) to be capable of reionizing the atom which has experienced only the first stage of recombination. Let N' be the concentration of such "partially recombined" atoms. The rate of formation of these atoms is $AN^2f(T)$ where $Af(T)$ is the coefficient of recombination, A being constant. The rate at which these atoms would change into normal atoms is given by RN' , where R is a transition probability. The rate of reionization of the partially recombined atoms would be $CN'N_0$, where N_0 is, as above, the concentration of electrons having energies in excess of E_0 . Now we are observing a steady state in the vapor stream and N' is constant. If we neglect a small term giving the diffusion rate of N' into the space observed, we get

$$AN^2f(T) - RN' - CN'N_0 = 0 \quad (3)$$

or

$$N' = AN^2f(T)/(R + CN_0). \quad (4)$$

Now except for the smaller values of T , R may be neglected with respect to CN_0 in the denominator of equation (4), since for larger values of T , RN' is negligible with respect to $AN^2f(T)$ and therefore with respect to $CN'N_0$. This follows since RN' is proportional to the intensity of the afterglow, I , which decreases very rapidly with increase in temperature while $AN^2f(T)$ varies not faster than $1/T^{3/2}$.

If $f(T)$ is taken equal to a constant we have from (4) $I = \text{const } N^2/N_0$, agreeing with the empirical equation (2) which expresses the experimental results. If $f(T)$ is taken equal to $1/T^{1/2}$, as suggested in the first paragraph of this section, we have $I = \text{const } (1/T^{1/2})(N^2/N_0)$ which gives equally good agreement with experiment. The value of E_0 in this case is about 7 percent lower than in the case of $f(T) = \text{constant}$.

In the above N_1 , the number of electrons having exactly the energy E_0 , may be substituted for N_0 without further change except that the corresponding values of E_0 would be increased by about 15 percent.

For the smaller values of T at which observations were taken and for small values of N , R may be no longer negligible with respect to CN_0 and we should then find the intensity less than would be expected from equation (2), and would further find for diminishing N that the intensity would vary more

* Compare this with the "initial recombination" postulated by J. Franck (Zeit. f. Physik 47, 509 (1928)): see also L. R. Maxwell (Phys. Rev. 32, 715 (1928)).

nearly as the second power of N . The experimental results give evidence that this is the case, but are not sufficiently reliable to test this in detail.

It is obvious that the first stage of recombination assumed above may not necessarily involve an electron and a positive ion but may be the formation of some kind of molecular state, which in breaking up leaves the atom with such excitation as is necessary for the radiation of the arc lines. Recent studies by Mohler and Boeckner⁹ of the photoionization of caesium indicate that the molecule ion plays a major part in that process and it is therefore probable that it is also an important factor in recombination. The picture given above represents only the type of process which the experimental results seem to indicate as necessary to account for the properties of the after-glow radiation in mercury vapor.

Lawrence¹⁰ and other investigators have found a series of ultra-ionization potentials lying above the normal 10.4 volts ionization potential. The first four of these lie 0.20, 0.89, 1.30 and 1.66 volt, respectively, above 10.4 volts. It is suggested that the critical potential E_0 may be related to one of these ionization potentials.

ON THE PERSISTENCE OF MOLECULAR ROTATION
AND VIBRATION IN COLLISION

BY O. OLDENBERG

JEFFERSON PHYSICAL LABORATORY, HARVARD UNIVERSITY

(Received December 5, 1930)

ABSTRACT

The present paper attempts to explain some observations on the exchange of vibrational and rotational energy of molecules on the basis of the laws of impact, taking into account the postulate of quantisation. It is pointed out that when one of the bodies involved in the impact is much lighter than the other the exchange of energy becomes improbable. The persistence of rotation of HgH molecules in an excess of nitrogen, suggested by Beutler and Rabinowitsch, is discussed. A related phenomenon is found in some chemical activations produced by H_2 molecules but not by any other molecule. The resonance rule for the probability of impacts of the second kind needs some modification for the exchange of vibrational and rotational energy between molecules. The transfer of vibration and rotation from the excited iodine molecule is discussed. In electron impact, the rotation of the molecule does not change, but the vibration does. This is interpreted on the basis of a hypothesis introduced by Franck and Jordan. Within ordinary gases, N_2 or H_2 or I_2 , no persistence of vibration or rotation should be expected.

IN THE present paper, an attempt is made to explain some observations, concerning molecular vibration and rotation from a classical standpoint, taking into account the postulate of quantisation. It should be emphasized, that this treatment of impact is intended to serve only as an approximate picture which may be of value as a starting point for experimental work.

I. ROTATION OF HgH IN N_2

In a recent paper, Beutler and Rabinowitsch¹ offer an interesting interpretation of an experiment carried out several years ago by Wood and Gaviola.² These authors investigated the "sensitized fluorescence radiation" of Hg vapor with the addition of very little hydrogen and a considerable amount of nitrogen. Exciting the mercury atoms, they observed in fluorescence the band spectrum of the HgH molecule. It is a strange fact that the intensity distribution within the individual band corresponds approximately to a temperature of 3000°K, although the experiment is carried out at room temperature.

In a thorough discussion, Beutler and Rabinowitsch come to the conclusion that the excited HgH molecules are produced in the following two steps. The first elementary process consists of the exchange reaction $Hg' + H_2 = HgH + H$. In this reaction the 0.62 volt excess atomic energy over the required chemical energy changes partly into rotational energy of the HgH molecule, thus producing a rotation far exceeding the normal value. In a

¹ H. Beutler und E. Rabinowitsch, *Zeits. f. Physik. Chem. (B)* 8, 403 (1930).

² E. Gaviola and R. W. Wood, *Phil. Mag.* 6, 1191 (1928).

later process, this HgH molecule is excited by an impact of the second kind with another excited mercury atom. There are, however, only a very few of these excited mercury atoms. Therefore the authors assume that the anomalous rotation of the molecule HgH, produced in the first process, persists until the HgH collides with an excited Hg atom, in spite of a great many (more than 1000) collisions, most of them with N_2 molecules. It is possible of course, that the HgH molecule is formed with a still higher energy of rotation and gives part of it away. At any rate it is unexpected that the great number of intermediate collisions should fail to reduce the rotational energy to the normal value before the excitation of the molecule takes place. Are we able to understand this apparent persistence of rotational energy by the laws of impact?

An essential feature of the experiment is the heavy molecule HgH, having but a small moment of inertia, colliding with the molecule N_2 , which is heavy compared with the H-atom. A reasonable picture of the collision is that the HgH molecule consists of the heavy mercury atom at rest and the H atom revolving about it with highest speed because of its small weight and the ab-

Fig. 1. Transfer of rotational energy of HgH to N_2

normal rotation produced by the excess energy of the reaction. This system collides with the N_2 molecule, supposed to be comparatively slow and not rotating. This impact is evidently related to the ordinary impact between a light and a heavy particle: the light particle is unable to give away any considerable fraction of its energy on account of the laws of impact.³ In collision, the rotational energy and the moment of momentum given up by the HgH, split up generally into two parts, one of them going over into *rotation* of the N_2 , the other into *translation* of the N_2 , knocked away from the heavy system HgH in the direction of the arrow (Fig. 1a).

Since the general discussion of this collision is complicated, it will be sufficient to treat two extreme cases. First, we assume that the fast H atom in its circular orbit collides in a head-on collision (Fig. 1b) with a rigid body, representing the N_2 molecule. Thus from classical mechanics, we come to the result that the H atom is able to give away $1/7.5$ of its energy (or less if the collision is not head on).

Let us next consider the other extreme case, in which the rotational energy of the HgH goes over as much as possible into *rotational* energy of the N_2 molecule (Fig. 1c). The fast H atom hits the left N atom, while moving toward its nucleus and perpendicular to the nuclear axis of the N_2 molecule. This col-

³ Cf. J. Franck, Zeits. f. Physik 25, 312 (1924) and G. Joos und H. Kulenkampff, Phys. Zeits. 25, 257 (1924).

lision accelerates the left N atom in a direction, in which it can move an infinitely small distance, without accelerating the right N atom. Therefore, we are allowed to compute the resulting motion of the whole N_2 molecule in two separate steps. In the first step, only the left N atom is accelerated by the fast H atom; and after the collision, in the other step, the kinetic energy of this N atom produces such a translation of the whole N_2 molecule that its center of gravity keeps its velocity constant and in addition the molecule starts its rotation. The result is that the HgH molecule can give away $1/4$, or probably less, of its rotational energy. The same reasoning should hold for the persistence of vibrational energy, although no observation of the phenomenon is known.

Since collisions are not head on in general, we understand that the rotational energy of HgH is given away in collision with N_2 molecules only in small steps—or with small probability if only large quanta are available. Thus we understand a persistence over let us say 10 or 20 collisions, but not over many thousand collisions, as suggested by Beutler and Rabinowitsch. This smaller amount of persistence, however, seems to be sufficient, if we assume a slightly different process of excitation. We assume that the metastable atom Hg' excites a HgH molecule with normal rotation, but with considerable vibration. This type of transition is understood by the Franck-Condon rule. When the H atom, vibrating as a part of the HgH molecule, collides with a comparatively heavy body, e.g., the N_2 molecule, its energy may change easily into its own rotational energy. On account of the laws of impact, the heavy N_2 molecule takes away only a small amount of energy. Thus a HgH molecule is produced with strong rotation which may collide, before it radiates, several times with N_2 without losing much of its rotational energy. When in a mixture of molecules containing light and heavy atoms some light atoms have a preferred energy, the general tendency is that equipartition of energy is reached first among the degrees of freedom of the light particles, much later among the degrees of freedom of the heavier particles. When N_2 is replaced by H_2O , we expect a rapid dissipation of the rotational and vibrational energy of HgH on account of the numerous H atoms present.⁴ This explanation differs from that of Beutler and Rabinowitsch in that it assumes a persistence of rotation only during the life-time of the excited state, i.e., over a few collisions, but not over the long period between formation and excitation of the HgH molecule.

2. RELATION TO ACTIVATION ENERGY

In the present theory, the persistence of vibration and rotation is interpreted not as a fundamental quality of these degrees of freedom, but as due to the special interaction of light and heavy bodies in collision. Therefore it

⁴ Presumably the peculiar intensity distribution in the HgH bands, observed in the electric discharge by W. Kapuscinski and J. E. Eymers (*Zeits f. Physik* 54, 252, 1929) is to be explained by the same phenomenon. However, the process of excitation in the electric discharge is not so well understood as in fluorescence; in the discharge, excitation could take place in the same elementary process as the formation of the molecule HgH, contrary to the fluorescence experiment.

should be expected that this persistence plays a part in chemical activation, because it may happen that some molecules are able to give away activation energy, as far as it is vibration or rotation, not to any partner but only to a selected type of molecule.

Professor G. B. Kistiakowsky has pointed out to me, that possibly this type of selection plays a part in the "mono-molecular" decomposition of some organic compounds. From a thorough experimental and theoretical discussion, Hinshelwood⁵ has drawn the conclusion that hydrogen, but no other gas, has a special power to activate the vapors of diethylether, dimethylether, propionic aldehyde and acetaldehyde by thermal impact. These organic molecules contain groups of H atoms. It might be assumed that the energy of activation consists largely of vibration of these H atoms. According to the present argument, their vibration should show a persistence in collision with heavier molecules but not with the lightest molecule H₂. This ability to *give away* vibrational energy should correspond, according to the principle of microscopic reversibility, with the ability to *take up* vibration from a colliding H₂ molecule, but not from heavy molecules.

It remains to explain, however, why helium fails to show the same effect, although it has only two times the weight of H₂. As in the interaction between HgH and N₂, we assume again that the vibration of an H atom, belonging to the organic molecule, is excited by ordinary collision with the H₂ molecule or the He atom. Both of them are somewhat heavier bodies which must have a sufficient excess of energy in order to give the energy of vibration to the bound H atom. From the Raman effect this energy level of vibration of the H atom attached to carbon is known⁶ to be approximately 3000 cm⁻¹. According to the laws of impact, the H₂ molecule must have 12.5 percent more energy, whereas the He atom must have 69 percent more energy. Assuming a temperature of 520°C as in Hinshelwoods experiments, we come to the conclusion, that the number of H₂ molecules, able to activate, is ten times larger than the corresponding number of He atoms. This ratio, calculated only from the masses of H₂ and He, seems to be not quite sufficient to explain the observed difference. It should be taken into account, however, that the H₂ molecule with its five or six degrees of freedom contains on the average much more total energy than the He atom with its three degrees of freedom.

3. PROBABILITY RULE FOR IMPACTS OF THE SECOND KIND

On the basis of a group of experiments, Frank and Jordan⁷ have established the general rule that in impacts of the second kind most probably the smallest possible amount of energy of *translation* is produced. Kallmann and London⁸ derived the same rule from wave mechanics, describing the transfer

⁵ C. N. Hinshelwood, Proc. Roy. Soc. A114, 84 (1927) and C. N. Hinshelwood and P. I. Askey, Proc. Roy. Soc. 115, 215 (1927) and 116, 163 (1927).

⁸ H. Kallmann und F. London. Zeits. f. physik. Chem. (B) 2, 207 (1929).

of excitation energy by a resonance phenomenon without introducing the translation in their equations explicitly. Corresponding to this rule, Beutler and Rabinowitsch discussed the persistence of rotation assuming that the rotational energy of HgH should change in collision mainly into *rotational* energy of N_2 , only the smallest possible fraction going over into energy of *translation*.

Franck and Jordan based their rule on experiments in which the initial state of the energy is represented by an excited *electronic level*. It is doubtful if this rule applies without modification to the exchange of vibrational and rotational energy between molecules. However, this exchange can be represented to some extent by classical mechanics.⁹ The mechanical treatment of exchange of vibrational and rotational energy between two colliding molecules leads necessarily to the formation of a considerable energy of translation, (cf. Fig. 1c) thus violating the rule that no energy for translation is produced. Hence the rule seems to apply strictly to a limiting very important case i.e. the exchange of energy between electronic levels.¹ For the motion of heavy masses, however, it requires some modification.

4. ROTATION AND VIBRATION OF I_2 IN He

Some related phenomena are known. Beutler and Rabinowitsch refer to the iodine fluorescence radiation, excited by monochromatic light and changed, according to the experiment of Franck and Wood,¹¹ by the addition of helium. This experiment shows a transfer, although a rather slow one, of rotational energy of the iodine molecule. Some persistence of rotational energy is in this case probably due to the large mass of each iodine atom making impossible the transfer of much energy in a single collision with a light He atom.

Wood and Loomis¹² describe the transfer of *vibrational* energy from I_2 to He , observed in the same experiment. It takes place very seldom, although from the standpoint of mechanics it could take place as well as the transfer of rotational energy.

We may explain the observation that the vibration is affected less than the rotation by taking into account a general distinction between rotation and vibration. The rotational energy is in any moment kinetic energy, where-

⁹ How successful this classical treatment of the nuclear motion is, can be seen in the accomplishments of the theory of intensity distribution in band spectra, based on a mechanical picture by Franck, extended and expressed in wave mechanics by Condon (Proc. Nat. Acad. Sci. 13, 462 (1927)).

¹⁰ If there is kinetic energy of a heavy mass produced—e.g. excitation of Hg going over into vibration of N_2 —it should take place indirectly as discussed below, footnote 14.

¹¹ J. Franck and R. W. Wood, Verh. d. d. phys. Ges. 13, 78 (1911).

¹² R. W. Wood and F. W. Loomis, Phil. Mag. 6, 231 (1928). This phenomenon in which the colliding H atom takes up only a small part of the vibrational energy of the heavy I_2 is related to the phenomenon described by Knudsen's "accommodation coefficient" which, in turn, defines the degree to which a reflected gas molecule adjusts its energy to that of the reflecting surface (Ann. d. Physik. 34, 519 (1911)). For Pt and W surfaces this coefficient increases with the molecular weight of the gases.

as in vibration the energy changes continually between the kinetic and potential form. It is available for impact only in the short time interval in which most of it is kinetic and in which the atoms are moving apart. Hence in collisions with a monatomic gas, vibrational energy should show a greater persistence than rotational energy.

In order to explain Wood's and Loomis' observation (the comparatively large persistence of vibration) still another difference between vibration and rotation should be taken into account. Let us consider the inverse process. He atoms of high speed colliding with I_2 molecules, which may be considered to have no appreciable energy. How probable is the transfer of the kinetic energy of the fast He atom into vibration or rotation or translation of the I_2 molecule? For exciting *vibration*, the most favorable direction is along the *line* of the nuclear axis (Fig. 2a). For exciting *rotation*, however,

Fig. 2. Excitation of vibration and rotation of the I_2 molecule by the He atom.

the most favorable direction of the He atom is any direction within the two *planes*, represented by dotted lines in Fig. 2b. Finally, for the transfer of energy of *translation* from the He to the I_2 , there is no direction preferred within the whole *spherical angle*. Therefore the chance for translation is larger than for rotation, and this again larger than the chance for vibration. We may conclude, that in the inverse process, where the He atom takes up energy, the vibration of the I_2 molecule should be more persistent than the rotation, in agreement with Wood's and Loomis' observation.

5. EXCITATION OF VIBRATION AND ROTATION BY ELECTRON IMPACT

Similar considerations may be applied to the excitation of molecular vibration and rotation by electron impact. From his experiments, Harries¹³ drew the conclusion, that a 5-volt electron is able to excite *vibration* of the N_2 molecule, but that it cannot excite *rotation* at all. It has been pointed out by Franck and Jordan,¹⁴ that this excitation of vibration cannot be understood by an ordinary elastic collision of the fast electron hitting the molecule head on (Fig. 2a), because the light mass of the electron is not able to give away this large fraction of its energy in elastic collision. The same inability of the electron holds for rotational energy, although the rotational quanta of N_2 are much smaller than the vibrational ones.¹⁵

¹³ W. Harries, Zeits. f. Physik 42, 26 (1927).

¹⁴ J. Franck and P. Jordan, Anregung von Quantensprüngen durch Stöße, pp. 255 and 244.

¹⁵ W. Rasetti, Phys. Rev. 34, 367 (1929); the 5-volt electron giving away 1/1400 of its energy to an N atom, cannot excite the rotational quanta of the N_2 molecule. The same result holds in collision with a H_2 molecule.

Instead of the ordinary elastic collision between the 5-volt electron and the N_2 molecule, Franck and Jordan assume that the approaching electron has some influence by its electric field on the law of force keeping the N atoms together. The main difference between both pictures of collision is the following: in the ordinary elastic collision, the impinging electron would transfer part of its energy and impulse directly into translation or vibration or rotation of the molecule. In the hypothesis of Franck and Jordan, however, the electron penetrates the structure of the molecule. Without exciting a higher electronic level of the molecule—the first level requiring 8 volts—the electron modifies by its field the law of force keeping the atoms together. Thus by its mere presence, the electron may shift the equilibrium position of the nuclei, represented by the minimum of the potential curve. The nuclei start the vibration, accelerated not directly by the impact of the electron, but indirectly by the modified law of force. If the passage of the electron across the molecule takes an appreciable time compared with the period of vibration, it may happen, that the electron leaves the molecule in the vibrating state. From our point of view, the main feature of this hypothesis is, that the acceleration of the nuclei is produced indirectly by the modified law of force. This can give rise only to vibration, not to rotation on account of the conservation of moment of momentum. Therefore in collision with 5-volt electrons, we should expect an energy transfer in vibration only, but a strong persistence of rotation. This conclusion is in full agreement with Harries' experiments.¹⁶

(It would be hard to introduce the corresponding assumption that in the collision between I_2 and He discussed above, the *neutral* He atom, colliding at room temperature with an energy as low as 0.03 volt, causes an appreciable change in the law of force of the I_2 molecule. In this collision between heavy bodies there is no reason to discard the ordinary mechanical picture of the collision.)

6. EXCHANGE OF VIBRATION AND ROTATION WITHIN ORDINARY GASES

In the examples discussed above, some persistence of vibration or rotation is due to the extreme ratio of masses, e.g. of electrons colliding with N_2 molecules. The most important case consists of collisions within the molecules of the same gas, N_2 or H_2 or I_2 . No restriction for the energy transfer and therefore no persistence of the same type should be expected.

Concerning these collisions, there are almost no optical data available.¹⁷

¹⁶ The marked resonance in the transfer of excitation of the Hg atom into vibration of N_2 or CO or H_2O (H. Beutler and E. Rabinowitsch, *Zeits. f. physik. Chem. B.* **8**, 411 (1930)) demonstrates that no appreciable translation is produced. Therefore, this process is very different from a mechanical impact, as should be expected because the initial state of the energy, the excited state of the atom, has no kinetic energy of a heavy mass. It should be described by a similar picture as Franck's and Jordan's, i.e., we assume that the close contact with the excited Hg atom modifies the electronic level and therefore the law of force of the molecule and changes the equilibrium position of the nuclei, thus starting vibration. (Cf. H. Beutler and W. Eisenschimmel, *Zeits. f. physik. Chem.* **10**, 103, 1930.)

¹⁷ The complicated background in Wood's photographs of the resonance series in I_2 with long exposure (*Phil. Mag.* **35**, Plate VI, f. 1918) should be due to this process.

Professor A. Eucken called my attention to the fact, that we may draw a conclusion from thermal measurements. It is consistent with our expectation that the ratio of specific heats, measured from the velocity of sound, does not change at the highest frequencies¹⁸ which means that, even for the quickest change of temperature, equipartition is maintained among all degrees of freedom of the diatomic molecule. It should be concluded that vibration and rotation are taking their full share in the exchange of energy. The great experimental difficulty, however, in these experiments should be emphasized.

The classical treatment of impact applied in the present paper is intended to serve only as an approximate picture which may be good as a starting point for experiments. An experimental investigation is under way. A more thorough treatment of these processes on the basis of wave mechanics is being developed by Dr. C. Zener. Some interesting results, published recently by R. Rompe¹⁹ lead to the conclusion that some specific influence of the electronic term takes place. This kind of influence does not lend itself to representation by a classical picture.

Our main conclusion is that the persistence of vibration and rotation can be explained largely by classical ideas. Especially in the complicated interpretation of the HgH fluorescence given by Beutler and Rabinowitsch, the most doubtful detail, i.e., the excitation of abnormally rotating molecules, is understood by a general rule, the equipartition of energy being reached at a rate depending largely on the ratio of the weights of the particles. This result supports the other steps of the interpretation given by Beutler and Rabinowitsch which are of importance in photochemistry.

The author greatly appreciates the criticisms of Professor J. Franck, Professor E. C. Kemble and Dr. C. Zener.

THE INTRAMOLECULAR FIELD AND THE DIELECTRIC CONSTANT

BY FREDERICK G. KEYES AND JOHN G. KIRKWOOD*
RESEARCH LABORATORY OF PHYSICAL CHEMISTRY,
MASSACHUSETTS INSTITUTE OF TECHNOLOGY.**

(Received November 28, 1930)

ABSTRACT

A statistical calculation of the average internal field in a dielectric is carried out. The following relation is obtained between the dielectric constant, ϵ , and the molecular polarizability, p_0 :

$$\frac{\epsilon - 1}{\epsilon + 2} V = \frac{4\pi N p_0}{3} \frac{1}{1 - \lambda_0 \rho}$$

where V is the molal volume, ρ is the density and

$$\lambda_0 = \frac{32\pi^2 N^2 p_0^2}{45B} \left(1 + \frac{1}{3} \frac{A}{BRT} \right).$$

Here A and B are the constants of a van der Waal type equation of state. This expression becomes identical with the familiar Clausius-Mosotti relation in the limit of zero density. The formula is applied to dielectric constant measurements on several gases.

INTRODUCTION

THE concept of the dielectric constant rests upon a simple empirical basis. Faraday's experiments suggested that the intensity of the field arising from a given distribution of charge was less in a material substance than in free space. There was, moreover, evidence that the field intensity in a non-conducting substance was proportional to the original field intensity in free space. These facts were formulated in the following equation:

$$D = \epsilon E \tag{1}$$

where D , the dielectric displacement, is most simply interpreted as the field intensity existing in free space for the given charge distribution and E is the field intensity arising from the same distribution in a substance of dielectric constant ϵ . In view of the molecular character of the dielectric, it is clear that the measured field E is an average value, for macroscopic measuring systems are incapable of detecting the fluctuations in E occurring in the intervals of space and time associated with the thermal motion of the molecules. The fluctuations in the molecular configuration must, nevertheless, play an important part in determining the average polarization of the moving molecules constituting the dielectric.

Before it is possible to correlate the dielectric constant with the polarizability of the molecules, it is necessary to calculate the average value of the

* National Research Fellow.

** Contribution No. 253.

field effective in polarizing a molecule. Moreover, it is evident that the average internal field, referred to the moving molecule will not be identical with the field E referred to a point fixed relative to the external measuring system.

The Clausius-Mosotti relation is usually accepted as giving the relation between the dielectric constant of a substance and the polarizability of its constituent molecules. The computation of the internal field which leads to this formula purports to be based upon molecular considerations, but in the analysis, use is made of the device of a spherical cavity excised about the molecule. This seems justifiable only when the dielectric material is considered to be a continuum. The empirical success of the resulting formula in no way answers the logical objections to this analysis. For this reason, the use of the Clausius-Mosotti relation except in the case of gases at low density, where it has received adequate empirical confirmation, has been attended by great uncertainty.

There is here presented a statistical calculation of the average internal field leading to a formula which becomes identical with the Clausius-Mosotti relation in the limit of zero density, but which deviates somewhat from it at higher densities.

LIMITATIONS OF THE CASE CONSIDERED AND DERIVATION OF DIELECTRIC CONSTANT FORMULA

The considerations to follow will be restricted to the relatively simple case of a gas of sufficiently low density so that the probability of molecular encounters involving more than two molecules is insignificantly small; and to temperatures sufficiently high so that an inappreciable fraction of the molecules are in quantized collision states such as may occur in molecular aggregation. Under these conditions the molecules may be regarded as continuously distributed in configuration, and moreover, the potential energy may be expressed as a sum of terms involving the relative coordinates of only two molecules.

It is desired to investigate the effect on the molecules constituting the fluid of an homogeneous external electric field. Take for consideration the region between the parallel plates of a condenser assumed to be filled with a fluid in equilibrium consisting of $n+1$ molecules of identical polarizability. Select for observation a molecule j not in the immediate neighborhood of the boundaries. The instantaneous and total field F_j acting on j may be written,

$$F_j = D + F_j' \quad (2)$$

where, as before, D , the dielectric displacement, is the field arising from the external charge distribution on the condenser plates and F_j' is the field arising from the other molecules of the dielectric. If, however, F_{jk}' is the field arising from an arbitrary molecule k we may write,

$$F_j' = \sum_{k=1}^n F_{jk}' \quad (3)$$

The average value of any F_{jk}' term may be written:

$$\bar{F}_{jk}' = \frac{\int \cdots \int F_{jk}' e^{-u^*/kT} d\tau_1 \cdots d\tau_n}{\int \cdots \int e^{-u^*/kT} d\tau_1 \cdots d\tau_n} \quad (4)$$

where u^* is the total potential energy of the system and $d\tau_1$ is an element of the complete configuration space of a single molecule. The integration is to be extended over all of configuration space available to the molecules.

It will occasionally be convenient to consider F_{jk}' as averaged only over the orientations of the molecules, designated by \bar{F}_{jk}' , while the final average of \bar{F}_{jk}' over all configurations of the centers of gravity of the molecule will be denoted by $\bar{\bar{F}}_{jk}'$.

[Fig. 1.]

We proceed to calculate F_{jk}' , the molecular field acting on the molecule j originating in an arbitrary molecule k . Choose a system of rectangular coordinates (x, y, z) whose origin is at the center of gravity of j and z axis parallel to the vector D . Similarly choose a second system (x', y', z') , with origin at the center of gravity of k with axes parallel to (x, y, z) see Fig. 1.

Suppose molecule k to consist of an assembly of charges $e_1 \cdots e_i$ whose average positions in the isolated molecule are given by the coordinates $x_{i0}', y_{i0}', z_{i0}' \cdots x_{i0}', y_{i0}', z_{i0}'$. When a field is present it will be assumed that the perturbed positions, x_i', y_i', z_i' are given by

$$\begin{aligned} x_i' &= x_{i0}' + f_i X_k \\ y_i' &= y_{i0}' + f_i Y_k \\ z_i' &= z_{i0}' + f_i Z_k \end{aligned} \quad (5)$$

where the f_i 's are constants and X_k, Y_k, Z_k are the components of the field acting on k . By expanding the potential at the center of j due to all the charges constituting k in a series of powers of x_i', y_i', z_i' there results for the potential ϕ_{jk}' .

$$\begin{aligned}\phi_{jk}' = & \sum \frac{e_i}{r} - \frac{1}{r^2} \left[\frac{x}{r} \sum e_i x_i' + \frac{y}{r} \sum e_i y_i' + \frac{z}{r} \sum e_i z_i' \right] \\ & + \frac{1}{2r^3} \left[\left(\frac{3x^2}{r^2} - 1 \right) \sum e_i x_i'^2 + \left(\frac{3y^2}{r^2} - 1 \right) \sum e_i y_i'^2 \right. \\ & + \left(\frac{3z^2}{r^2} - 1 \right) \sum e_i z_i'^2 + 6 \frac{xy}{r^2} \sum e_i x_i' y_i' + 6 \frac{xz}{r^2} \sum e_i x_i' z_i' \\ & \left. + 6 \frac{yz}{r^2} \sum e_i y_i' z_i' \right] + \dots\end{aligned}\quad (6)$$

of which the first term is zero for a neutral molecule. Here x, y , and z represent the coordinates of the center of gravity of k relative to j and r is the separation of the centers. We assume that the field, F_{jk}' , defined by this potential may be regarded as homogeneous over the small region occupied by a molecule. For its z component we may write

$$\begin{aligned}Z_{jk}' = & -\frac{\partial \phi_{jk}'}{\partial (-z)} = \frac{1}{r^3} \left[\left(\frac{3z^2}{r^2} - 1 \right) \sum e_i z_i' + \frac{3xz}{r^2} \sum e_i x_i' + \frac{3yz}{r^2} \sum e_i y_i' \right] \\ & - \frac{1}{2r^4} \left[\left(15 \frac{z^3}{r^3} - 9 \frac{z}{r} \right) \sum e_i z_i'^2 + \left(15 \frac{x^2 z}{r^3} - 3 \frac{z}{r} \right) \sum e_i x_i'^2 \right. \\ & + \left(15 \frac{y^2 z}{r^3} - 3 \frac{z}{r} \right) \sum e_i y_i'^2 + \left(30 \frac{xz^2}{r^3} - 6 \frac{x}{r} \right) \sum e_i x_i' z_i' \\ & \left. + \left(30 \frac{yz^2}{r^3} - 6 \frac{y}{r} \right) \sum e_i y_i' z_i' - 30 \frac{xyz}{r^3} \sum e_i x_i' y_i' \right] + \dots\end{aligned}\quad (7)$$

Using this expression for Z_{jk}' in Eq. (4) and integrating over all possible molecular orientations¹ we obtain

$$\bar{Z}_{jk}' = \frac{\int \dots \int \bar{Z}_{jk}' e^{-u/kT} dx_1 dy_1 dz_1 \dots dx_n dy_n dz_n}{\int \dots \int e^{-u/kT} dx_1 dy_1 dz_1 \dots dx_n dy_n dz_n}\quad (8)$$

where u is that part of the potential energy dependent upon the configuration of the centers of gravity of the molecules, $x_1 \dots z_n$. With the aid of Eq. (4) we may express \bar{Z}_{jk}' , the value of Z_{jk}' averaged over all orientations of the molecules with respect to their centers of gravity as

¹ P. Debye, *Polar Molecules*, 27 (1929).

$$\bar{Z}_{jk}' = \frac{\beta_1}{r^3} + \frac{\beta_2}{r^4} + \cdots = \sum_{m=1}^{\infty} \frac{\beta_m}{r^{m+2}} \quad (9)$$

where

$$\begin{aligned} \beta_1 &= p_0[(3z^2/r^2 - 1)\bar{Z}_k + 3xz\bar{X}_k/r^2 + 3yz\bar{Y}_k/r^2] \\ \beta_2 &= \frac{1}{2}k_0[(15z^3/r^3 - 9z/r)\bar{Z}_k^2 + (15xz^2/r^3 - 3z/r)\bar{X}_k^2 \\ &\quad + (15yz^2/r^3 - 3z/r)\bar{Y}_k^2 + (30xz^2/r^3 - 6x/r)\bar{X}_k\bar{Z}_k \\ &\quad + (30yz^2/r^3 - 6y/r)\bar{Y}_k\bar{Z}_k - 30xyz\bar{X}_k\bar{Y}_k/r^3] \end{aligned}$$

and $p_0 = \alpha + \mu^2/3kT$

$$k_0 = \sum e_i f_i^2 + \frac{2\mu}{3kT} \sum e_i r_{i0} f_i + \frac{\mu^2}{15k^2 T^2} \sum e_i r_{i0}^2.$$

Here α is the sum of the electronic and atomic polarizabilities, $\sum e_i f_i$, μ is the permanent electric moment of the molecule, r_{i0} the distance of the charge e_i from the center of gravity of the molecule k , k is Boltzmann's constant and T the absolute temperature. \bar{X}_k , \bar{Y}_k , \bar{Z}_k , etc., are the components of the field acting on k , averaged over all molecular orientations.

We shall write Eq. (9) in a slightly different manner:

$$\bar{Z}_{jk}' = \left\{ \frac{\beta_1'}{r^3} + \frac{\beta_2'}{r^4} + \cdots \right\} + \left\{ \frac{\beta_1''}{r^3} + \frac{\beta_2''}{r^4} + \cdots \right\} \quad (10)$$

where β_1' , β_2' , \cdots are formed by replacing \bar{Z}_k , \bar{X}_k , \bar{Y}_k etc. in β_1 , β_2 , by their average values $\bar{\bar{Z}}_k$, $\bar{\bar{X}}_k$, $\bar{\bar{Y}}_k$. Likewise, β_1'' , β_2'' , are formed by replacing these quantities in β_1 , β_2 , \cdots by the fluctuations from their average values, $\bar{Z}_k - \bar{\bar{Z}}_k$, $\bar{X}_k - \bar{\bar{X}}_k$, $\bar{Y}_k - \bar{\bar{Y}}_k$, etc. It is apparent that the first series on the right hand side of Eq. (10) gives the magnitude which \bar{Z}_{jk}' would have if the molecule k remained rigidly polarized by the average field $\bar{\bar{F}}_k$ throughout all configurations of the centers of gravity of the molecules. The second series gives the contribution to \bar{Z}_{jk}' resulting from the fluctuation of \bar{F}_k from its average value $\bar{\bar{F}}_k$.

From Eqs. (2) and (3) we have

$$Z_j' = \sum_{k=1}^n Z_{jk}'$$

and

$$\bar{Z}_j' = \sum_{k=1}^n \bar{Z}_{jk}'. \quad (11)$$

Moreover, it is evident that all of the \bar{Z}_{jk}' must be identical, since the molecule k was selected at random from the n molecules surrounding j . Therefore

$$\bar{Z}_j' = n\bar{Z}_{jk}'. \quad (11a)$$

From Eqs. (8), (10) and (11) we obtain

$$\bar{Z}_j = I_1 + I_2$$

where

$$I_1 = n \frac{\int \cdots \int \left(\sum_{m=1}^{\infty} \beta_m' / r^{m+2} \right) e^{-u/kT} dx_1 dy_1 dz_1 \cdots dx_n dy_n dz_n}{\int \cdots \int e^{-u/kT} dx_1 dy_1 dz_1 \cdots dx_n dy_n dz_n}$$

$$I_2 = n \frac{\int \cdots \int \left[\sum_{m=1}^{\infty} \beta_m'' / r^{m+2} \right] e^{-u/kT} dx_1 \cdots dz_n}{\int \cdots \int e^{-u^0/kT} dx_1 \cdots dz_n}$$

The potential energy of the system may be written

$$u = \frac{1}{2} \sum_{j=1}^n \sum_{k=1}^n (u_{jk}^0 + u_{jk}')$$

where u_{jk}^0 is the normal potential energy of two molecules j and k which has been assumed to depend only upon the relative coordinates of the two, and u_{jk}' is the additional energy when there is an external field present.

It is easily shown that for weak fields, u_{jk}' is always so small relative to kT , that it may be neglected in the evaluation of the integrals of Eq. (10). It will therefore suffice to consider u as given by the normal potential energy u_{jk}^0 .¹

Note I. If \bar{m}_j and \bar{m}_k designate the electric moments of j and k along the z axis, averaged over all molecular orientations, then there may be written approximately, neglecting a term which is constant throughout the region considered.

$$u_{jk}' = - \frac{\bar{m}_j \bar{m}_k}{r^3} \left\{ \frac{2z^2}{r^3} + \frac{\alpha}{r^3} \left(\frac{3z^2}{r^2} + 1 \right) \right\} \quad (a)$$

where

$$\bar{m}_j = p_0(D + \bar{F}_j') \quad \bar{m}_k = p_0(D + \bar{F}_k')$$

We may anticipate the result of the calculation of \bar{F}_j' by assigning to it the approximation $-(8\pi/3)\rho N p_0 D$, where ρ is the density. Also approximately

$$|(\bar{F}_j' - \bar{F}_j'')^2|^{1/2} = \frac{8\pi}{3} N p_0 D \left(\frac{3\rho}{4\pi N \sigma^3} \right)^{1/2}$$

where σ is the distance of nearest approach of two molecules. It may therefore be safely assumed that m_j and m_k are in general of the order of magnitude of $p_0 D$. Thus from Eq. (a), the maximum value assignable to $|u_{jk}'|$ is the order of magnitude of

$$|u_{jk}'| = (2p_0^2 D^2 / \sigma^3) (2 + \alpha / \sigma^3).$$

For hydrogen at 300°K we have

$$kT = 4.11 \times 10^{-14} \text{ ergs}$$

$$p_0 = \alpha = 8 \times 10^{-25} \text{ cc}$$

$$\sigma = 2.3 \times 10^{-8} \text{ cm.}$$

For a value of D of 900 volts/cm, there results:

$$|u_{jk}'|/kT \sim 4 \times 10^{-10}.$$

Since the series

$$\beta_1'/r^3 + \beta_2'/r^4 + \dots$$

depends only upon the relative coördinates of j and k , the first integral I_1 becomes

$$I_1 = n \frac{\int \int \int \left(\sum_{m=1}^{\infty} \beta_m'/r^{m+2} \right) e^{-u_{jk}^0/kT} dx_k dy_k dz_k}{\int \int \int e^{-u_{jk}^0/kT} dx_k dy_k dz_k}.$$

In evaluating the latter integral it will be sufficient to employ the van der Waal's or rigid-sphere molecular model. It is assumed then, that the molecules have spherical symmetry relative to the coordinate system fixed in space by the vector D . Lack of spherical symmetry resulting from the orientation of a permanent dipole in the molecule, as well as from the induced deformation of the average configuration of the charges constituting the molecule, will be negligible unless the external field is very large. It will be further assumed that a distance of nearest approach, σ , exists such that

$$u_{jk}^0 = \infty \text{ for } r_{jk} \leq \sigma$$

When $r_{jk} > \sigma$, $e^{-u_{jk}^0/kT}$ is to be expanded as

$$1 + \sum_{s=1}^{\infty} \frac{1}{s!} \left(-\frac{u_{jk}^0}{kT} \right)^s.$$

The evaluation of I_1 leads to the result

$$I_1 = -\frac{8\pi}{3} n \frac{p_0}{V} \bar{Z}_k.$$

If $I_2 = \lambda \bar{Z}_k$ there results,

$$\bar{Z}_j' = -\bar{Z}_k \left(\frac{8\pi}{3} \frac{n}{V} p_0 - \lambda \right).$$

There is no physical distinction between molecules j and k and accordingly \bar{Z}_j and \bar{Z}_k must be equal.¹¹

Note II. First make the approximation

$$\iiint e^{-u_{jk}^0/kT} dx dy dz$$

where V is the total volume between the plates of the condenser. It will differ from the above integral only by a quantity of the order of magnitude of the volume of a single molecule. After transforming to polar coordinates we obtain:

$$I_1 = \frac{n p_0}{V} \int_0^{2\pi} \left[\int_0^{\pi/2} \int_{\sigma}^{z_1 \sec \theta} + \int_{\pi/2}^{\pi} \int_{\sigma}^{z_2 \sec \theta} \right] \left\{ \frac{\beta_1'}{r} + \frac{\beta_2'}{r^2} + \dots \right\} \\ \left\{ 1 + \sum_{s=1}^{\infty} \frac{1}{s!} \left(-\frac{u_{jk}^0}{kT} \right)^s \right\} dr \sin \theta d\theta d\phi$$

where z_1 and z_2 are the distances of the molecule j from the two plates of the condenser.

It is possible to expand u_{jk}^0 in powers of $1/r$ of which the dominant term is a/r^6 .² It is therefore obvious that when the multiplication indicated in the integrand is carried out, all terms except β_1'/r will contain $1/r$ to the second or higher powers. The contribution of these terms to the integral will decrease so rapidly with r that we may safely take the upper limit in the integration over r as ∞ . We then may write

$$I_1 = \frac{n p_0}{V} \int_0^{2\pi} \left[\int_0^{\pi/2} \int_{\sigma}^{z_1 \sec \theta} + \int_{\pi/2}^{\pi} \int_{\sigma}^{z_2 \sec \theta} \right] \frac{\beta_1'}{r} \sin \theta d\theta dr d\phi + \frac{n p_0}{V} \int_{\sigma}^{\infty} \int_0^{2\pi} \int_0^{\pi} \frac{\beta_1'}{r} \sum_{s=1}^{\infty} \frac{1}{s!} \left(-\frac{u_{jk}^0}{kT} \right)^s \\ + \left\{ \frac{\beta_2'}{r^2} + \dots \right\} \left\{ 1 + \sum_{s=1}^{\infty} \frac{1}{s!} \left(-\frac{u_{jk}^0}{kT} \right)^s \right\} \sin \theta d\theta d\phi dr.$$

It is to be remembered that u_{jk}^0 is independent of θ and ϕ , since it has spherical symmetry around j because of the averaging over all mutual orientations of j and k . Moreover, each of the coefficients $\beta_1', \beta_2', \dots$ satisfies the relation

$$\int_0^{2\pi} \int_0^{\pi} \beta_m' \sin \theta d\theta d\phi = 0.$$

It follows that through integration over the angles the second integral vanishes term by term and there remains when we insert the value of β_1'

$$\frac{n p_0}{V} \int_0^{2\pi} \left[\int_0^{\pi/2} \int_{\sigma}^{z_1 \sec \theta} + \int_{\pi/2}^{\pi} \int_{\sigma}^{z_2 \sec \theta} \right] \left\{ \bar{Z}_k (3 \cos^2 \theta - 1) + 3 \bar{X}_k \sin \theta \cos \phi \right. \\ \left. + 3 \bar{Y}_k \sin \theta \sin \phi \right\} \sin \theta d\theta \frac{dr}{r} d\phi$$

Integration over r and ϕ yields

$$\frac{2\pi n}{V} p_0 \bar{Z}_k \left\{ - \int_0^{\pi} (3 \cos^2 \theta - 1) \log \cos \theta \sin \theta d\theta + \int_0^{\pi/2} (3 \cos^2 \theta - 1) \log \frac{\sigma}{z_1} \sin \theta d\theta \right. \\ \left. + \int_{\pi/2}^{\pi} (3 \cos^2 \theta - 1) \log \frac{\sigma}{z_2} \sin \theta d\theta \right\} = -\frac{8\pi}{3} \frac{n p_0}{V} \bar{Z}_k.$$

It is to be noted that this quantity is independent both of z_1 and z_2 as well as of σ .

The subscripts may therefore be neglected and the average value of the Z -component of the internal field becomes, if it is remembered that $Z = Z' + D$ (Eq. 4).

$$\bar{Z} = \frac{D}{1 + \frac{8\pi}{3} \frac{n}{V} p_0 - \lambda}. \quad (13)$$

A similar calculation shows that \bar{Y}_i and \bar{X}_i vanish, and the average value of the resultant internal field F is merely,

$$\bar{F} = \frac{D}{1 + \frac{8\pi}{3} \frac{n}{V} p_0 - \lambda}. \quad (14)$$

² Eisenschitz and London, *Zeits. f. Physik*, **60**, 491 (1930).

This equation when combined with the usual classical relations,

$$D = \epsilon E$$

$$D = E + 4\pi P$$

$$P = \frac{n}{V} p_0 \bar{F}$$

gives;

$$\frac{\epsilon - 1}{\epsilon + 2} V = \frac{4\pi}{3} N p_0 \frac{1}{1 - \lambda} \quad (15)$$

where v is the molal volume and ϵ is the dielectric constant. Equation (15) reduces to the familiar Clausius-Mosotti relation

$$\frac{\epsilon - 1}{\epsilon + 2} v = \frac{4\pi}{3} N p_0 \quad (16)$$

only if λ is identically zero for all temperatures and pressures. This is not in general true. The quantity λ is a measure of the contribution of the fluctuations in \bar{F} . It will be shown that λ is proportional to the density as long as only binary molecular encounters need be considered. For very dense gases, on the other hand, the effect of the fluctuations is less important and λ will be smaller than the formula indicates.

In evaluating the quantity λ it will be sufficient to retain only the dipole term in the \bar{Z}_{jk} series. It will be convenient to make use of the identity

$$\bar{Z}_k - \bar{\bar{Z}}_k = \sum_{l=1}^{n-1} (\bar{Z}_{kl}' - \bar{\bar{Z}}_{kl}') + \bar{Z}_{ki}' - \bar{\bar{Z}}_{ki}'$$

λ may then be written

$$\frac{n}{\bar{\bar{Z}}} \frac{\int \cdots \int \psi e^{-u/kT} dx_1 \cdots dz_n}{\int \cdots \int e^{-u/kT} dx_1 \cdots dz_n}$$

where

$$\begin{aligned} \psi = \frac{p_0}{r^3} & \left\{ \left(\frac{3z^2}{r^2} - 1 \right) \left[\sum_{l=1}^{n-1} (\bar{Z}_{kl}' - \bar{\bar{Z}}_{kl}') + (\bar{Z}_{ki}' - \bar{\bar{Z}}_{ki}') \right] \right. \\ & + \frac{3xz}{r^2} \left[\sum_{l=1}^{n-1} (\bar{X}_{kl}' - \bar{\bar{X}}_{kl}') + (\bar{X}_{ki}' - \bar{\bar{X}}_{ki}') \right] \\ & \left. + \frac{3yz}{r^2} \left[\sum_{l=1}^{n-1} (\bar{Y}_{kl}' - \bar{\bar{Y}}_{kl}') + (\bar{Y}_{ki}' - \bar{\bar{Y}}_{ki}') \right] \right\}. \end{aligned}$$

If the integration over the coordinates of all the l molecules is carried out under the assumption that each of the \bar{Z}_{kl} terms is independent of the relative

positions of j and k , there results (consistent with the original postulate of binary encounters)

$$\lambda = \frac{n}{\bar{Z}V} \int \int \int \frac{p_0}{r^3} \left[\left(\frac{3z^2}{r^2} - 1 \right) (\bar{Z}_{kj'} - \bar{Z}_{ki'}) \right. \\ \left. + \frac{3xz}{r^2} \bar{X}'_{kj} \frac{3yz}{r^2} \bar{Y}'_{kj} \right] e^{-u_{jk}/kT} dx dy dz$$

where $\bar{X}_{kj'}$, $\bar{Y}_{kj'}$, $\bar{Z}_{kj'}$ now denote the values of these quantities when the *average field* from the other molecules is acting on both j and k . It is obvious that

$$\bar{Z}_{kj'} = \bar{Z}_{jk'}.$$

Transformation to polar coordinates and integration over the azimuthal angle ϕ yields, since $\bar{X}_{kj'}$ and $\bar{Y}_{kj'}$ are obviously independent of ϕ .

$$\lambda = \frac{2\pi n}{\bar{Z}V} \int \int \kappa [\bar{Z}_{kj'} - \bar{Z}_{jk'}] e^{-u_{jk}/kT} r^2 \sin \theta dr d\theta$$

and

$$\kappa = \frac{p_0}{r^3} (3 \cos^2 \theta - 1).$$

It will be seen immediately that the contribution arising from $\bar{Z}_{kj'}$ may be ignored since it amounts to

$$-\frac{8\pi n p_0}{V} \frac{\bar{Z}_{kj}}{\bar{Z}}$$

a quantity of the order of magnitude of $1/n$ since $\bar{Z}' = n\bar{Z}'_{kj}$. Moreover, it is obvious that after the integration over ϕ

$$\bar{Z}_{kj'} = \kappa \bar{Z}_i = \kappa \left(\sum_{l=1}^{n-1} \bar{Z}_{il} + \bar{Z}_{jk'} \right)$$

$\sum_{l=1}^{n-1} \bar{Z}_{il}$ differs from \bar{Z} by a quantity of the order of magnitude of $1/n$. Since $\bar{Z}_{jk'} = \bar{Z}_{kj'}$ the expression for λ becomes, after solving for \bar{Z}_{kj} :

$$\lambda = \frac{2\pi n}{V} \int_0^\pi \int_0^\infty \frac{\kappa^2}{1-\kappa} e^{-u_{jk}/kT} r^2 \sin \theta dr d\theta.$$

When $2p_0/\sigma^3$ is small relative to unity and only the first two terms are retained in the expansion of $e^{-u_{jk}/kT}$, the above expression is closely approximated by^{III}

$$\frac{32\pi^2 N^2 p_0^2}{45BV} \left(1 + \frac{1}{3} \frac{A}{BRT} \right)$$

where A and B are the constants of the van der Waal type of equation of state and v is the molal volume. The condition that $2p_0/\sigma^3$ be small relative to unity is in general fulfilled by non-polar substances. (hydrogen; $2p_0/\sigma^3 = 0.12$). For polar substances where $2p_0/\sigma^3$ often exceeds unity (ammonia; $2p_0/\sigma^3 = 1.6$), it is probable that the above expression is still a fair representation of λ .

Note III. If $\kappa^2/1 - \kappa$ is expanded and only the first term of the resulting series retained, the expression for λ becomes

$$\frac{2\pi n}{V} \int_0^\pi \int_\sigma^\infty \frac{p_0^2}{r^4} (3 \cos^2 \theta - 1) e^{-u_{jk}^0/kT} \sin \theta d\theta dr.$$

If $e^{u_{jk}^0/kT}$ is expanded and only the first two terms

$$1 - \frac{u_{jk}^0}{kT}$$

are retained, and further if it is assumed that

$$u_{jk}^0 = -\frac{a}{r^6} + \dots$$

one obtains

$$\lambda = \frac{16\pi p_0^2}{15\sigma^3} \frac{n}{V} \left(1 + \frac{Na}{3RT\sigma^3} \right).$$

Since the van der Waal's cohesive pressure constant, A , is given by

$$\frac{\pi N^2}{3} \int_\sigma^\infty e^{-u_{jk}^0/kT} \frac{\partial u_{jk}^0}{\partial r} r^3 dr = \frac{2\pi N^2 a}{3\sigma^3} + \dots$$

and the volume constant is

$$B = \frac{2\pi}{3} N\sigma^3.$$

It is found approximately that

$$\lambda = \frac{1}{v} \frac{32\pi^2 N^2 p_0^2}{45B} \left(1 + \frac{1}{3} \frac{A}{BRT} \right).$$

If the aggregation effect is ignored and one sets $e^{u_{jk}^0/kT}$ equal to unity, one has

$$\lambda' = \frac{2\pi n}{V} \int_0^\pi \int_\sigma^\infty \frac{p_0^2 (3 \cos^2 \theta - 1)}{r^3 - p_0 (3 \cos^2 \theta - 1)} \sin \theta d\theta \frac{dr}{r}.$$

This integral may be exactly evaluated as

$$\frac{2\pi p_0}{3} \frac{n}{V} \left[4x^2 - \frac{8}{3} + (2x - 2x^3) \ln \frac{x+1}{x-1} \right]$$

where

$$x = \left(\frac{1 + p_0/\sigma^3}{3p_0/\sigma^3} \right)^{1/2}.$$

The quantity remains finite as long as $2p_0/\sigma^3 < 1$. When the logarithm is expanded the first term is

$$\frac{16\pi p_0^2}{15\sigma^3} \frac{n}{V}$$

which agrees with the previous result. Moreover when p_0/σ^3 is in the neighborhood of 0.1, the error introduced by neglecting the remaining terms is found to be less than 3 percent represen-

tation of λ . Even in this case $2p_0/r^3$ remains small until very small values of r are reached. Thus for ammonia $2p_0/r^3 < 0.2$ when $r > 2\sigma$. For smaller values of r , the formulation of the integral ceases to be exact. Here the intensity of the mutual field of j and k becomes so great that an electrical saturation sets in and the electric moments of the two molecules are no longer proportional to the field intensity. If in a very rough manner one replaces p_0 by

$$p_0 + \left\{ \frac{1}{\bar{Z}_k} L\left(\frac{\mu \bar{Z}_k}{kT}\right) - \frac{\mu^2}{3kT} \right\}$$

where $L(x)$ is the Langevin function, it is seen that while $1-\kappa$ may differ appreciably from unity, it never becomes extremely small. Moreover, the effect will produce a corresponding diminution in κ^2 so that it should not strongly affect the magnitude of the factor $\kappa^2/(1-\kappa)$ in the integrand.

If one sets $\lambda = \lambda_0 \rho$ where ρ is the density in moles per cc and designates $4\pi Np_0/3$ by P_0 , Eq. (15) becomes

$$\frac{\epsilon - 1}{\epsilon + 2} v = \frac{4\pi Np_0}{3} \frac{1}{1 - \lambda_0 \rho} \quad (18)$$

where

$$\lambda_0 = \frac{2P_0^2}{5B} \left(1 + \frac{1}{3} \frac{A}{BRT} \right).$$

Equation (18) becomes identical with the Clausius-Mosotti formula only in the limit of zero density. When ρ is small, they may, however, approximate each other very closely over a considerable range of density. A calculation of λ_0 for air, nitrogen and hydrogen indicates that the factor $1/1 - \lambda_0 \rho$ gives rise to a deviation of less than .05 percent from the Equation (16) at 100 atm. and 20°C. This is in accord with the experimental results of Tangl³ who found no measureable deviation from the Clausius-Mosotti law for these substances. Measurements of the dielectric constant of carbon dioxide⁴ at high densities indicate that the Clausius-Mosotti function, $(\epsilon - 1/\epsilon + 2)v$, increases with increasing density as Eq. (18) demands. However, the rate of increase is about twenty times that to be expected from the value of λ_0 calculated from the equation of state constants. It is probable that this gas may not be treated as an assembly of molecules of identical polarizability at the temperatures of the dielectric constant measurements.^{IV}

Note IV. [Suppose a mixture of several molecular types corresponding to various vibrational states of the molecule. It is easy to see that if these various states differed in polarizability, a shift in the distribution among them due to a change in density, might well increase the mean molecular polarizability in such a manner as to give rise to the observed effect.]

Measurements of the dielectric constant of ammonia⁵ yield values of $(\epsilon - 1)/(\epsilon + 2)$ which to 30 to 40 atm. follow Eq. (14), with a value of λ_0 calculated from the equation of state constants. In the higher pressure region the slope of the experimental curve decreases rapidly and a negative deviation from

³ K. Tangl, Ann. d. Physik 29, 59 (1908).

⁴ F. G. Keyes and J. G. Kirkwood, Phys. Rev. 36, 754 (1930).

⁵ F. G. Keyes and J. G. Kirkwood, Phys. Rev. 36 (1930).

Eq. (14) occurs. This is not surprising since the assumptions underlying the whole of the present analysis are highly simplified.

In the present discussion it has been assumed that the boundaries of the dielectric material consist of two planes perpendicular to the direction of an homogeneous external field. It seems probable that if the boundary surface of the dielectric is of an irregular character, inhomogeneity in the average internal field will arise and Eq. (18) will no longer be strictly valid. Such considerations would of course not be of importance at low densities where \bar{F} is small compared to D . Under the latter conditions the simple relation

$$\frac{\epsilon - 1}{3}v = \frac{4\pi}{3}Np_0$$

is valid regardless of the character of the boundary surface.

It is a matter of great interest that the observed deviations from the Clausius-Mosotti relation at high densities are much lower than Eq. (18) predicts. This is not difficult to understand when it is observed that collisions involving more than two molecules will decrease the value of λ , the measure of the contributions of the fluctuations to the average molecular field. In fact, barring effects due to quantized vibrations or rotations, the Clausius-Mosotti function would be expected, on the basis of the present theory, to approach absolute constancy when the molecules were at all instants continuously under one another's mutual influence. The dielectric constant data for liquid carbon dioxide under various pressures proves the supposition tentatively, for the computed Clausius-Mosotti function shows no variation.

SYMBOLS

E	Mean field intensity.
D	Dielectric displacement.
n	Number of molecules.
ϵ	Dielectric constant.
F_j	Total field (sum of molecular and external fields) acting on a molecule j in a dielectric.
F_j'	Molecular field acting on j .
F_{jk}'	The component of F_j' arising from a single molecule k .
\bar{F}_j'	Average value of F_j' over all molecular orientations.
$\overline{\bar{F}}_j'$	Average value of F_j' over all configurations of the centers of gravity of the molecules.
$d\tau$	Element of configuration space of a single molecule k .
$[x, y, z]$	Rectangular coordinate system with origin at center of gravity of the molecule j and with z axis parallel to D .
$[x', y', z']$	Rectangular coordinate system with origin at center of molecule k .
$e_1 \cdots e_i$	The charges constituting the molecule k .
$x_{i0}' y_{i0}' z_{i0}'$	Average coordinates of the charge e_i when there is a perturbing field.
f_i	Elastic constant for linear displacements of e_i from its average position in the molecule.
ϕ_{jk}'	Potential in the interior of the molecule j due to the molecule k .
r	Separation of the centers of gravity of j and k .
X_j, Y_j, Z_j	Components of F_j along the axes of the coordinate system $[x, y, z]$.
X_j', Y_j', Z_j'	Components of F_j' along the axes of the coordinate system $[x, y, z]$.

U^*	Total potential energy of the ensemble of molecules.
U_{jk}^*	Mutual potential energy of the two molecules j and k .
U_{jk}	That part of U_{jk} dependent only upon the configuration of the centers of gravity of j and k .
U_{jk}^0	The value of U_{jk} when there is no external field.
p_0	Polarizability of a molecule.
α	Sum of electronic and atomic polarizabilities.
μ	Fixed dipole moment of a molecule.
σ	Distance of closest approach of two molecules.
V	Volume of the system.
v	Molal volume.
ρ	Molal density.

LETTERS TO THE EDITOR

Prompt publication of brief reports of important discoveries in physics may be secured by addressing them to this department. Closing dates for this department are, for the first issue of the month, the twenty-eighth of the preceding month; for the second issue, the thirteenth of the month. The Board of Editors does not hold itself responsible for the opinions expressed by the correspondents.

Hyperfine Structure and Polarization of Mercury Resonance Radiation

In a letter to the Editor appearing in the November 15th issue of this Review, S. Mrozowski has described certain experiments on the polarization of the $\lambda 2537\text{\AA}$ resonance radiation of mercury which he finds difficulty in reconciling with the previous work of MacNair and the author.¹ We showed that the low polarization of this resonance line was due to the two outer of its five hyperfine structure components, not the -25.4 m.a. component alone, as Mrozowski appears to assume. He concludes that resonance radiation excited by the -25.4 m.a. component only should show a lower polarization than that excited by the entire pattern. This he finds is not the case. This in itself involves no contradiction, for whether excitation by part of the pattern will produce a polarization different from that due to excitation by the entire pattern depends upon whether the relative population of the upper hyperfine structure levels is changed. For example if all five components originated in a single upper level no change would occur. Other arrangements might lead to the same conclusion, and as the levels are unknown there is no essential contradiction here.

However Olson² showed that this resonance radiation excited by an arc run on very low current might be as high as 86 percent polarized instead of the usual 79–80 percent. He supposed this change in the polarization was due to a change in the relative intensities in the h.f.s. pattern, and in fact there appears to be no other possibility. Olson also showed that the product of mean life into Larmor precession frequency did not change. This shows that the polarization is not then independent of *all* relative intensity changes and raises the question why Mrozowski observed no change. The writer has carried out these experiments.

Light from a mercury arc is passed through

¹ Ellett and Mac Nair, Phys. Rev. **31**, 180 (1928).

² Olson, Phys. Rev. **32**, 443 (1928).

an absorption cell 8 cm long containing mercury vapor at a pressure of 1.3×10^{-3} mm Hg (20°C) placed in a magnetic field of 2000 gauss intensity. The light passing through this cell polarized with its electric vector parallel to the field was used to excite resonance radiation in Hg vapor. The resonance bulb was placed in a magnetic field of 50 gauss parallel to the electric vector of the exciting light. The resonance radiation so excited showed a polarization very much less than 80 percent. This was shown clearly by two photographs of the resonance radiation taken through a Wollaston prism, one of four minutes duration with the absorption cell in place as mentioned above, and one of one minute with no absorption. In the one minute exposure the strong image ($E||H$) was stronger than the strong image in the four minute exposure, while the weaker image in the four minute exposure was stronger than the weak image in the one minute picture. No attempt was made to measure accurately the polarization of the resonance radiation so excited. It is safe to say that it was not greater than 60 percent.

Precisely similar results were obtained with a magnetic field of 50 gauss parallel to the exciting light beam. Here the excitation is by $E \perp H$. No attempt was made to excite resonance radiation in zero field with this filtered radiation. In order for such results to be significant the stray field of the magnet used on the filter must be very exactly compensated and time for this is not at present available. Spectroscopic stability would lead us to expect the same polarization in zero field as in a field parallel to the electric vector of the exciting light, unless such a field produces a Paschen-Back effect upon the hyperfine structure. If this were the case such a field should also affect the polarization where the excitation is by the entire line, and it is known that this is not the case.

It may be noted further that resonance

radiation excited by the unfiltered light from an arc polarized with E parallel to a magnetic field of 1700 gauss shows all five h.f.s. components. This resonance radiation after passing through 7 cm of Hg vapor at 2×10^{-4} mm pressure consists of *both* the outer h.f.s. components and these very little reduced in intensity, while the central three are too weak to appear in the Lummer plate pattern, which seems to require that both outer components are shifted by the field, though MacNair observed a shift of only the short wave-length one.

On this account I think that the excitation in the experiments described above was by both outer components. I have not been able to devise a filter to transmit the -25.4 m.a. component only, as Mrozowski has done, though I have tried fields of various values from 1000–3500 gauss. When -25.2 comes through it is accompanied by $+22.1$.

Application of the Fermi-Thomas Model to Positive Ions

Recently, Baker¹ has attempted to apply the Fermi-Thomas method to the calculation of positive ions. He gives a general discussion of the solutions of Eq. (1) (For notation see Baker's paper) including those which do not satisfy the usual boundary condition $v(\infty) = 0$. There are solutions of this equation above and below that given by Fermi and Thomas, and Baker applies the above functions to the physical problem of a positive ion. We believe, however, that these functions have no physical meaning, and that one gets the potential distribution in an ion with the aid of the functions below, which intersect the x -axis. This can be seen from the following argument:

One gets the usual Fermi-Thomas equation by assuming that every cell in phase space for which the energy $p^2/2m - ev$ lies below a given value E_0 contains two electrons and those with higher energy are empty. The value of E_0 is then defined by the total number of electrons. In the case of a neutral atom, the necessary value of E_0 is zero (i.e. equal to the potential at $r = \infty$) and therefore one never introduced it as a parameter. In order to make the number of electrons less than Z , one has to choose a negative value of E_0 , so that the

number of electrons per unit volume will be given by

$$n = \frac{2^{3/2} \pi m^{3/2}}{3h^3} (ev - E_0)^{3/2} \text{ if } r < r_0 \\ \text{and } n = 0, \text{ if } r > r_0$$

where r_0 is defined by $ev(r_0) = E_0$. The function

$$W(r) = v(r) - \frac{1}{e} E_0$$

then again satisfies Eq. (1) for values $r < r_0$ and

$$\Delta W = 0$$

for $r > r_0$. It vanishes at $r = r_0$ and is continuous together with first and second derivatives. The potential distribution of a positive ion can therefore be obtained from one of the curves designated by $\sigma < 0$ in Baker's Fig. 1, up to the point where it intersects the x -axis. Beyond this point one simply has a Coulomb field.

Diffusion of Metallic Vapor in Condensed Spark Discharges

Recently, Beams¹ in a paper on "Spectra in Spark Discharges," referring to the diffusion of metallic vapor into the spark gap during the process of discharging, remarks: "These streamers have been previously observed by several experimenters* but whether they are jets of luminous vapor or pulses of luminosity in the vapor has not yet been completely settled."

¹ Beams, Phys. Rev. **35**, 24 (1930).

* E. C. C. Baly, Spectroscopy **2**, 153, Longmans (1927).

The writer² begs to submit two shadowgraphs of sparks taken by him at Indiana University in 1926 which suggest at least one mode by which this process takes place, namely, that of vapor pulses. Referring to the accompanying figures, both sparks were photographed under the same circuital conditions with the exception that in the case of Fig. 2 which exhibits a spark somewhat older than that of Fig. 1, the

² Zinszer, Phys. Rev. **29**, 752 (1927); Phil. Mag. **5**, 1098, (1928).

retarding capacity of the illuminating gap was about 1.4 times as great as that under which Fig. 1 was photographed.

A characteristic of the diffusion as noted

Fig. 1

Fig. 2

in Fig. 2, one that is quite general in all of my plates, is the inequality of velocity of positive and negative diffusion. This is proven by the fact that here the diffusion from the negative electrode has almost arrived at the center of the gap space while that from the positive electrode is much less mobile.

Other modes of vapor diffusion as indicated by my collection of negatives show in some cases depending upon the circuitual arrangement a discontinuous diffusion, that is, diffusion in the form of small discrete clouds of vapor superimposed on the heated air of the "pilot" spark; also a forced diffusion in the form of tiny globules of vapor corresponding probably to the "jets" mentioned above. A more comprehensive discussion of this matter will follow later.

Positive Ions Emitted by Iron and Copper

A mass spectrograph study of the positive ion emission from Fe and Cu has shown that at temperature slightly below the melting points of the metals singly charged atoms of Fe and Cu are emitted. In both cases the metals were supported and heated by a tungsten filament. The accompanying curve, Fig. 1, is typical of data obtained from Cu and shows its two isotopes at atomic weights 63 and 65. The Cu used was at least 99.99 percent pure and the gas pressure in the mass spectrograph was kept at or below 10^{-6} cm Hg. The values of the positive ion currents are only relative but the values of the atomic weights are absolute, having been computed from the potentials and magnetic fields used to accelerate and deflect the moving ions, and from the radius of the ion path.

No absolute measurements of the positive ion currents from these metals have yet been made but the mass spectrograph measurements indicate that the currents produced at temperatures very near the respective melting points of these metals are of the order of one one-hundredth of the value of the positive ion currents of potassium which are produced when these metals are first heated.

In an abstract of a paper to be given by H. B. Wahlin at the December meeting of the American Physical Society in Cleveland, there appears a list of metals which it is claimed

"give only alkaline ions." Among the metals thus listed are Fe and Cu. The discrepancy between the two reports may be due to a difference of sensitivity in current measurements or to a difference in the temperatures to which the metals were raised.

Fig. 1. Positive ion current from Cu

Preliminary measurements indicate that it is possible to obtain positive ions of nickel by raising its temperature to a value just below its melting point.

Spark Spectrum of Rubidium (Rb II)

The resonance lines of the first spark spectrum of rubidium have been excited in a hollow cathode in helium and photographed with a 1 m vacuum spectrograph. The excitation in helium is only about three volts more than sufficient to excite the resonance lines (Sawyer, Phys. Rev. **36**, 44, 1930) so that all difficulty with higher spectra is avoided and only the resonance lines appear in the vacuum region. The three resonance lines are, $\lambda 711.17$, $\nu 140612$, p_0-d_5 ; and $\lambda 697.04$, $\nu 143464$, p_0-s_2 in the Paschen-Meissner notation.

With the separations of the resonance lines as a guide, it has been possible to classify a large number of lines given by Reinheimer (Reinheimer, Ann. d. Physik **71**, 162, 1923) and Otsuka (Otsuka, Zeits. f. Physik **36**, 786, 1926) in the rubidium spark spectrum. The energy level scheme given by Reinheimer is

correct but incomplete. It is to be interpreted as transitions from the $4p^55p$ levels to the $4p^55s$ and $4p^54d$ levels. The $4p^55s$ levels show hyperfine structure which led to their identification. The p^5s and p^5d levels overlap as in K II (Bowen, Phys. Rev. **31**, 494, 1928).

It is interesting to note that the positions of the resonance lines are in good agreement with the excitation potential measurements of Mohler (Mohler, Phys. Rev. **28**, 46, 1926). The calculated resonance potentials are $\lambda 711.17$, 16.65 volts; $\lambda 711.17$, 17.36 volts; $\lambda 697.04$, 17.71 volts, while Mohler gave 16.0 ± 0.5 volts.

The Optical Spectra of Rhenium

Although the discovery of rhenium (75 Re) was announced¹ in 1925, and its characteristic Röntgen spectra were described² several years ago, I am not aware that any details concerning its optical spectra have been published. The arc and spark emission spectra of rhenium have recently been photographed in the interval 2300–8000 Å with the large concave grating at the Bureau of Standards. A

sharp division between lines characterizing neutral atoms and those belonging to ionized atoms has been made, and preliminary values of wave-lengths and relative intensities have been obtained. The spectra are of considerable complexity and it appears that the majority of lines have hyperfine structure. A partial list of principal lines of the Re I spectrum is as follows:

Wave-length	Intensity	Wave-number	Combination
3424.6	40 c	29192.2	
3451.9	50 c	28961.3	
3460.5	200 c	28889.3	$a^6S_{2\frac{1}{2}} - b^6P_{1\frac{1}{2}}$
3464.7	100 c	28854.3	$a^6S_{2\frac{1}{2}} - b^6P_{3\frac{1}{2}}$
4133.4	40 c	24186.4	$a^6S_{2\frac{1}{2}} - b^6P_{2\frac{1}{2}}$
4136.46	50	24168.5	
4227.4	100 c	23648.6	
4394.4	40 c	22749.9	
4513.3	200 c	22150.5	
4522.70	50	22104.5	
4791.4	50 c	20864.9	
4889.2	500 c	20447.6	$a^6S_{2\frac{1}{2}} - a^6P_{3\frac{1}{2}}$
4923.92	60	20303.4	
5271.0	100 c	18966.5	$a^6S_{2\frac{1}{2}} - a^6P_{1\frac{1}{2}}$
5275.6	200 c	18946.3	$a^6S_{2\frac{1}{2}} - a^6P_{2\frac{1}{2}}$
5834.31	80	17135.2	
6307.7	40 c	15849.3	$b^6P_{2\frac{1}{2}} - z^6S_{2\frac{1}{2}}$
6321.9	60 c	15813.7	$b^6P_{3\frac{1}{2}} - z^6S_{2\frac{1}{2}}$
6350.7	20 c	15742.0	$b^6P_{1\frac{1}{2}} - z^6S_{2\frac{1}{2}}$

The lines marked *c* are complex and have from 2 to 6 or more components; for such lines the mean wave-length of the group is here

rounded off to the nearest 0.1 Å. The components of the widest lines extend over an interval of about 2 wave-number units; for some

the intervals and intensities diminish toward the red and for others to the violet. The hyperfine structure of many of the lines has been resolved; 4889.2Å has 6 components, 3460.5 has 6 also while 3451.9Å has 4 and 3464.7Å has 5.

The strongest line in the Re spectrum is 4889.2Å; it is undoubtedly the *raie ultime* for the spectro-chemical identification of rhenium. This blue line and the green ones at 5271.0 and 5275.6Å are the most brilliant lines in the visible spectrum. The ultraviolet lines at 3451.9, 3460.5 and 3464.7Å are also very intense and persistent.

An analysis of the spectrum is in progress;

it appears that the normal state is represented by a sextet S term, $(5d^6 6s^2) {}^6S_{5/2}$. Both a^6P^0 and b^6P^0 violate the interval rule but the relative intensities and the hyperfine structure of combinations indicate that the levels are correctly identified.

Note on the Heat Capacity of Gases at Low Pressure

In a paper by the writers that appeared in the program for the Chicago meeting on November 28 and 29, 1930, the results of calculations on various physical properties of compressed nitrogen were given. These physical properties are the specific volume, density, fugacity, $-(p/v) (dv/dp)_T$, $(1/v) (dv/dT)_p$, $C_p - C_v$, C_p , C_v , and μ , all calculated at twelve temperatures and fourteen pressures between -70° and 600°C and between 20 and 1200 atm, mainly from the compressibility data taken by E. P. Bartlett and his collaborators. The calculations were made possible by a sensitive graphical scheme for determining derivatives, which will be described in a complete article that will appear soon. At this time we wish to discuss one of the conclusions that was published in the abstract of the paper, *viz.* the one that says that the power series expressing C_p along an isotherm at pressures not too high must be of the form

$$C_p = C_p^* + bp^2 + cp^3 + \dots$$

These calculations of the change in heat capacity with pressure along an isotherm depend on the evaluation of $-T(d^2v/dT^2)_p$ along that isotherm, through the thermodynamic relation $-T(d^2v/dT^2)_p = (dC_p/dp)_T$. Experimental data below 20 atm throughout this temperature range are lacking and it is therefore impossible to decide definitely from them just what course the $-T(d^2v/dT^2)_p$ vs. p isotherms should follow as p approaches zero. At first we thought our determinations of the second derivative indicated that $-T(d^2v/dT^2)_p \rightarrow 0$ as $p \rightarrow 0$ for at least some of the temperatures. However, Dr. P. H. Emmett of this laboratory, and Professor Beattie of the

Massachusetts Institute of Technology, have pointed out to us that our curves do not definitely prove this. We wish to discuss the consequences of the course of these curves in the region of zero pressure.

Since most of the direct calorimetric measurements of C_p have been made at 1 atm, it is necessary that the $-T(d^2v/dT^2)_p$ vs. p isotherms be extended below 20 atm to 1 atm. We have no experimental points in this region, but Professor Beattie has kindly showed us that here an equation of state can perform a great service. This is true if it actually takes account of physical phenomena, for then, by using in it parameters determined by compressibility data from (say) 20 to 100 atm, extrapolation to low pressures can probably be accomplished. It seems likely that the van der Waals' pressure and the tendency toward association should exist clear down to the lowest pressures where they may be identified as A_0/v^2 and c/vT^3 in the Beattie-Bridgeman formula, which gives

$$-T(d^2v/dT^2)_p = 2A_0/RT^2 + 12c/RT^4 \text{ when } p=0.$$

This does not vanish at finite temperatures unless A_0 and c are both zero, or unless the exponents of v in A_0/v^2 and c/vT^3 are both changed and made greater than 2 and 1 respectively. The van der Waals' and Callendar equations of state, and possibly many others, likewise give expressions for $-T(d^2v/dT^2)_p$ that are not zero.

Accepting the implications of these equations of state, $(dC_p/dp)_T \neq 0$ when $p=0$, and the first power of p in the above series for C_p would be present; C_p^* would then be the heat capacity at zero pressure. If $(dC_p/dp)_T \rightarrow 0$ as

$p \rightarrow 0$, the first power of p would be absent and C_p^* would then be sufficiently defined as the heat capacity at very low pressure, that is, there would exist some low pressure beyond which further expansion is not accompanied by a comparable change in C_p .

The two ideas are different in principle; in the former case there is a property of the gas that is realized only at complete zero pressure; in the latter case the property is realized at some sufficiently low pressure. Apparatus for compressibility or direct calorimetric measurements at low pressures might be devised to settle this matter experimentally.

It should be noted that for the calculations of the physical properties mentioned above, it is not essential to decide between these two points of view, because the area under a $-T(d^2v/dT^2)_p$ vs. p isotherm from $p=1$

to $p=20, 40, 60, \dots$ atm. is not much affected by its course in the region of a few atmospheres pressure. Our calculations were first made assuming $(dC_p/dp)_T \rightarrow 0$ as $p \rightarrow 0$, and were then repeated using the intercept at most temperatures as given by the Beattie-Bridgeman formula, and the two sets do not differ by more than a few hundredths of a calorie/mole degree, which is well below the probable error of any calorimetric measurement.

The calculations on nitrogen will appear shortly.

The Entropy of Hydrogen

The writer (Proc. Nat. Acad. 15, 678 (1929)) calculated the exact value for the entropy of hydrogen at 298°K by quantum statistics using the partition function with intercombination of odd and even states. Previous to this, Fowler (Proc. Roy. Soc. 118A, 52 (1928)) and Giauque and Johnston (J. Am. Chem. Soc. 50, 3221 (1928)) had discussed the entropy of hydrogen. Fowler neither made himself clear nor, apparently, reached the right conclusion. Giauque and Johnston did not state the exact numerical value to be expected for the entropy of hydrogen, but discussed the method by which the entropy should be calculated. The writer regrets that he misunderstood their proposed method of calculation, and assumed that it would lead to a value differing from the one he had obtained. In a recent note (Phys. Rev. 36, 1592 (1930)) they have pointed out that it leads to the same result. Since we are in agreement there need be no further discussion on this point.

The writer expects to discuss elsewhere the conditions under which the entropy of matter in a metastable state can be calculated by statistics, but there should be no confusion on this point.

Giauque and Johnston are entirely correct of course in saying that the entropy of hydrogen can be calculated without reference to a possible equilibrium between hydrogen and helium. We can define arbitrarily the entropy of any metastable state of a substance, e.g.; monoclinic sulfur. As soon as we

do this the entropy of every other state of the substance which can be reached by a *reversible* transformation is defined. The difficulty with the analogy between a mixture of hydrogen and helium and a mixture of the two kinds of hydrogen is that ortho and para-hydrogen do transform into each other and that the equilibrium will be attained, if the writer is correctly informed, in any ordinary chemical reaction involving hydrogen. The only entropy that can have significance for chemical equilibrium therefore is the entropy of the equilibrium mixture. The non-equilibrium mixture of hydrogen at low temperatures is not a pure substance and yet its entropy must be calculated as a pure substance to have any meaning.

Two other points require brief comment. It is certainly not consistent with the current idea of a molecule in chemistry or physics, to say that there are ten varieties of molecules in hydrogen. There are at most two varieties of molecules. Also the choice of a value of 31.23 E.U. for the entropy of hydrogen seems hard to justify since it is neither a theoretical value nor *as yet* an experimental value. On the other hand it is entirely probable that the value of 33.98 E.U. can be verified experimentally if the heat data are obtained on hydrogen with a suitable catalyst present.

ERRATUM

MAGNETIC SUSCEPTIBILITY OF GASES. PART I, PRESSURE DEPENDENCE

BY FRANCIS BITTER

(Phys. Rev. 36, 1572, 1930)

On page 1572 of the above mentioned paper a gas mixture is discussed whose composition is given as 89% CO₂+11% O₂. This is obviously an error in transcription, and should read 98.9% CO₂+1.1% O₂. That this is so follows from the fact that, as stated, the concentration of the mixture was calculated from the ratio of the susceptibility of the mixture to that of pure CO₂. This ratio is given as -0.83. If α represents the fraction by volume of O₂ in the mixture, the following relation must be satisfied

$$\frac{(1-\alpha)K_{CO_2} + \alpha K_{O_2}}{K_{CO_2}} = -0.83$$

and substituting $K_{CO_2} = -8.3 \times 10^{-10}$ and $K_{O_2} = 0.14 \times 10^{-6}$ this gives for α 1.1×10^{-2} .

In all references to this CO₂-O₂ mixture, the O₂ content should consequently be divided by 10.

The experiment involving this mixture was undertaken to repeat observations made by Glaser, and the intention was to produce a mixture containing about 1% of O₂, as was actually done. I wish to express my indebtedness to H. Buchner¹ for calling my attention to the above error.

BOOK REVIEWS

Sammlung Götschen: Nr. 698, Allgemeine und Physikalische Chemie, Zweiter Teil; von PROFESSOR DR. HUGO KAUFFMANN. Nr. 804, Grundbegriffe der Chemie, von DR. E. RABINOWITSCH. Published by Walter de Gruyter and Company, Berlin and Leipzig, 1930. Price R.M. geb. 1.80 each.

These volumes of the Sammlung Götschen present in a brief but clear manner the fundamental ideas and principles of the subjects which they cover. The volume on "Allgemeine und physikalische Chemie" covers the following subjects in 145 pages. (1) Chemical Constitution (2) Thermochemistry (3) Electrochemistry (4) Photochemistry (5) The Properties of Atoms (a) atoms and electrons (b) radioactivity. The little volume on "Grundbegriffe der Chemie" has 148 pages of subject matter divided into two parts. In the first section the elements and chemical compounds are discussed under the headings (a) Constitution, Kind and State of Matter (b) Structure of Matter. Section two is devoted to chemical reactions. Here are discussed reactions and their symbolic representation, heats of reaction and chemical equilibrium. While the consideration of the subject matter must necessarily be brief, the material is correctly and carefully presented. Students in other fields of science should find these volumes especially useful in giving them a brief but clear picture of the field of theoretical chemistry. Students of chemistry wishing to review the subjects will also find these volumes very satisfactory.

L. H. REYERSON

The Theory of The Potential. W. D. MACMILLAN. Pp. xiii+469. Figs. 112. McGraw-Hill Book Co., New York, 1930. Price \$5.00.

A short chapter on the calculation of the force of attraction between finite bodies of constant density and simple form is followed by a longer chapter on the Newtonian potential function. Next comes a chapter on vector fields, in which the theorems of Green, Gauss, and Stokes and Poisson's equation are developed. Chapter IV deals with the attraction of surfaces and lines with particular attention to cases where the attraction is not well-defined. This is followed by a chapter on surface distributions of matter in which Green's problem is developed, and one on two-layer surfaces such as are involved in electrostatics and magnetostatics. The last two chapters are on spherical harmonics and ellipsoidal harmonics. A brief bibliography and index close the book. A few problems, more of a mathematical than of a physical nature, are placed at the end of most of the chapters.

Scalar notation is employed throughout, and the potential is taken with the opposite sign to the potential energy in the major part of the text. While this question of sign may not be of much importance in gravitational theory, the confusion necessitated by the change of sign when two-layer surfaces are treated could easily be avoided if the potential were always taken with the same sign as the potential energy, as is the general usage in electrostatics and magnetostatics.

The subject is clearly and logically developed, and only a reasonable amount of mathematical preparation is required of the reader. The book is excellently printed and very free from printer's errors.

LEIGH PAGE

Mechanics for Students of Physics and Engineering. HENRY CREW AND K. K. SMITH. Pp. xvi+371. 215 figures. Macmillan Co., New York, 1930. Price \$4.00.

Although an outgrowth of the senior author's "Principles of Mechanics," published a quarter of a century ago and for some time out of print, this text is more than a revision of the earlier work. Not only is the arrangement new, but chapters on statics and wave motion have been added, and the historical setting, which the senior author is so skillful in portraying, has been given a more prominent position than before.

By beginning with statics and its applications, the authors are able to defer the use of the calculus until a quarter of the text has been covered. This makes the book especially suitable for use with elementary students who are starting calculus and mechanics at the same time. The authors point out the value of vector methods at the very beginning, and introduce the vector product as soon as they have occasion to deal with torques. This simplifies the analysis and puts the emphasis where it belongs, that is, on the physical concepts involved instead of upon the auxiliary mathematical methods required for solution.

Statics is followed by kinematics and kinetics, particular emphasis being laid on the parallelism of the dynamics of translation and that of rotation. The concepts of force and mass are analysed more carefully than is customary in elementary texts, a careful distinction being drawn between gravitational and dynamical mass. The applications chosen to illustrate the mechanical principles presented have been most happily chosen, as regards both the stimulation of the reader's interest and the exemplification of the particular point under discussion. Kinetics is followed by chapters on friction, properties of elastic bodies, hydro-mechanics, and wave motion.

The historical rather than the logical method of approach has been followed in the main. While this method of treatment may be subject to criticism in a more advanced text, it doubtless possesses pedagogical advantages in an elementary book. Unquestionably the historical atmosphere which pervades the whole of the treatment is a source of much added interest, particularly to the student who does not intend to specialize in physics.

PROCEEDINGS
OF THE
AMERICAN PHYSICAL SOCIETY

MINUTES OF THE LOS ANGELES MEETING, DECEMBER 12-13, 1930

The 167th regular meeting of the American Physical Society was held in Rooms 29 and 137 of the Physics-Biology Building of the University of California at Los Angeles, jointly with the Acoustical Society of America, on Friday, December 12th and Saturday, December 13th, 1930. The meeting was called to order by the local secretary of the Pacific Coast at 10:15 on Friday morning. On vote of the members of the Society Professor S. J. Barnett, chairman of the Physics Department, University of California at Los Angeles, presided.

The morning session was devoted to papers on spectroscopy, while the afternoon session consisted of a joint session of the Acoustical Society of America and the American Physical Society dealing with problems of mutual interest. On Saturday morning the program of the Physical Society was continued, dealing largely with topics of general interest exclusive of spectroscopic and mathematical-physical subjects. On Saturday afternoon at four o'clock the meetings resumed for the presentation of papers on mathematical-physical subjects and on x-rays. The meetings adjourned at 5:30.

The members of the Acoustical and Physical Societies attended a joint luncheon on Friday noon in the Y.W.C.A. building of the University of California at Los Angeles. There was a subscription dinner on Friday evening for both societies at the Beverley Hills Hotel. At noon Saturday the members of both societies were entertained at a luncheon given by the members of the Acoustical Society of America resident in Los Angeles, which had been kindly arranged by Professor Vern Knudsen, the luncheon being given at the Hotel Roosevelt.

There were some sixty members of the American Physical Society in attendance, covering representatives from the Pacific Coast as far north as Oregon.

As there were no questions of importance to come before the society at this time the meeting adjourned without holding a business session.

The regular scientific session consisted of thirty-one papers. The abstracts of these papers are given in the following pages. An *Author Index* will be found at the end.

LEONARD B. LOEB
Local Secretary for the Pacific Coast

ABSTRACTS

1. Optical constants of CS_2 -gasoline mixtures, at approximately 20°C , over the whole concentration range. L. E. DODD, *University of California at Los Angeles*.—Optical constants, particularly n_D and dispersion values, are obtained with a refractometer of the Abbé type, having heatable prisms. The gasoline used is of the commercial type, and the CS_2 is commercial.

2. Metastable molecules and active nitrogen. JOSEPH KAPLAN. *University of California at Los Angeles*.—Strong uncondensed discharges through mixtures of nitrogen and mercury vapour at pressures of about 5 cm, yielded spectra of the first positive group of nitrogen with intensity distribution remarkably similar to that observed in the nitrogen afterglow. The bands originating on the B_7 and B_9 levels were strongly enhanced whereas in active nitrogen the bands arising on B_8 , B_{10} , B_{11} and B_{12} are the unusually intense ones. The difference $C_0 - A_0$ in nitrogen is almost equal to the energy of the mercury atom in the 2^3P_1 level and the difference $C_0 - A_1$ equals the energy of the 2^3P_0 state of mercury. Thus collisions of the second kind between nitrogen molecules in the C_0 or C_1 levels (which are plentiful in the discharge) and Hg atoms, would account for a high concentration of metastable nitrogen molecules in the A_0 and A_1 levels. A second method for producing metastable molecules in these levels arises from the fact that the X_{18} and X_{19} levels of N_2 agree almost exactly with the 2^3P_0 and 2^3P_1 levels of Hg. An accumulation of nitrogen molecules in these levels would yield a large number of metastable N_2 molecules and nitrogen atoms in the electric discharge. The relationship of this experiment to the auroral spectrum is discussed.

3. The ultraviolet band system of sulfur monoxide, a $^3\Sigma \rightarrow ^3\Sigma$ transition. EMMET V. MARTIN AND F. A. JENKINS, *University of California*.—The SO bands discovered by Henri (Jour. Phys. Rad. 10, 81, (1929)) in the region $\lambda\lambda 2500-3500$ have been photographed in the first order of the 15-foot Rowland grating. The source was a quartz discharge tube containing SO_2 at 30 mm pressure, actuated by a condensed discharge with spark gap and inductance. The spectrum appears to be closely analogous to the Schumann-Runge system of O_2 (Holtgreven and Dieke, Ann. d. Physik 3, 937, (1929)). The characteristic structure found there for a $^3\Sigma \rightarrow ^3\Sigma$ transition is clearly shown in the SO bands. Thus each band contains only P and R branches, in each of which the lines split into narrow doublets with increasing K . The short-wave component is stronger (in contrast to O_2) and at the highest K values this in turn splits in two, giving clearly resolved triplets. The components of these are of equal intensity and correspond to the triplet levels $J=K+1$, K , and $K-1$. This structure is best shown in the bands with $v'=0$. In the $v'=1$ progression, the P and R branches are usually almost superposed, and irregularities are present which must be ascribed to a number of small perturbations in the rotational levels of the upper state.

4. Zeeman effect of the hyperfine structure in thallium II and III. R. F. BACHER (National Research Fellow), *California Institute of Technology*.—The positions and intensities of the Zeeman components of lines which have hyperfine structure can be calculated for intermediate field strengths. This has been done for several of the lines of the first and second spark spectra of thallium which have recently been studied experimentally by McLennan and Durnford. (Roy. Soc. Proc. A129, 48, (1930)) The line ($6s7s\ ^3S_1 - 6s7p\ ^3P_2$) $\lambda 5949$ of Tl II and the line ($7s\ ^2S_{1/2} - 7p\ ^2P_{1/2}$) $\lambda 4110$ of Tl III have been studied particularly. For field strengths between 20 and 25 kilogauss the former shows an intermediate type of Zeeman effect while the latter shows an incomplete Paschen-Back effect. A comparison shows that there is agreement between the calculated results and experiment, although the observed patterns do not seem to be completely resolved.

5. Preliminary report on an investigation of the spectrum of columbium. ARTHUR S. KING, *Mount Wilson Observatory* AND WILLIAM F. MEGGERS, *Bureau of Standards*.—Analyses of the structures of the very rich spectra of neutral and ionized columbium, although partly successful (Meggers, Jour. Washington Academy of Science 14, 442, (1924) Meggers and Kiess, J.O.S.A. and R.S.I. 12, 431, (1926)), could not be extended without new descriptive data and improved

wave-lengths. A comparison of the furnace spectrum with the arc and spark spectra has therefore been made, and has resulted in the temperature classification of 650 of the stronger lines. The wave-lengths of more than 4000 lines have been measured in the arc and spark spectra from $\lambda 2640$ to $\lambda 6900$. Tested by "constant differences" between wave-numbers, the average error appears to be less than one part per million, or about 1/10 of the tolerance on values heretofore available. A feature of special interest is the large proportion of columbium lines showing hyperfine structure. Such lines are plentiful in the spectra of both neutral and ionized columbium, and are not confined to groups requiring high excitation. Much variety in width of patterns is found. While some lines are more than one wave-number in width, the components are so closely spaced that high resolution will be required for a study of their structure.

6. New data on the absorption bands of atmospheric oxygen. H. D. BABCOCK AND W. P. HOGE, *Mount Wilson Observatory*.—From numerous new spectrograms and further measurements of earlier plates, revised wave-lengths are derived for 382 oxygen band lines. Significant differences from previous Mount Wilson results occur only for lines most difficult to measure. Principal lines in the *A* band, strong in solar spectrum, were observed with interferometers as fine sharp lines in 30 meters of air. Solar grating spectra of dispersion ranging from 0.8 to 0.12 Å per mm and resolving power 200,000 to 400,000 were used for other bands. Due to the variety of instrumental equipment available and amount of measurement done, observational errors were reduced to approximately 0.001 Å for the best material. Improved resolution has thus been obtained and band structure extended to higher rotational states. Accurate wave-lengths are determined for 241 lines in 5 bands of $O^{16}-O^{16}$, 116 lines in 2 bands of $O^{16}-O^{18}$, and 25 lines in 1 band of $O^{16}-O^{17}$. For the *A* band our results differ from those of Badger and Mecke by amounts far exceeding our observational errors. Following a rigorous theoretical study of the isotope effect in band spectra by Birge, a full discussion of the new data will appear in a joint paper giving precise relative masses of O^{16} and O^{18} .

7. Precision determination of atomic mass ratios from band spectra. RAYMOND T. BIRGE, *University of California*.—With sufficiently extensive data available, it is preferable to calculate directly the band constants of two isotopic molecules (such as $O^{16} \cdot O^{16}$ and $O^{18} \cdot O^{16}$), rather than to use the customary method of calculating each line of $O^{18} \cdot O^{16}$ from the observed constants of $O^{16} \cdot O^{16}$. Each pair of constants involves ρ to some power, and $mass_{18} = mass_{16} / (2\rho^2 - 1)$. Two important relations are $\omega_e^i = \rho \omega_e$ (vibrational isotope effect), and $B_e^i = \rho^2 B_e$ (rotational effect). These relations should be theoretically correct to the extent that the electric field is identical for the two molecules (as indicated by the proportional size of the electronic isotope effect). Other relations such as $\alpha_e^i = \rho^3 \alpha_e$, and $x_e^i = \rho x_e$ should be correct only to the extent that the old mechanics is true (as contrasted with the new mechanics). An independent calculation of α_e^i (or of α_e) requires data from two bands, and x_e^i (or x_e) requires three bands. These constants (α_e and x_e) are needed for the extrapolation to B_e and ω_e from the observed B_v and ω_v . A precision method for calculating B_v has been published, and a similar method for obtaining ω_v is now devised. This method is being applied to new data on oxygen obtained by Babcock and Hoge.

8. The rotational Raman effect in carbon dioxide. W. V. HOUSTON AND C. M. LEWIS, *California Institute of Technology*.—By the use of a large, water-cooled mercury arc, and a highly polished reflector, we have been able to reduce the exposure time necessary to secure a spectrum of the light scattered by gases. This has made it possible to use a large spectrograph and to resolve the rotational Raman band of carbon dioxide. The results indicate that, for rotation about an axis perpendicular to the line joining the two oxygen atoms, the spectrum is similar to that of O_2 , and indicates a moment of inertia of about 7×10^{-39} . The rotational quantum number jumps by two units, which shows that there are no *Q* branches in the transitions from the ground state to the upper electronic state which is active in producing the Raman spectrum. Alternate lines are very weak, and it seems probable that they are missing altogether. There is a slight indication of another very much smaller moment of inertia.

9. A determination of e/m from the Zeeman effect. J. S. CAMPBELL AND W. V. HOUSTON, *California Institute of Technology*.—Values of e/m have been obtained from the Zeeman separations of the Cd line $\lambda 6439$ and the Zn line $\lambda 6362$. Magnetic fields up to 7500 gauss are produced in a solenoid giving less than 0.1% departure from uniform field strength over a length of 6 cm at the center. The current-field ratio of the solenoid is evaluated by balancing its field against those of single layer standard solenoids. Evaporation of Zn and Cd in the short (6 cm) positive column of a helium discharge at the center of the solenoid gives the desired lines, the Zeeman patterns of which are photographed with a Fabry-Perot interferometer crossed by a prism spectrograph. Measurement of the separations at orders of interference in the neighborhood of 100,000 gives the following values of e/m : Zn $\lambda 6362$, seven exposures: 1.7577×10^7 e.m. units per gram with a mean deviation of ± 0.0005 . Cd $\lambda 6439$, eleven exposures: 1.7573×10^7 with the mean deviation ± 0.0015 .

10. Emission and absorption spectra of CaF. A. HARVEY (*Commonwealth Fund Fellow*) *University of California*.—High dispersion spectrograms of these bands have been studied for the purpose of (1) searching for possible evidence of the isotopes of Ca, (2) interpreting the appearance of the two visible systems in terms of the known structure types of ${}^2\Pi \rightarrow {}^2\Sigma$ and ${}^2\Sigma \rightarrow {}^2\Sigma$ transitions. The observed heads and their intensity distribution have been accounted for in detail in terms of the above transitions, by an approximate evaluation of the molecular constants. Due to the near equality of these constants in the upper and lower states, the heads are in general formed at very high J values. This results in two important modifications in passing from emission to absorption. (1) Certain heads disappear, or are greatly weakened, due to the lower temperature; (2) the intensity maximum in a sequence is shifted toward earlier members. The remarkable appearance of the ${}^2\Sigma^{(v)} \rightarrow {}^2\Sigma^{(v)}$ sequence in absorption is a natural consequence of these factors, as are also the presence of only one set of heads in the ${}^2\Pi_{3/2}^{(v+1)} \rightarrow {}^2\Sigma^{(v)}$ sequence, and of a new set—shaded toward the red—in ${}^2\Pi_{1/2}^{(v+1)} \rightarrow {}^2\Sigma^{(v)}$, which had previously been thought to be absent. Support for these conclusions has been found in a study of the analogous SrF spectrum.

11. An apparatus for the evaporation of various materials in vacuo. JOHN STRONG AND C. HAWLEY CARTWRIGHT, *California Institute of Technology*.—The evaporation process is much easier and requires less time than sputtering and permits the deposition of many more materials. Moreover, the thickness of the deposited film can be brought under more delicate control. The method is useful for making fine reflecting mirrors of many metals and these can be protected from tarnishing by depositing onto them an extremely thin transparent film of some non-metal such as quartz. Charcoal cooled with liquid air was satisfactory for maintaining the necessary high vacuum. The metallic elements deposited were Al, Sb, Be, Bi, Ca, Cr, Co, Cu, Au, Fe, Pb, Mg, Mn, Ni, Se, Ag, Te, Sn, and Zn. Some alloys may be deposited, such as speculum metal. Some non-metals deposited were quartz, fluorite, the alkali halides, and silver chloride. These materials may be deposited on any surface that is not affected by the high vacuum, such as glass, metal, paper, cloth, rubber, and nitrocellulose.

12. Effects of phase and time shifts on binaural sensation of direction. A. W. NYE AND A. K. STEUNENBERG, *University of Southern California*.—Experiments were made to test the effect of phase and time shifts of pure tones on the binaural sensation of direction. Separately generated tones were led to two ears via independent telephone receivers. Sources consisted of a metal disk rotated by a variable speed motor. Periphery was cut in sine wave and located in front of slits through which light passed to photoelectric cells and associated amplifiers. Two slits were used, one being adjustable so that any desired location with respect to the phase of the sine wave could be obtained. Means for interrupting the two light beams independently were provided. Between 180 dv and 725 dv, 27 observers consistently judged direction as that of the leading phase, with tendency toward greater angle shift at higher frequencies. Interrupted tones gave effect of sound origin on side where sound first arrived. Phase shift exaggerated this if in same direction; if opposed, the temporal ruled first and effect shifted later in favor of phase.

13. On the measurement of galvanometer or radiometer deflections which are ordinarily masked by Brownian movement. SINCLAIR SMITH, *Mount Wilson Observatory*.—Under certain conditions the following technique enables one to measure galvanometer or radiometer deflections which are small compared to the mean amplitude due to Brownian motion. A beam of light from the instrument mirror is brought to a focus on a photographic film and the intensity of the light is reduced to such a value that a relatively long time interval, Δt , is required to record the image on the film. Δt should be several times the average "period" of the Brownian excursions.

When a measurement is made, the instrument is set at the zero position and the recording lamp is turned on for a time Δt . The "effect" is then allowed to act, the photographic film is given a displacement, and when the instrument has had time to reach full deflection, the light is again turned on for a time Δt . The actual deflection is determined later on a comparator. If the damping factor of the instrument, and Δt are properly chosen, and the instrument is free from drift, the photographic image builds up in such a way that it has a sharp maximum making possible excellent comparator settings.

14. Ionization of helium, neon, and argon by alkali positive ions. RICHARD M. SUTTON AND J. CARLISLE MOUZON, *California Institute of Technology*.—A more extensive investigation of the ionizing properties of several positive ions from Kunsman sources has been carried forward by a method previously reported (Phys. Rev. 33, 364, (1929) and 35, 694, (1930)). Evidence of ionization of the three lighter noble gases by alkali positive ions from lithium to caesium has been found, setting in at accelerating potentials in the neighborhood of 150 volts and increasing steadily to the highest potential used, 750 volts. Comparison of the relative efficiencies of the process indicates that, for a particular gas, ionization is produced most intensely by that alkali ion which lies closest to the gas in atomic number; i.e., Li^+ ions in helium, Na^+ ions in neon, and K^+ ions in argon. Moreover, the maximum of ionization increases markedly with the atomic weight of gas used, being greatest for argon. Similar results have been determined by Dr. Otto Beeck, (Ann. d. Physik 6, 1001 (1930)) using a magnetic analysis method well adapted to the purpose. Experiments are now in progress to determine whether mass or electron configuration plays the predominating part in the process. Neither energy nor velocity of the positive ions, or ballistic transfer considerations appear sufficient at present to account for the striking results obtained.

15. Nuclear scattering of high velocity electrons. H. VICTOR NEHER, *California Institute of Technology*.—A homogeneous beam of fast electrons, two millimeters in diameter and equal to a current of $1.5 (10^{-6})$ amperes, is allowed to fall normally upon a thin foil. The thickness of the foil is such that single scattering predominates in the angular range through which the scattered electrons are collected. Secondary electrons up to one-fourth the voltage of the primary beam are eliminated by interposing an absorbing foil of known stopping power which allows 98–99% of the electrons scattered by nuclei to pass through. The majority of the secondary electrons from the interposed foil on the collector side are stopped by a retarding potential of 1500 volts. Scattering is obtained as a function of various angles between which the electrons are collected, thickness of foil and voltage of the primary beam. A range of voltage from 45 to 145 K.V. is used. Results show that for aluminum, the absolute value for scattering is from 25 to 50% lower than that obtained by previous workers in this field, and from 20 to 30% higher than the predicted value of wave mechanics with spin and relativity corrections. The large experimental value may be due to radiative effects, which would tend to increase the scattering at larger angles and which have not been incorporated into the theories of scattering to date.

16. The probability law governing ionization by electron impact in mercury vapor. CURTIS R. HAUPT (Introduced by Ernest O. Lawrence) *University of California*.—In order to detect any fine structure in the ionization probability function, such as that observed by Lawrence in mercury vapor, it is necessary to employ electron beams of a high degree of homogeneity. The method of magnetic separation, with Faraday cylinder type of ionization chamber used by Lawrence is open to the objection that magnetic orientation of the atoms or

spurious effects arising from electron reflection at the walls of the ionizing chamber might account for the results. With an electron gun type of ionization tube which eliminated the above sources of error, and which permitted realization of a rather high degree of homogeneity in the electron beam, the ultra-ionization potentials discovered by Lawrence were completely checked. In addition, his probability law was verified to within the limits of experimental error and new ionization potentials in the mercury atom were found at 12.3; 12.45; 12.85 and 13.2 volts. On account of striking numerical agreements with spectroscopic data, it is suggested that these new critical potentials are connected with the ionization of metastable mercury atoms. This suggestion is supported by the current-voltage characteristics of the tube itself.

17. **Photoelectric properties of atomic layers of potassium on a silver surface.** JAMES J. BRADY, *University of California*, (Introduced by Ernest O. Lawrence).—In this work atomic layers of potassium were deposited on a silvered glass surface which was maintained at liquid air temperature. By means of a specially designed vacuum tube a well defined beam of potassium atoms could be obtained. The film thickness was determined from the vapor pressure of the heated potassium and the length of time taken for the deposit. The pressure, in turn, was determined from the table given by H. Rowe (*Phil. Mag.* **3**, 540 (1927)); the temperature of the heated potassium being determined by means of a thermocouple. Spectral distribution curves were taken for various thicknesses of film. The threshold was found to be at a longer wavelength for a monomolecular layer (3×10^{15} atoms per cm^2) than for any other thickness. The maximum emission, however, occurs at about 5 atomic layers. The curves approach the wavelength axis quite steeply for thicknesses of a monomolecular layer or less, in contrast to an asymptotic approach for a greater number of layers. The curves are identical for thicknesses greater than 12 atomic layers.

18. **A visual study of the initial stages of spark breakdown in air.** FRANK G. DUNNINGTON, *University of California*. (Introduced by Ernest O. Lawrence).—With the Kerr cell electro-optical shutter it has been found possible to observe visually the breakdown of a single spark at any stage of its development. This provides a means of determining the initial regions of breakdown (as indicated by their luminosity) and the manner in which the breakdown progresses. At atmospheric pressure in an initially homogeneous field a faint diffuse path first appears connecting the electrodes. A bright spot then develops at the cathode and a conducting filament builds out from it meeting a filament of later origin which has come from the anode. The entire process requires slightly over 10^{-8} sec. for a gap of 6 mm. Initially non-homogeneous fields give various types of breakdown, the initial breakdown region being in the central part of the gap in some cases instead of at the cathode. Space charges that can produce field distortion sufficient to cause localized regions of luminosity can form within 5×10^{-9} sec. In general the effect of moisture in the air increases the field distortion. The low capacity nitrobenzene Kerr cells developed for this study have a time of cut-off less than 10^{-9} sec. Increasing the capacity of the Kerr cell, keeping other factors the same, causes a retardation in cut-off (2.5 times the capacity gave a delay of 2×10^{-9} sec.).

19. **The mobility of aged ions in air.** N. E. BRADBURY, *University of California*. (Introduced by L. B. Loeb).—Investigations by Marshall (*Phys. Rev.* **34**, 618, (1929)) and Luhr (*Phys. Rev.* **35**, 1394, (1930)) on the recombination of ions produced by intense x-radiation have shown that the coefficient of recombination decreases continuously as the age of the ions increases after the sharp initial drop due to non-random distribution. An investigation by Luhr and Bradbury (*Phys. Rev.* **35**, 1398, (1930)) using the same source of ionization and ionization chamber on the mobilities of air ions aged over the same lengths of time using a Langevin method of low resolving power gave negative results. In the present investigations the value of the mobility of air ions produced in pure air by x-rays has been studied for ions between the ages of 0.04 sec and 1 sec. An absolute method devised by Tyndall and Grindley (*Proc. Roy. Soc.*, **110**, 341, (1926)) is used which consists essentially of the application of an intermittent alternating field to parallel plates immersed in a gas. The frequency of the alternations may be varied by means of a commutator system, and at a critical frequency a maximum occurs

in the electrometer current-frequency curve from which the mobility may be calculated. For new ions of age less than 0.08 sec the average of all determinations gives 2.21 cm/sec/volt/cm for the mobility of the negative ion and 1.59 cm/sec/volt/cm for the positive ion in agreement with absolute values obtained by Loeb and Tyndall and Grindley. By varying the constants of the commutator system the ions could be aged for varying lengths of time. Mobilities measured after ageing show a decrease whose magnitude increases with increasing age until values 10 percent lower than the normal are reached at ages of 1 sec. This effect can be partially correlated with the decrease in the coefficient of recombination.

20. The collision cross-section of thallium atoms for slow electrons. ROBERT B. BRODE, *University of California*.—The average collision cross-section of thallium atoms has been measured by sending a beam of electrons through thallium vapor and observing the decrease in intensity of the beam as a function of the pressure of the vapor. From these data the absorption coefficient, α , i.e. the sum of the collision cross-sections of the atoms in one cubic centimeter of the gas at 1 mm pressure, has been calculated. α plotted as a function of the velocity of the electrons shows a sharp minimum at 1.4 volts, $\alpha=15$, a maximum at 4.5 volts, $\alpha=51$, and then sloping off gradually with $\alpha=31$ at 25 volts and $\alpha=20$ at 100 volts. The thallium atom appears to have about $\frac{1}{2}$ of the effective collision cross-section of a mercury atom for 100 volt electrons. The numerical magnitude of α depends on the density of the thallium vapor which is calculated from the vapor pressure, using the equation, $T \log p = 8890 + 8.55 T$. However, the data from which this equation was obtained can not be relied upon sufficiently to attach much significance to the difference in size of the Hg and Tl atoms as measured by their effective collision cross-sections. The precision with which the relative values of the absorption coefficients can be observed is independent of this uncertainty of the vapor pressure.

21. The production of high speed mercury ions without the use of high voltages. ERNEST O. LAWRENCE AND DAVID H. SLOAN, *University of California*.—For studies of collision processes involving high speed charged particles we are developing methods for the production of such high speed particles which do not require high voltages. A method for obtaining high speed protons was described at the September meeting of the National Academy of Science (Science 72, 376, (1930)). For heavier ions we are using a succession of cylinders arranged in line and connected alternately to the inductance of an oscillatory circuit. High frequency voltages of proper amount and frequency accelerate successively ions traveling through the tubes. This method has been demonstrated in principle by R. Wideroe (Ark. F. Elektrot, 21, 387, (1929)). Our initial experimental arrangement has yielded with little difficulty mercury ions of about 90,000 volt electrons energy using a high frequency exciting voltage of 11,000 volts at a wave-length of 70 meters. A tube capable of much greater voltage amplification is under construction.

22. Polarization of light scattered by H-atoms. BORIS PODOLSKY, *Los Angeles*.—In the solution of the dispersion problem, if the size of the atom is not neglected in comparison with the wave-length of light, the scattered light is found to have a component of the electric vector in the direction of propagation of the incident light. The relative intensity of the two components of scattered light, when observed at right angles to the direction of propagation of the incident light, is computed as a function of the frequency.

23. Selection rules and the angular momentum of light quanta. J. R. OPPENHEIMER, *California Institute of Technology*.—One may deduce the selection rules for angular momentum from the conservation laws for angular momentum by applying these laws to the system atom plus light quantum field. This is done most readily by taking a linear Hamiltonian for light quanta: this gives an angular momentum for the quanta which is in part orbital, and in part a spin momentum which is determined by the polarization of the quanta. In this way one obtains very simply the probability of a violation of the selection rules by the multipole radiation of the atom.

24. On the theory of the scattering of high velocity electrons in hydrogen. HUGH C. WOLFE (*National Research Fellow*), *California Institute of Technology*.—The scattering of

electrons by free protons and by free electrons at rest is investigated, using the Dirac transition probability method. The wave functions used are Darwin's solutions for a free particle of Dirac's linear wave equation. The interaction energy is the perturbation causing transitions. Random distribution of spins is assumed. The relativistic variation of mass with velocity is taken into account. It is found that spin and retardation effects are negligible in the protonic scattering, Mott's formula for nuclear scattering being therefore the best. For the scattering by electrons, three interactions are treated (1) electrostatic, (2) the Gaunt-Eddington form, including spin, (3) the Breit form, including also retardation. The resulting formulae are different from each other and from Mott's non-relativistic formula by terms of order $(v/c)^2$, differing in symmetry as well as in absolute magnitude. These formulae apply to scattering in hydrogen for velocities high enough to treat the proton and electron in the atom as independent but not high enough to require keeping higher powers of (v/c) , a good experimental region being from 125,000 to 200,000 volts.

25. Dependence of Compton line breadth on scattering angle with the multicrystal spectrograph. JESSE W. M. DUMOND AND HARRY KIRKPATRICK, *California Institute of Technology*.—Jauncey, Wentzel and DuMond have each attributed the observed breadth of the Compton line to the velocities possessed initially by the electrons in the scattering body. To test the correctness of this assumption the authors have obtained photographic spectrograms of the Compton effect with the multicrystal spectrograph with extremely homogeneous scattering angle for three scattering angles $63\frac{1}{2}^\circ$, 90° , 155° (inhomogeneity less than one degree). DuMond has shown (Phys. Rev. 33, 643, (1929)) that the Compton line breadth for a given scattering material and primary wave-length should increase with the scattering angle if the initial electron velocities cause the breadth. If $\Delta\lambda$ is the line breadth at say half maximum and θ the scattering angle then, according to DuMond's theory

$$\Delta\lambda = K \sin \frac{1}{2}\theta \text{ approximately.}$$

The spectrograms and microphotometer curves show an increase in breadth of the Compton shifted line in agreement with this formula. The Compton line breadths however appear to be larger than those observed with the double spectrometer by Bearden and Gingrich and by the balanced filter method of Ross. Further investigations are in progress to determine if possible the cause of this discrepancy.

26. Intensity of monochromatic x-rays reflected from platinum in the neighborhood of the critical angle. HIRAM W. EDWARDS, *University of California at Los Angeles*.—X-radiation from a water-cooled tungsten tube, operated at 50,000 volts, is made monochromatic by reflection from a calcite crystal. The monochromatic ray ($\lambda=0.69\text{\AA}$) is reflected from a platinum sputtered mirror at various small glancing angles in the region of the critical angle. The intensity of the ray reflected from platinum is measured by an ionization chamber and string electrometer. Experimental values of intensity are found to agree closely with those calculated by the Fresnel classical formula as extended by Thibaud.

27. The natural widths of some x-ray lines in the L -spectrum of uranium. JOHN H. WILLIAMS, *University of California*.—The double x-ray spectrometer, with previously examined crystals, has been used to measure the natural widths of the more intense lines in the L -spectrum of uranium at 50 kv. Most of the widths are observed in the (1, 1) anti-parallel position. Geometric corrections arising from the vertical spread of the beam have been applied. A broad focus tube has been used in order to insure a true measure of the width. These widths have been found to be greater than those observed for the MoK_α doublet. The half widths at half maximum of the following lines are: UL_{α_1} (in 3 orders), 0.44 X.U. ; UL_{α_2} , 0.50 X.U. ; UL_{β_1} , 0.32 X.U. ; UL_{β_2} , 0.38 X.U. ; UL_{γ_1} , 0.25 X.U. Possible correlations with the transitions involved are suggested.

28. Note on the statistics of nuclei. J. R. OPPENHEIMER, *California Institute of Technology*.—Consider two similar stable configurations, each with p protons and e electrons. It is then possible to give a simple purely analytical proof that the exclusion principle for the electrons and protons requires that the total wave function for the two configurations be

symmetric or antisymmetric in the coordinates of the center of gravity of the two configurations, according to whether p plus e is even or odd. To establish this it is necessary to assume that the configurations are so stably bound that the interaction between the two systems does not appreciably distort their internal motion. This condition, which may be made precise, is necessary and sufficient for the validity of the theorem.

29. Precision determination of the mass ratio of oxygen 18 and 16. H. D. BABCOCK and R. T. BIRGE, *Mount Wilson Observatory and University of California*. The theoretically simple upper level ($^1\Sigma$) of the atmospheric oxygen bands has alone been used in this analysis. Each of the four series (P_1 , P_2 , R_1 , and R_2) gives an independent evaluation of the vibrational interval $\Delta G_{1/2}$ of the A and B bands (similarly for $\Delta G_{1/2}$ of the A' and B' bands). One thus has an invaluable criterion for the detection of inconsistent data due to blended lines. 54 consistent lines of the A and B bands, and 54 of the A' and B' bands are thus revealed. Using also the results of an analysis of the α and α' bands, we obtain from the *vibrational* isotope effect, mass $O^{18} = 18.0065$ (assuming $O^{16} = 16$ exactly), with an apparent probable error of about one part in a hundred thousand. For the rotational effect only the P_1 and R_1 series are available, and it is more difficult to detect inconsistent data. From the four bands A , A' , B and B' , mass values varying from 18.002 to 18.016 can be obtained, depending upon the data included. The final results of this *rotational* isotope effect,—as calculated from consistent data by different methods,—are 18.0064 and 18.0074. These are in complete agreement with the vibrational result, when their greater probable error is considered.

30. A tungsten surface with a dual work function. A. H. WARNER, *University of California at Los Angeles*.—In a previous paper (Phys. Rev. **33**, 815 (1929)) the author has attempted to explain certain photoelectric characteristics of a tungsten surface by making the assumption that contaminations occur in patches, which have a different work function than that of the metal. This assumption has been tested by means of a new tube in which one filament of commercial tungsten has been evaporated onto the walls to form a contaminated surface for which the photoelectric properties have been determined. Another filament of the same material has been used to measure the thermionic work functions of the clean and contaminated surface. It also acts as the anode for the photoelectric measurements.

A photo-current first appears at 5800Å. The current, though extremely small (about 10^{-14} amps) exhibits maxima and minima corresponding to the illuminating source. It suddenly increases in the vicinity of 2650Å, and beyond this point is characteristic of a clean tungsten surface.

It has been possible to activate the filament until it had a work function of 2.29 volts (5400Å). It is well known that for pure tungsten the work function is 4.54 volts (2690Å). These values are obtained by the use of the equation $i = AT^2e^{-b/4T}$.

31. Air resistance of high velocity projectiles. PAUL S. EPSTEIN, *California Institute of Technology*.—The resistance of a rigid body in a current of air is, for high velocities, due almost exclusively to the inertia terms of the hydrodynamic equations. It is, therefore, permissible to neglect viscosity, and then the problem can be solved rigorously, in the two dimensional case, for polygonal contours. The result is that in the limiting case of extremely high velocities v the resistance is given by $\rho v^2 \cos^2 \alpha S$, where ρ is the density of air, S the cross section of the projectile and $\cos^2 \alpha$ the mean square of the cosine of the angle between v and the normal to the surface of the projectile. For lower velocities the resistance is considerably above this limit.

THE PHYSICAL REVIEW

A MORE ACCURATE AND MORE EXTENDED COSMIC-RAY IONIZATION-DEPTH CURVE, AND THE PRESENT EVIDENCE FOR ATOM-BUILDING

BY ROBERT A. MILLIKAN AND G. HARVEY CAMERON
CALIFORNIA INSTITUTE

(Received December 9, 1930)

ABSTRACT

The cosmic-ray *ionization-depth curve* has been extended at both its upper and lower ends and made more accurate throughout. The *absorption coefficients* obtained directly from the slope of the curve run from $\mu=0.35$ per m. of water at the top (Pike's Peak) to $\mu=0.028$ at the bottom (80 m. or 262 ft. of water below the top of the atmosphere, thus bringing to light both softer and harder components than the authors had before found. Strong quantitative evidence is presented, on the basis of the Klein-Nishina formula, that the strongest and most absorbable cosmic-ray band arises from the act of formation of helium out of hydrogen. Striking qualitative evidence is found that the three more penetrating bands are due to the formation out of hydrogen of the only other abundant elements oxygen (C, N, O) silicon (Mg, Al, Si, S) and iron (Iron group). Two independent proofs are given that the cosmic-rays enter the earth's atmosphere as photons, namely, (1) they are quite uninfluenced by the earth's magnetic field, and (2) the ionization produced by them in a closed vessel does not increase continually in going to the top of the atmosphere but passes through a maximum. It is shown to follow that the cosmic rays, in coming from their place of origin to the earth have not passed through an amount of matter that is appreciable in comparison with the thickness of the earth's atmosphere and that they must therefore originate in interstellar space rather than in the atmospheres of the stars. Some participation of the nucleus in the absorption of cosmic-rays is brought to light.

1. OBJECTIVES

THE new series of measurements presented herewith on the relation between cosmic-ray ionization and depth in equivalent meters of water beneath the surface of the atmosphere was undertaken for two very specific reasons.

First.—Our preceding experiments, published in full in 1928,¹ had brought to light what seemed to us very striking evidence that the cosmic rays have their origin in the acts of formation "in the depths of space" of the atoms of the celestially common elements helium, oxygen (C, N, O), and silicon (Na, Mg, Al, Si, S) out of hydrogen. This evidence consisted:

¹ Millikan and Cameron, Phys. Rev. 32, 533 (1928).

(a) In our experimental proof that within the limits of our observational uncertainty these rays show a uniformity of distribution, i.e., an independence of both latitude and of sidereal time. Both of these conclusions had been established by our trip to the Bolivian High Andes² in 1926, the first point not having been previously tested at all by other observers, the second having been so tested but with opposite results, though subsequent more careful experimenting by Hoffmann and Lindholm,³ Steinke,⁴ Hess,⁵ and by one of us⁶ has confirmed our conclusion;

(b) In our proof shown unambiguously by the curve itself, of the *banded character* of the rays;

(c) In the general rough agreement between our observed sequence of band-absorption coefficients and intensities, and the sequence of energies released, in accordance with Einstein's equation and Aston's curve, when the celestially most abundant elements helium, oxygen, and silicon are formed out of hydrogen; and

(d) In the rough agreement between the observed absorption coefficients and those computed from Dirac's formula connecting ray-energy with ray-absorption.

If our interpretation of our cosmic-ray results is correct, rays of still higher penetrating power should exist corresponding to the formation of still heavier elements out of hydrogen. Iron, at least, is abundant enough so that our theory suggested that we might find a cosmic-ray band, or cosmic-ray bands, of higher penetrating power than any we had thus far definitely observed. Such rays could be brought to light only by working at still lower depths in snow-fed lakes with electroscopes still more sensitive than any we had thus far used, and this new series of experiments was started in the spring of 1928 in part to test this point.

Second.—Our 1927–8 ionization-depth curve⁷ showed characteristics at its upper end, i.e., at the highest altitudes at which we had ionization-depth readings, which seemed to be a bit out of line with the theory. Thus, our analysis, by means of the Gold tables, of our curve into its "monochromatic" absorption coefficients yielded as the strongest and most absorbable component $\mu = 0.35$ per meter of water, while the Dirac formula gave for the coefficient of rays due to the formation of helium out of hydrogen $\mu = 0.30$. While this was of the right order of magnitude, indeed quite close in view of our accuracy, *the divergence was in the wrong direction*, for our computed value 0.30 had applied to a monochromatic beam, but the actual beam, even if it entered the atmosphere as monochromatic would, where observed, have secondary, tertiary, etc., components, due to Compton encounters with electrons, and all such encounters tend, *until the beam has got completely into equilibrium with its secondaries*, to push down the observed μ , i.e., the μ ob-

⁷ Millikan and Cameron, Phys. Rev. **31**, 925 (1928).

tained from the observed slope. The theory, then, shows no way by which the *computed* absorption coefficient of the pure radiation due to the formation of helium out of hydrogen can be *less than* the observed coefficient. It rather requires that the computed μ be at least as large as, and if equilibrium has not yet been obtained at the observation point, appreciably larger than the observed μ . We thought that our observations at high altitudes showed some slight indications that our uppermost lake-readings were accidentally high and we therefore wished to repeat these observations with more sensitive instruments and under better conditions, and to extend them, if possible, to still higher altitudes, hoping that a crucial test of our theory might come out of such more accurate high-altitude readings. In a word, then, we undertook the present series of observations to extend and improve our observational data at both the upper and the lower ends of the ionization-depth curve.

2. TECHNIQUE

Our mode of procedure was precisely the same as that used in obtaining the last ionization-depth curve published in 1928, save that in order both to bring out weak effects at greater depths under water, and to obtain increased precision in high altitude observing, we were obliged to increase still further the sensitivity of our electroscope. To do this we built a new spherical instrument of steel, wall-thickness 3 mm, internal capacity 1622 cc, and filled it to a pressure of 30 atmospheres. (See Fig. 1.) This procedure, according to direct observational data to be presented later, multiplied our electroscope sensitivity 13.82 fold over that obtained under a pressure of one atmosphere. It represented, too, a sensitivity more than double that used in our published 1928 observations.⁸ We determined the capacity of this electroscope with much precision by the method heretofore described,⁸ finding it to be 0.979 absolute electrostatic units. Although we have not reached with this instrument the extreme limit of possible electroscope sensitivity, since increases in volume, slight decreases in fiber-capacity and still higher pressures are possible, yet, for the purposes for which it was to be used, this instrument came close to the limit of possible efficiency as a high frequency radiation detector.

In order to test the insulating properties of our quartz supports, before filling with air under pressure we pumped the chamber entirely free of air and found that it then leaked, to cite one particular test, from 226.5 volts to 226.0 volts *in four hours*. The support-leak was thus not as much as one-tenth of the slowest rate of discharge ever observed in this work, and a small fraction of a percent of the average rate. Further, it disappears entirely in our computations on rate of ion-formation because it is included in what we call the zero of our electroscope. Such minuteness of the leak of the supports, however, shows the completeness with which this source of error has been pushed into the background in these experiments.

As in all of our cosmic-ray work we followed here the procedure of reducing the fiber-deflection to volts at the instant at which it is read. This is done

⁸ Millikan and Cameron, *Phys. Rev.* **31**, 922—5 (1928).

by calibrating the scale in the eyepiece just before or after each reading. This procedure eliminates completely all temperature effects on the fibers or on any of the electroscope parts. Thus in under-water work our procedure is to calibrate the scale for the deflection to be used under quiet reading-conditions *at the surface*, then to sink the electroscope to the desired depth and leave it for say twelve hours, then to bring it quickly to the surface, read and calibrate again. A small correction is applied for the discharge during lowering and raising by going through the operation of lowering and at once raising and seeing whether an observable change is detectable, or by doing so re-

Fig. 1.

peatedly for the sake of magnification and then computing the correction for a single operation. These corrections are small and quite accurately obtainable. In some of our earlier work we used self-registering electroscopes, but for this work we considered them of no advantage.

The electroscope with which all of the results herein reported were obtained is shown in Fig. 1. It was pumped up to a pressure of 30.14 atmospheres, one atmosphere being reckoned from the conditions existing in the Norman Bridge Laboratory at the time of filling, namely, 24°C , 74 cm pressure, and this pressure has held with no trace of leak for now two years since the time of filling.

The "electroscope constant" of this instrument in ions per cc per sec. is

$$I \text{ cc/sec} = \frac{\text{volts}}{\text{hours}} \times \frac{0.979}{300} \times \frac{10^{-10}}{4.770 \times 1622 \times 3600} = 1.172 \frac{\text{volts}}{\text{hours}}.$$

For observations on land this electroscope was provided with an accurately fitted, spherical lead shield 7.64 cm thick consisting of four layers of carefully shaped and fitted hemispherical shells, and two layers of shells divided into quadrants so as to fit closely the exterior electroscope wall, with its flange and bolts, and to facilitate the entrance of the necessary leading-in wires. The "water equivalent" of this lead shield as obtained by multiplying thickness by density was 85 cm. On account of the space occupied by the steel flange about which the inner layers of lead were fitted, the water equivalent was actually a trifle less than 85 cm, but in any case by careful experiments with radium and thorium in about the proportions in which they occur in surface rocks the percentage of local rays getting through this lead shield was found to be 2.4 percent, and save for this small correction-factor, always determined and applied to all readings, the rays inside the lead were pure cosmic rays and could be compared, as shown below, with readings at the same equivalent depth in water beneath the top of the atmosphere.

3. READINGS IN SNOW-FED LAKES

The results reported in this section were taken partially during the summer of 1928 and partially during the summer of 1929 in the two different California lakes 250 miles apart, Arrowhead Lake (altitude 5100 feet) and Gem Lake (altitude 9120 feet). Since we showed in our first work in snow-fed lakes in 1925 that the measured intensity of the cosmic rays is a single valued function of the depth of the superincumbent atmosphere, it of course follows that it depends upon the barometric pressure, as has since that time been many times noted. Accordingly, in Table I the barometer height is given for each observation, or group of observations. At the higher levels, i.e., down to about sixteen meters beneath the top of the atmosphere, where readings at the same depth beneath the surface of the lake are made at different barometric pressures, the results are reduced to a common pressure by applying a small correction, which is computed from the Gold tables,⁹ for the value of the absorption coefficient shown by the ionization-depth curve at the elevation considered. This computation, however, checks nicely with the observed slope of the curve and this slope is of course independent of any theory, so that these small barometric corrections may properly be said to be purely empirical, and hence free from any other than observational uncertainties. This correction is negligible below sixteen meters but amounts at Gem Lake to slightly more than 1% and at Pikes Peak to about 2% per tenth-inch of mercury. The under-water readings, taken in two lakes and over the period from August 1928 to September 1929, are all collected in Table I. It will be seen from columns 7 and 9 that these readings extend from a level equivalent to

⁹ Gold, Proc. Roy. Soc. A82, 43 (1909).

8.25 meters of water beneath the top of the atmosphere down to a level of 80 meters, or 262.5 feet, beneath the top, and that in that range of levels, or depths, the observed rate of discharge of the electroscope changes by more than thirty fold, namely, from a value represented by an intensity of ionization within the electroscope of 64.1 ions per cc per sec. down to 2 ions per cc

per sec. The absorption coefficients as computed from the Gold tables at successive points along this curve are given in Table II.

The curve starts a little higher up than does the 1928 curve, analyzed on page 927, Physical Review, Vol. 31, and it is significant that the absorption coefficient at the top is now a little higher than it was there, namely 0.27 in-

stead of 0.22, i.e., it is *larger, not smaller*, then before. Also, in keeping with this fact the bend, or knee, at about 10 meters is sharper than ever, as shown by the change from $\mu=0.27$ to $\mu=0.16$ between 9.5 m and 10.5 m, when on

TABLE II. *Absorption coefficients at various depths, in meters of water, below top of atmosphere.*

Depth in m. of water beneath top of atmos.	Absorption coef. μ	Depth in m. of water beneath top of atmos.	Absorption coef. μ
8.25-9.5	0.27	20-30	0.045
9.5-10.5	0.16	30-40	0.038
10.5-11.5	0.11	50-60	0.028
11.5-12.5	0.095	50-60	0.028
12.5-15.0	0.067	60-80	0.028
15.0-20.0	0.058		

the old curve we got $\mu=0.20$ between 9.5 and 10.5. *Of course this means that the most absorbable cosmic-ray band springs into view from these figures more insistently than before.*

4. LAND-READINGS UP TO GREAT ALTITUDES

The highest altitude snow-fed lake used for the foregoing readings was Gem Lake (altitude 9120 feet) and for the sake of being free from the possibility of effects due to the radioactive emanations of the atmosphere (though over large bodies of water these effects are actually very small) we used no reading nearer the surface of Gem Lake than 0.85 m, a level corresponding to 8.25 m of water beneath the top of the atmosphere. At this level, as indicated above, the curve was already beginning to show departures in the wrong direction for satisfactory explanation from the standpoint of the Dirac formula. However, in accordance with the second of the objectives discussed in §1, the most significant data were to be expected at still higher altitudes, and in order to obtain accurate data at least a meter of water higher up we arranged for a series of land observations as follows:

With the aid of the radiations emitted by known quantities of radium and thorium set up at suitably chosen points, from 2 to 10 meters away, and all around our 7.64 cm lead screen we took readings when the screen was in place and when it was removed from our electroscope, and thus found that about 2.4% of the local radioactive rays from surface rocks and soils get through the lead screen and produce ionization within our electroscope. We then took a series of land observations in various localities, situated in widely different latitudes and at varying elevations from sea level up to 14,100 feet (the top of Pike's Peak), half a dozen or more readings being in general taken at each locality over a period of several days, first, when the lead screen was in place, then when the screen was removed. By comparing these observations with those taken at the same levels beneath the surfaces of snow-fed lakes the water equivalent of the lead screen was quite accurately determined, as shown below, and in this way the depth-ionization curve was reliably extended upward the equivalent of about a meter of water above the highest point obtainable in Gem Lake. This last meter proves to be of great significance for

TABLE III. Ionization-depth readings at various elevations with and without lead screens.

Date	Locality	Elevation	Latitude	Barometer readings	Depth below top of atmosphere	Mean ions outside lead	cc/sec inside lead	% cos. rays getting through lead	Mean ions corrected for local rays

the purposes of the second objective (§1) and in general for the interpretation of the cosmic radiations. Table III contains the record of these land-readings, which were taken during the summer and fall of three consecutive years, 1928, 1929, and 1930. The two readings on Pikes Peak taken two years apart are rather noteworthy. They differ by 2%, but in view of the difference in the barometer reading this difference is not only in the right direction but of the right amount.

The figures given in the last and the third from the last columns are in all cases the means of from three to nine different readings, the fluctuations in which are illustrated, for example, by the nine consecutive readings taken on Mt. Manitou at about two hour intervals beginning at 10:30 a.m. These nine readings, in ions per cc per sec, run 54.7, 52.8, 55.5, 54.3, 52.5, 53.7, 52.4, 52.2, 54.3. Mean = 53.6.

5. THE DEPTH-IONIZATION CURVE AND ITS SIGNIFICANCE

The graphical representation of the results in Tables I and III is given somewhat inadequately in Figs. 2 and 3,—inadequately because no small scale graph can reflect the consistency and precision of these readings. For this reason the readings themselves have been given in Tables I and III so that the reader may plot his own large-scale graph if he so desires. However, two important results stand out immediately and conspicuously from the graphs:

1. At great depths, i.e., between 40 m and 80 m (see Fig. 3) the readings are so consistent as to show that even a blanket of 80 m or 262 ft. of water is insufficient to absorb completely the cosmic rays. The curve has here reached a value of 2 ions per cc per sec., not a fiftieth of its value at Pike's Peak, *but it is still falling*. In order to find the zero of the instrument, or the ionization *when all external rays have become absorbed* and at the same time the absorption coefficient of these hardest rays, we analyzed the curve by the trial and error method between 40 m and 80 m with the aid of the Gold tables, and found that with a zero of 1.2 *I* per cc/sec. and an absorption coefficient of 0.028 per meter of water, *the whole long stretch of curve between 40 m and 80 m was very accurately reproduced. In a word, our curve shows at its lower end just such a band of hard rays as we had been looking for, and a single coefficient is adequate for the whole range between 40 m and 80 m.*

The significance of the value of this coefficient will be discussed presently, but the very existence of such a coefficient means that a hundred meters farther down, i.e., at 180 m, an ionization of about 0.03 *I* per cc/sec. should be observable by an instrument capable of detecting such an amount. We checked this conclusion qualitatively in 1928 by taking our electroscope and its lead shield down into a shaft 185 m deep, beside Lake Arrowhead, and finding, after allowing for the local rays, a fraction of an ion still left for the cosmic rays, though, on account of the location of the shaft *beside the lake* we could not reliably estimate the equivalent water depth.

However, Regener¹⁰ has reported more dependable deep water observa-

¹⁰ E. Regener, *Die Naturwissenschaften* 15, 183 (1929).

tions which are in substantial agreement with the results here given. He reports his results in volts per hour, which is nearly the same as our ions per cc

Fig. 2.

per sec., since the multiplying factor of 1.171 reduces in our case I volt/hour to I per cc/sec. His lowest really detectable reading is at 186 m, though he takes

one observation at 230 m. He obtains both his zero and his absorption coefficient by essentially the same trial and error method that we use, and we take

Fig. 3.

it that both he and we may have an uncertainty of as much as $0.2 I$ per cc./sec. in our zeros. Such a change in our zeros, if taken in the right direction for

both of us, would bring our coefficients into fairly good agreement. His value is 0.018 per meter of water. However, for reasons which we shall presently detail, the precise value of the coefficient for this most penetrating cosmic radiation is not particularly significant. The important result that appears both from Regener's deep water work and from our own is merely that there exists a component of the cosmic rays which can penetrate as much as 180 meters of water and which is therefore approximately twice as hard as the hardest component we had before *directly observed* on our former curve namely, $\mu = 0.05$ per m of water.

2. The second immediately striking result that appears from our curves is that the quite accurate observations we have now taken *at high altitudes*—up to 14,100 feet, show that the absorption coefficient now rises *far above anything the Dirac formula will in any way permit*. The absorption coefficient shown at the top of our 1928 curve was 0.22 per m of water, that at the top of our present curve taken in water is 0.27 per m of water, and that at the top of the land-curve is 0.35 per m of water. This new curve then brings out more strikingly than ever the banded structure of the cosmic rays.

We have analyzed this new curve with the aid of the Gold tables precisely as we did the former one in our 1928 article. We at that time found that the peculiar sharp bend in the curve at between 10 and 12 meters could not be reproduced without invoking *three definite bands* having roughly the relative frequencies 1, 4, 8. The new curve revealed the same necessity through the shape of its upper and middle portion, while its shape at great depths requires the introduction of a fourth band, as indicated above. Fearing that we might have become special pleaders for our banded structure, we asked Dr. Bowen, who had not thus far helped in this kind of analysis, to start from first principles with our curve and see, without any suggestions from us, what kind of structure it demanded. He proceeded without reference to any theory to build up with the aid of the Gold tables our observed curve out of four components—no smaller number would do—and in such a way that the synthetic and the observed curve fitted exceedingly nicely from one end to the other.

The components from which the synthetic curve was thus built up to yield the ionization *observed in our electroscope* were as follows:

TABLE IV. *Assumed absorption coefficients and intensities of synthetic curve.*

Assumed absorption coefficients	Assumed I_0 at top of atmosphere	Total $I = I_0/\mu$
0.03	33	1100
.10	80	800
.20	130	650
.80	141,000	176,250

The foregoing of course assumes that the ionization has its maximum value I_0 at the surface of the atmosphere (see below, where this is shown to be incorrect), and the last column then shows that the total energy of formation

of the iron group, the silicon group and the oxygen group is of the same general order of magnitude. This checks reasonably well with that we know of the relative abundance of these elements, and it would probably check better if suitable corrections could be made for the foregoing incorrect assumption. Table V then gives a comparison of the calculated and observed ionization.

TABLE V. *Comparison of synthetic and observed curves.*

Depth in meters	Calculated I	Observed I	Difference
7.5	89.7	90.8	-1.0
8.0	70.6	70.6	0
9.	48.2	48.1	-.1
10.	37.1	36.9	-.2
12.	26.4	26.5	+.1
15.	19.1	19.1	.0
20.	12.53	12.55	+.02
25.	8.87	8.75	-.12
30.	6.58	6.56	-.02
40.	3.93	3.83	-.10
50.	2.49	2.62	+.13
60.	1.63	1.88	+.25
70.	1.11	1.29	+.18
80.	.74	.80	+.06

Not only can the observed curve not be fitted accurately with less components than four, but also the four must be roughly of the foregoing type, though of course the lower bands can be split up into a finer structure if desired, i.e., 0.03 can easily be replaced by 0.02 and 0.04, for example. Not very much liberty, however, can be taken with the upper bands.

We shall now compare the results of this purely empirical study of our curve with the results computed by the Klein-Nishina formula,¹¹ the Einstein equation $mc^2 = E$, and Aston's curve. This formula has the form

$$\mu = \frac{2\pi N e^4}{m^2 c^4} \left\{ \frac{1 + \alpha}{\alpha^2} \left[\frac{2(1 + \alpha)}{1 + 2\alpha} - \frac{1}{\alpha} \log(1 + 2\alpha) \right] + \frac{1}{2\alpha} \log(1 + 2\alpha) - \frac{1 + 3\alpha}{(1 + 2\alpha)^2} \right\}.$$

Where $\alpha = h\nu/mc^2$, N = no. of electrons per cc. The values of α for the atom-building processes, according to Aston, are

$$H \rightarrow He = 0.029 \div 5.479 \times 10^{-4} = 52.9$$

$$H \rightarrow O = 0.1245 \div 5.479 \times 10^{-4} = 227$$

$$H \rightarrow Si = 0.232 \div 5.479 \times 10^{-4} = 423$$

$$H \rightarrow Fe = 0.48 \div 5.479 \times 10^{-4} = 876$$

5.479×10^{-4} is the atomic weight of an electron obtained from e/m spectroscopically determined. The numerical value of the constant factor is then

¹¹ Nature 122, 399 (1928).

$$\begin{aligned}
 \frac{2\pi N e^4}{m^2 c^4} &= \frac{2\pi N e^2}{c^4} \left(\frac{e}{m} \right)^2 \\
 &= \frac{2 \times \pi \times 6.064 \times 10^{23} \times 10}{(2.998)^4 \times 10^{40} \times 18} \times (4.77 \times 10^{-10})^2 \times (5.279 \times 10^{17})^2 \\
 &= 0.16614.
 \end{aligned}$$

Then Table VI is the comparison of μ obtained from the Klein-Nishina formula and those of the synthetically obtained curves. The closeness of the agreement at the top is most significant. The progressive departures as the atoms become heavier look at first sight like a difficulty, but the next section goes into possible causes of this behavior.

TABLE VI. μ in meters of water.

	Computed	Observed
H→He	0.7957	0.80
H→O	.2409	.20
H→Si	.1418	.10
H→Fe	.0754	.028

6. CONDITIONS OF EQUILIBRIUM BETWEEN A BEAM OF PHOTONS AND ITS SECONDARIES PRODUCED BY THE COMPTON PROCESS

When a beam of photons strikes matter it is obvious that a certain thickness of matter must be traversed before the beam gets into equilibrium with its secondaries, tertiaries, etc., this condition of equilibrium being attained when as many of each kind of secondary is disappearing per second from the beam as is forming per second in it. While this process of getting into equilibrium is going on, the absorption coefficient of the beam, as measured by the rate of change with distance of the ionization produced per cc, is obviously smaller than it can be after equilibrium has been reached. Further, the absorption coefficient of the pure photon beam when it first strikes matter must be the same as that of the beam after it has got into equilibrium with its train of secondaries, provided the secondaries are more absorbable than the primaries,¹² for the reason that in this equilibrium condition the percentage of these secondaries is not changing at all as the beam moves on, the only element that is so changing being simply the number of primaries; but this is precisely the situation in which the beam found itself when it first entered matter.

¹² The apparent absorption coefficient when equilibrium is reached is equal to the absorption coefficient of the primary or the secondary, depending upon which has the smaller coefficient, the general relation being

$$I = \frac{I_0 \mu}{\mu_2 - \mu_1} (e^{-\mu_1 x} - e^{-\mu_2 x}).$$

Of the last two terms that having the larger coefficient will die out, leaving the effective coefficient the one having the smaller value. It is practically certain from Bothe and Kolhörster's work that the coefficient of the beta-rays at sufficiently high frequencies approaches that of the photons, and it is entirely possible that it may even fall below it for the hardest rays.

One of us¹³ has recently shown that the cosmic rays enter the earth's atmosphere as streams of pure photons. This means that the ionization in a closed vessel should not be a maximum at the top of the atmosphere, but that there must be an optimum position somewhere beneath the top where this maximum ionization is reached. This is precisely what the 1922 high balloon flights of Millikan and Bowen, when taken in conjunction with Hess and Kolhörster's earlier and lower balloon flights proved experimentally to be the case. For in the 1922 flights a recording electroscope rose to a height of 15.5 kilometers, at which height 0.92 of the earth's atmosphere had been left behind, and the total ionization recorded by the self-registering mechanism proved to be only about one-fourth of that calculated from the absorption coefficient of 0.57 per meter of water, which had been found by Hess and Kolhörster in rising in manned balloons to from 5 to 9 kilometers. The discrepancy seemed to be eliminated in 1923 when Kolhörster in experiments in the Alps got a coefficient only about 0.25 per meter of water, a value not in conflict with Millikan and Bowen's high flight. But up to the present day, though the lower value has been accepted, it has remained a mystery why the earlier European flights yielded such high values. This is now quite clearly explained, for the completely reliable curve shown in Fig. 1 is at the top rising quite as fast as did the Hess-Kolhörster curves, *while the 1922 work shows unambiguously that it cannot continue to do so up to 15.5 kilometers.* In other words, the coefficient has passed through a maximum somewhere between these two levels, and at 15.5 kms. has fallen back again to low values. This is obviously what, from the foregoing considerations, it must do if the cosmic rays enter the atmosphere as pure ether waves.

It will be seen from the foregoing that the Klein-Nishina formula, combined with Aston's measurements and Einstein's equation, yields quite accurately the observed absorption coefficient of the most absorbable band, when it is assumed that that band arises from the synthesis of helium out of hydrogen. Also there is good reason to assume that at the level corresponding to the top of our curve this radiation has already reached a condition of equilibrium with its secondaries, so that the comparison is probably here legitimate. The less absorbable the radiation, however, the farther must it traverse matter thus to get into equilibrium with its secondaries, and it is most illuminating to see how the absorption coefficients computed by the Klein-Nishina formula (see Table VI) for the formation of oxygen, silicon, and iron out of hydrogen *are progressively higher than the observed coefficients* as obtained from the curve, thus indicating that these progressively harder rays are farther and farther removed from the situation in which they have traversed enough matter to get completely into equilibrium with their secondaries. Further, such attainment of equilibrium should become more and more difficult the nearer the absorption coefficient of the beta-rays released by Compton encounters with photons approaches that of the photons themselves, and Bothe and Kolhörster's recent experiments¹⁴ show that this condi-

¹³ R. A. Millikan, Phys. Rev. **36**, 1595 (1930).

¹⁴ Bothe and Kolhörster, Zeits. f. Physik **56**, 751 (1929).

tion is somewhat nearly approached for the harder rays, though it is probably not so for the softer components. It may be that for these very penetrating radiations the secondary electrons are more penetrating than the primary photons and consequently even when equilibrium is reached a lower absorption coefficient should be observed than that called for by the Klein-Nishina formula.¹²

7. EVIDENCE FOR ATOM BUILDING

In a word, then, the general qualitative evidence that the cosmic rays are due to the formation out of hydrogen of the only four abundant groups of elements that there are, namely, helium, oxygen (C, N, O), silicon (Mg, Al, Si) and iron (the iron group), which elements, barring hydrogen, constitute more than 99 percent of all matter;¹⁵ is quite extraordinarily good, but this evidence only becomes *quantitative* in the case of helium. That this band, however, which contains within itself probably more than 90 percent of all the cosmic-ray energy, has so closely the absorption coefficient predicted for it by the Klein-Nishina formula, taken in conjunction with Einstein's equation and Aston's curve, is exceedingly significant. By a process of exclusion we are well-nigh forced to adopt the synthesis of helium out of hydrogen as the origin of this cosmic-ray band; for the Einstein equation and Aston's curve leave us no other alternative, provided the Klein-Nishina formula yields a result of even the right order of magnitude for the relation between absorption coefficient and photon frequency or energy. The only other act that has been suggested, namely, the falling together of a positive and negative electron, *actually releases an energy 35 times that observed as obtained through the Klein-Nishina formula*. This formula has been proved by Millikan and Bowen,¹⁶ by Chao,¹⁷ by Tarrant¹⁸ and by Meitner¹⁹ to be approximately correct for the gamma rays from Th C'' while the cosmic ray band under consideration, in accordance with our direct measurement, *is but five times* as penetrating as these gamma rays, so that wholly apart from its theoretical credentials, the extrapolation from Th C'' up to the least penetrating cosmic-ray band is not a very long one. In other words, the Klein-Nishina formula ought to hold reasonably well for this softest cosmic-ray band.

8. PARTICIPATION OF THE NUCLEUS IN COSMIC-RAY ABSORPTION

The Klein-Nishina formula, however, cannot be rigorously correct, for it makes the absorption proportional to the number of extra-nuclear electrons. We reported at the fall meeting of the National Academy in 1928 our definite evidence that the nucleus plays a role in cosmic-ray absorption. This evidence is found in the two curves of Fig. 2. If the mass absorption law held, the water equivalent of our lead screen would be 0.85 cm, this being obtained

¹⁵ H. N. Russell, *Astro. Phys. Jr.* **70**, 11 (1929). The enormous abundance of H and He is the most striking feature of this article.

¹⁶ Millikan and Bowen, *Proc. Nat. Acad.* **16**, 421 (1930).

¹⁷ Chao, *Proc. Nat. Acad. Sci.* **16**, 426 (1930) and *Phys. Rev.* **36**, 1519 (1930).

¹⁸ Tarrant, *Proc. Roy. Soc.* **129**, 342 (1930).

¹⁹ Meitner, *Naturwissenschaften* **18**, 534 (1930).

merely from the thickness of the screen (7.64 cm) and the relative densities of water and lead. The actual water equivalent of the lead screen for the softer cosmic rays is seen from the distance apart, on the x -axis, of the upper parts of the two curves, to be 122 cm. This distance would of course be expected to increase for harder rays, and the curves show that this is indeed the case, since for rays of the hardness that are found at sea level (10 m) the water equivalent of the lead has become 170 cm. Chao¹⁷ has recently brought to light a similar behavior for gamma rays, though of less magnitude, thus suggesting again the identity in nature of the gamma rays and the cosmic rays. The existence of such nuclear influences on absorption means that the Klein-Nishina formula must itself be but an approximation.

9. THE UNIFORMITY OF DISTRIBUTION OF THE COSMIC RAYS

One of us has recently presented at length new evidence that the small fluctuations that have been reported in the intensity of the cosmic rays are due merely to changes in the thickness of the absorbing atmospheric blanket which surrounds the earth, and that the cosmic rays themselves are streaming into the earth with entire constancy and uniformity of distribution over the celestial sphere. The correctness of this conclusion with respect to latitude could scarcely be more beautifully attested than by the left-hand curve of Fig. 2. The observations there presented were taken with the same instrument under identical conditions as to observational technique, but at times extending over three different summers and in widely different altitudes and latitudes, the latter ranging from 34 to 59 degrees north. *Yet they fit with quite surprising exactness one single ionization-depth curve.* The observations at Lake Louise in Canada, latitude $51\frac{1}{2}$, at Colorado Springs, latitude $39\frac{1}{2}$, and at Lake Arrowhead, latitude 34, are especially comparable because taken at about the same heights, as are also the near sea-level observations at Pasadena (latitude 34) and Churchill, Manitoba (latitude 59).

This entire constancy in distribution of the cosmic rays is their most significant as well as most amazing property, and must mean, when taken in connection with their absorption coefficient, first, that the temperature existing even in the atmosphere of the sun, whence alone they could get to us from this star, and the same is true for other stars, is inimical to the union of hydrogen into the heavier elements, for hydrogen is present in enormous quantity in the sun's atmosphere. In the second place, these facts must mean that the cosmic rays do not originate in any places in the universe from which they are obliged to come to us *through any appreciable amount of matter whatever.* If they had done so they would on entering the earth be partly beta-rays and partly photons, and, on account of the earth's magnetic field, the beta-ray part would of necessity be stronger near the magnetic pole than at lower latitudes. *But no trace of such an influence can be discovered!* That, however, all about us "*in the depth of space*" hydrogen is somehow uniting into helium at least seems to us to be convincingly shown by the foregoing data, and that it is also uniting into the only other measurably abundant elements, the oxygen group, the silicon group, and the iron group, is strongly indicated, though

precise quantitative proof becomes here impossible because of the change—always a decrease—in the absorption coefficient of a beam of highly penetrating photons while it is getting into equilibrium with its Compton secondaries. This phenomenon—the existence of which was demonstrated by the 1922 Millikan and Bowen experiments—renders futile a more precise analysis of our curve than we have given above.

10. SUMMARY

The foregoing results may be summarized as follows:

1. Much the most dependable ionization-depth curve which we have thus far presented, especially at very high and very low elevations, has been obtained and analyzed.

2. This curve shows, as did its predecessor, an unmistakable banded structure, and it further presents excellent quantitative evidence that the most intense and least penetrating band is due to the particular photon released when four hydrogen atoms unite to form an atom of helium.

3. Excellent evidence has been presented that these cosmic-ray bands enter the earth's atmosphere as ether waves and must penetrate far into it before getting into equilibrium with their secondaries; also, that until such equilibrium is attained the observed absorption coefficient is smaller than that of the initial monochromatic radiation. This means, as shown in the 1922 Millikan and Bowen experiments that there is a level beneath the top of the atmosphere at which the ionization due to a pure cosmic-ray beam is a maximum, this maximum moving rapidly farther down as the frequency of the initial photon increases.

4. The observed cosmic-ray curve has been shown to be consistent with the theory that it is made up of four bands due to the formation out of hydrogen of helium, oxygen, silicon, and iron the only atoms of sufficient abundance to render the radiation released by their formation detectable anyway, and it has been shown that the differences between the calculated and observed absorption coefficients of the photons produced by the formation out of hydrogen of oxygen, silicon, and iron are very nicely explained by the non-equilibrium theory given in (3), the departures all being in the right direction and increasing with frequency in the right way.

5. The constancy and the uniformity of distribution of the cosmic rays over the celestial sphere has been again brought strikingly to light, and the significance of this for the place and mode of origin of the cosmic rays has been again pointed out.

6. Some participation of the nucleus in the absorption of cosmic rays has been experimentally established.

We wish to express our appreciation to Professor Bowen for assisting, as indicated above, in the analysis of the curve.

RADIATION OF MULTIPOLES

BY KARL F. HERZFELD

DEPARTMENT OF PHYSICS, THE JOHNS HOPKINS UNIVERSITY

(Received December 23, 1930)

ABSTRACT

The radiation of multipoles formed by putting together elementary dipoles is investigated according to the classical theory and wave mechanics. It turns out that the radiations are of two kinds:

The first part has the same frequency as the dipoles and is present only if the multipole structure is present even without vibration.

The second part is always present. If n , the order of the multipole, is even then the frequencies are $2\nu, 4\nu$, up to $n\nu$. If n is odd then the frequencies are $\nu, 3\nu$, up to $n\nu$.

The relative intensities of subsequent multipoles are proportional to the square of the ratio: dipole amplitude to wave-length, as has been found in other cases. This calculation would apply to the infrared radiation of molecules.

RECENTLY there have appeared a number of papers on the radiation of higher poles;¹ this radiation seems to explain the presence of forbidden lines.² Although e.g. Rubinowicz' paper gives rather complete general formulas for the classical theory, it seems not useless to bring out the physical facts as clearly as possible by considering the case of a combination of linear oscillators, as they are present in molecules like CO₂ (two) or CCl₄ (four).

I. CLASSICAL THEORY

We consider quadrupoles, but there is no difficulty in generalizing to higher poles. The simplest quadrupole consists of two equal dipoles vibrating in the direction of the line joining them but with opposite phases.

If the direction of vibration is the z -axis, the field of one dipole can best be described by a Hertz-vector Z

$$\begin{aligned} Z_x = Z_y &= 0 \\ Z_z = Z &= a \frac{\cos 2\pi\nu(t - r/c)}{r} \end{aligned} \quad (1)$$

$$E = \Delta Z - \frac{1}{c^2} \frac{\partial^2 Z}{\partial t^2}, \quad H = \frac{1}{c} \text{rot} \frac{\partial Z}{\partial t}. \quad (2)$$

If we have now the two dipoles the distance l apart along the Z axis and vibrating with the same amplitude but opposite phase, we will get the re-

Bartlett, Phys. Rev. 34, 125 (1929); A. F. Stevenson, Proc. Roy. Soc. A128, 591 (1930); L. Huff and R. W. Houston, Phys. Rev. 36, 842 (1930).

² I. Bowen, Proc. Nat. Ac. 14, 30 (1928); Astrophys. J. 67, 1 (1928); R. Frerichs and I. S. Campbell, Phys. Rev. 36, 1460 (1930).

sultant Hertz vector at any point by taking the difference between the contributions from the two dipoles. The resultant Hertz vector will consist of three parts:

$$Z_2 = - \frac{a \cos 2\pi\nu(t - r/c)}{r} \frac{l}{r} \cos \theta. \quad (3)$$

This part will not contribute to the radiation in distant places on account of the factor l/r

$$Z_2 = 2\pi \frac{a \sin 2\pi\nu(t - r/c)}{r} \frac{l}{\lambda} \cos \theta. \quad (4)$$

This part does give radiation which will represent a spherical wave of the *same frequency* as the one which would be emitted by a dipole, although its intensity varies in a different manner with θ and its amplitude is diminished by the factor $2\pi l/\lambda$. The formula is

$$+ H_\phi = E_\theta = \frac{2\pi l}{\lambda} \cos \theta \left\{ \frac{4\pi^2}{\lambda^2} a \frac{\sin 2\pi\nu(t - r/c)}{r} \sin \theta \right\}. \quad (4a)$$

The total intensity emitted is the fraction $(8\pi^2/5) (l^2/\lambda^2)$ of that emitted by one dipole.

The third part is the most interesting one; it is always present, even if the two dipoles are not apart ($l=0$) when at rest, that is to say if there were e.g. two negative charges vibrating on opposite sides of a positive charge with the same position of equilibrium. It arises from the difference of position caused by the vibration itself. That is to say, we have to take r now not as the distance from the point of observation to the dipole, or quadrupole, but to the vibrating charge. If we call the deviation from the equilibrium position in a given moment z' , we have to put in (1)

$$r = r_0 + z' \cos \theta \quad (5)$$

and have for the dipole

$$\begin{aligned} Z &= a \frac{\cos 2\pi\nu(t - r_0/c) + 2\pi/\lambda z' \cos \theta \sin 2\pi\nu(t - r_0/c)}{r} \\ &= \frac{a \cos 2\pi\nu(t - r_0/c)}{r} + \frac{2\pi a^2}{\lambda} \cos \theta \frac{\sin 2\pi\nu(t - r/c) \cos 2\pi\nu(t - r/c)}{r} \\ &= \frac{a}{r} \frac{\cos 2\pi\nu(t - r_0/c)}{r} + \frac{2\pi a^2}{\lambda} \frac{\cos \theta}{2} \frac{\sin 2\pi\nu(t - r_0/c)}{r}. \end{aligned} \quad (6)$$

If the two dipoles of opposite phase are present, the first member drops out, and we have

$$Z_3 = \frac{2\pi}{\lambda} a^2 \frac{\cos \theta}{r} \frac{\sin 2\pi\nu(t - r_0/c)}{r}, \quad (7)$$

That represents a spherical wave, with the same angular distribution as Z_2 , but with the *double* frequency and an amplitude proportional to the square of the amplitude of oscillation. The total amount radiated is $(4\pi^2/\lambda_0^2(a^2)2/5)$ times the amount radiated by one dipole.

Generalization to higher poles will give the following result: Assume that we have a pole whose order is n . n is defined in this manner: Let the unit vector \mathbf{p}_i indicate the direction of one of the constituent unit dipoles which make up the higher pole. Let \mathbf{r} be the unit vector in the direction of observation.

Then a pole of order n is one for which

$$\sum_i (\mathbf{p}_i \mathbf{r})^{n'} = 0$$

for all \mathbf{r} and $n' < n$ and $\sum_i (\mathbf{p}_i \mathbf{r})^n \neq 0$ for some \mathbf{r} . In fact the left hand side is a spherical harmonic of order n . With this definition, a dipole has $n=1$, a quadrupole $n=2$, a tetrahedron $n=3$.

Let us now define a vector which will depend only on the orientation of \mathbf{r} to a system of coordinates fixed in one pole

$$\mathbf{L}_n = \sum_i \mathbf{p}_i (\mathbf{p}_i \mathbf{r})^{n-1}$$

we will need later besides a scalar, defined by

$$\sigma_n = (\mathbf{L}_n \mathbf{r}')$$

where \mathbf{r}' is a unit vector perpendicular to \mathbf{r} .

We find then two different kinds of radiation.

(1) If there is a "static" multipole structure of order n and strength p_n present, we get a radiation (Hertz vector) of the same frequency as the frequency of the constituent dipoles, but with the factor

$$\frac{1}{n!} \left(\frac{2\pi}{\lambda} \right)^{n-1} p_n \mathbf{L}_n$$

(2) If the multipole has its origin only in the motion (that is if the field in equilibrium corresponds to a pole of higher order), part (1) is absent. But there is always present a radiation with a Hertz vector

$$Z = \frac{1}{n!} \frac{a^n}{r} \mathbf{L}_n \cos^{n-1} 2\pi\nu(t - r/c) \frac{\partial^{n-1}}{\partial r^{n-1}} \cos 2\pi\nu(t - r/c).$$

If n is odd, we have

$$\begin{aligned} Z &= \frac{1}{n!} (-1)^{(n-1)/2} \frac{a^n}{r} \mathbf{L}_n \left(\frac{2\pi}{\lambda_0} \right)^{n-1} \cos^n 2\pi\nu(t - (r/c)) \\ &= \frac{(-1)^{(n-1)/2}}{2^{n-1} n!} \frac{a^n}{r} \left(\frac{2\pi}{\lambda_0} \right)^{n-1} \mathbf{L}_n \left\{ \sum_{2s=0}^{2s=n-1} \binom{n}{s} \cos 2\pi(n-2s)\nu(t - (r/c)) \right\} \quad (8) \end{aligned}$$

If n is even

$$Z = \frac{(-1)^{n/2}}{2^{n-1}n!} \frac{a^n}{r} \left(\frac{2\pi}{\lambda_0} \right)^{n-1} L_n \left\{ \sum_0^{2s=n-2} \left(\binom{n}{s} - \binom{n}{s-1} \right) \sin 2\pi(n-2s)\nu(t - (r/c)) \right\}. \quad (8a)$$

Accordingly we get radiation which has the frequency $(n-2s)\nu$.

The only similar case where this seems to have been stated explicitly³ is the case of n equal particles moving equidistant on a circle, which arrangement of course forms a pole of n fold multiplicity.

II. WAVE MECHANICS

In this case it is simpler to treat absorption instead of emission. The transition to emission is always easily made by using as external field the Landé-Dirac ghost field.

We assume a harmonic oscillator, whose Schrödinger equation is

$$\frac{d^2\psi}{dz^2} - \frac{8\pi^2 M}{h} 2\pi^2 M \nu^2 z^2 \psi = \frac{4\pi i M}{h} \frac{\partial \psi}{\partial t} \quad (9)$$

with the solution

$$\psi = \sum c_k \psi_k e^{-2\pi i k \nu t} \psi_k = e^{-i^2/2} H_k(\zeta) b_n$$

with the abbreviation

$$\zeta = 2\pi \left(\frac{M\nu}{h} \right)^{1/2} z.$$

H_n is a Hermitian polynomial.

$$b_n = \left(2^{-k} \frac{1}{n!} \left(\frac{4\pi M\nu}{h} \right)^{1/2} \right)^{1/2}.$$

If there is now a perturbation function present of the form

$$V = e^{2\pi i s \nu t} g'$$

we find

$$\frac{dc_{k+s}}{dt} = \frac{2\pi i}{h} c_k \int V' \psi_k \psi_{k+s} d\zeta. \quad (10)$$

If we have a light wave polarized parallel to z and propagated parallel to x , its electric field will be

$$E_z = E \cos 2\pi \nu s(t - x/c). \quad (11)$$

The perturbation function is then given in the first case (of a static multipole structure) by

$$V = \frac{z}{n!} \sigma_n p_n \frac{\partial^{n-1}}{\partial x^{n-1}} E_z$$

³ J. J. Thomson, Phil. Mag. (VI) 6, 673 (1903); G. A. Schott, Electromagnetic Radiation, Cambridge 1912, p. 102.

⁴ See f. e. E. U. Condon and P. M. Morse, Quantum Mechanics, New York, 1930, p. 47. A. Sommerfeld, Wellenmechanischer Ergänzungsband, Braunschweig 1929 p. 17.

from which we get⁵

$$\frac{dc_{n+s}}{dt} = \frac{2\pi i}{h} c_k \left(\frac{2\pi}{\lambda_0} \right)^{n-1} p_n \sigma_n E \frac{1}{n!} \int z \psi_k \psi_{k+s} dz.$$

The latter integral gives of course the same selection rule as for a dipole $s = \pm 1$ and only modifies the intensity of the absorption by the same factors as in the corresponding classical example.

More interesting is the case arising from the existence of the oscillatory We will put the perturbation function multipole.

$$V = \frac{1}{n!} z^n \sigma_n e \frac{\partial^{n-1}}{\partial x^{n-1}} E_z$$

which leads to

$$\begin{aligned} \frac{dc_{k+s}}{dt} &= \frac{2\pi i}{h} c_k \frac{eE}{n!} \left(\frac{2\pi}{\lambda_0} \right)^{n-1} \sigma_n \left(\frac{1}{2\pi \left(\frac{M\nu}{h} \right)^{1/2}} \right)^{n+1} b_k b_{k+s} I_{k,s}^n \\ &= \frac{ic_k}{(\pi M\nu h)^{1/2}} eE \frac{\sigma_n}{n!} \left(\frac{h\nu}{Mc^2} \right)^{(n-1)/2} \frac{1}{2^{k+s/2} (k!(k+s)!)^{1/2}} I_{k,s}^n \end{aligned} \quad (12)$$

where

$$I_{k,s}^n = \frac{1}{b_k b_{k+s}} \int \zeta^n \psi_k \psi_{k+s} d\zeta = \int \zeta^n e^{-\zeta^2} H_k H_{k+s} d\zeta. \quad (13)$$

To evaluate this integral, we use first the following formula,⁶ where an upper index j indicates j fold differentiation in respect to the argument

$$H_k^{(1)} = 2k H_{k-1}$$

and therefore

$$H_k^{(j)} = 2k \cdot (2k-2) \cdots (2k-2j+2) H_{k-j}. \quad (14)$$

If we write

$$H_k = \sum_i a_i^{(k)} \zeta^i$$

we have

$$H_k^{(j)}(0) = j! a_j^{(k)} = 2^j k(k-1) \cdots (k-j+1) H_{k-j}(0). \quad (15)$$

But on account of the formula⁵

$$H_k = (-1)^k e^{\zeta^2} \frac{d^k}{d\zeta^k} e^{-\zeta^2}$$

⁵ Of course, we have been quantizing not the motion of one charge, but of a characteristic vibration (normal coordination). As these are independent (no natural interaction), there are only transitions between different states of the *same* vibration possible, as G. Dieke has kindly pointed out.

we have

$$\begin{aligned} H_{k-j}(0) &= (-1)^{k-j} \left\{ \frac{d^{k-j}}{d\zeta^{k-j}} \left(\sum_0^\infty (-1)^l \frac{\zeta^{2l}}{l!} \right) \right\}_{\zeta=0} \\ &= 0 \text{ for } k-j \text{ odd} \\ &= (-1)^{(k-j)/2} \frac{(k-j)!}{\left(\frac{k-j}{2}\right)!} \text{ for } k-j \text{ even} \end{aligned}$$

and finally

$$\begin{aligned} a_i^{(k)} &= \frac{k!}{(i!)^2} 2^i (-1)^{(k-i)/2} \frac{(k-i)!}{\left(\frac{k-i}{2}\right)!} \text{ for } k-i \text{ even} \\ &= 0 \text{ for } k-i \text{ odd.} \end{aligned} \quad (16)$$

We now use Sommerfeld's method⁷

$$\begin{aligned} I &= \int_{-\infty}^\infty \zeta^n \left(\frac{d^{k+s}}{d\zeta^{k+s}} e^{-\zeta^2} \right) H_k d\zeta \\ &= \int_{-\infty}^\infty e^{-\zeta^2} \frac{d^{k+s}}{d\zeta^{k+s}} (\zeta^n H_k) d\zeta \\ &= \int_{-\infty}^\infty e^{-\zeta^2} \frac{d^{k+s}}{d\zeta^{k+s}} \left(\sum_{i=0,1}^k a_i^{(k)} \zeta^{i+n} \right) d\zeta \\ &= 0 \text{ for } k+s > k+n \text{ or } s > n \\ &= \sum_i \int_{-\infty}^\infty a_i^{(k)} (i+n)(i+n-1) \cdots (i+n-k-s) \zeta^{i+n-k-s} e^{-\zeta^2} d\zeta \text{ for } s \leq n \end{aligned}$$

if we now put

$$i+n-k-s=l$$

we have

$$I = \sum_{l=0,1}^{n-s} a_{l+k+s-n}^{(k)} (l+k+s) \cdots l \int_{-\infty}^\infty e^{-\zeta^2} \zeta^l ds.$$

The integral is 0 if l is odd and $\pi^{1/2} \frac{(2l)!}{l! 2^{2l}}$ if l is even $= 2j$.

Accordingly, we have

$$\begin{aligned} I_{k,s}^{(n)} &= 0 \text{ if } s-n \text{ odd} \\ &= \pi^{1/2} \sum_{j=0}^{(n-s)/2} \frac{(4j)!}{2^{4j} (2j)!} (2j+k+s) \cdots 2j \\ &\quad \cdot (-1)^{j+(s-n)/2} 2^{2j+k+s+n} k! \frac{(n-s-2j)!}{\left(\frac{n-s}{2}-j\right)!} \frac{1}{(2j+k+s-n)!^2} \end{aligned}$$

⁶ Condon and Morse, reference 4, p. 50.

⁷ Sommerfeld, reference 4, p. 59.

$$= \pi^{1/2} (-1)^{(s-n)/2} 2^{k+s-n} k! \sum_{j=0}^q (-1)^j \frac{(4j)!}{(2j)!^2} \frac{1}{4^j} (2j+k+s)! \quad (17)$$

$$\frac{(2q-2j)!}{(q-j)!} \frac{1}{(2j+k-q)!^2}$$

with $n-s=2q$.

That means that for n odd the transitions $1, 3, 5 \dots n$ and n even the transitions $2, 4, 6, \dots n$ are permitted, and accordingly the frequencies $\nu, 3\nu, 5\nu \dots n\nu$ or $2\nu, 4\nu \dots n\nu$ absorbed and emitted, in analogy to the classical theory. In normal cases, the formula are not as terrible as they look. For example, for $n=2$ (quadrupole) we have $s=2$

$$I_{k,2}^{(2)} = (\pi)^{1/2} 2^k k! \frac{(k+2)!}{(k!)^2} = (\pi)^{1/2} 2^k (k+1)(k+2).$$

If $n=3$ (tetraeder) there are possible two transitions $s=1$, frequency ν

$$I_{k,1}^{(3)} = -(\pi)^{1/2} 2^{k+2} k! \left\{ \frac{(k+1)!^2}{(k-1)!^2} - \frac{4!}{(2!)^2} \frac{1}{4} \frac{(k+3)!}{(k+1)!^2} \right\}$$

$$= -(\pi)^{1/2} 2^{k+2} \left\{ 2k^2(k+1) - \frac{1}{4} \frac{(k+2)(k+3)}{k+1} \right\}$$

$s=3$ frequency 3ν

$$I_{k,3}^{(3)} = (\pi)^{1/2} 2^k \frac{k!(k+3)!}{k!^2} = (\pi)^{1/2} (k+1)(k+2)(k+3).$$

In general, we have for $s=n$, frequency $n\nu$

$$I_{k,n}^{(n)} = (\pi)^{1/2} 2^k \frac{k!(k+s)!}{k!^2} = (\pi)^{1/2} 2^k (k+1) \dots (k+2) \quad (18)$$

which will make the factor in (12) proportional to $[k \cdot (k+1) \dots (k+n)]^{1/2}$ or $k^{n/2}$, if $k \gg n$; this corresponds to the fact that the amplitude of light emitted classically is proportional to a^n as $a^2 \sim k \sim$ the energy of one dipole.

The relative transition probability from $k+s$ to k for a pole of the n order to the same probability of a pole of $(n-1)$ the order is

$$\frac{1}{n} \frac{\sigma_n^2}{\sigma_{n-1}^2} \left(\frac{I_{k,s}^{(n)}}{I_{k,s}^{(n-1)}} \right)^2 \left(\frac{h\nu}{Mc^2} \right)^{1/2}$$

$h\nu/Mc^2$ is the ratio of the energy of vibration to the intrinsic energy and can be rewritten

$$\frac{M/2v_{\max}^2}{Mc^2} = \frac{1}{2} \left(\frac{v_{\max}}{c} \right)^2 = \frac{1}{2} \left(\frac{2\pi\nu a}{c} \right)^2 = 2\pi^2 \left(\frac{a}{\lambda_0} \right)^2.$$

Rubinowicz² has found a similar result for atoms.

THE MOTION OF ELECTRONS IN ARGON

BY H. B. WAHLIN

DEPARTMENT OF PHYSICS, UNIVERSITY OF WISCONSIN

(Received December 27, 1930)

ABSTRACT

The motion of electrons in argon containing 1.53 percent N_2 has been investigated. For low fields the mobility is a constant, but rises rapidly as the field is increased due to the increase of the electron free path with increasing thermal velocity.

The mean free path of electrons in pure argon and in thermal equilibrium with the argon is 0.385 cm at 1 mm pressure.

IN A series of earlier papers¹ results of investigations on the motion of electrons in N_2 , H_2 , He and CO have been presented. The method used was the alternating potential method of measuring mobilities. Since in the case of the electron motion through a gas the mobility is in general not a constant, this method does not lead to a direct determination of the mobility. It is possible, however, as was done in this earlier work, to make an indirect comparison of the experimental results with the theoretically calculated mobilities. In all the cases presented so far, with the exception of N_2 , a good agreement with the theory proposed by K. T. Compton² was shown to exist, provided it is assumed that the energy loss of an electron on impact with a molecule is greater than it would be if due to momentum transfer only. In N_2 the variation of the electronic free path with the electron velocity enters into the experimental results to such an extent that a check is impossible. Compton's theory takes no such variation into account.

In the present paper results on argon corresponding as much as possible to those on the other gases, are presented.

The argon used in these experiments contained, after being freed of oxygen, 1.53 percent nitrogen. This was not removed, but instead, as shall be seen, corrections were made for its presence. All the measurements were made at a pressure of 760 mm.

When the mobility is a constant, it may be calculated exactly from the voltage intercept of the mobility curves by the expression

$$K = \pi n d^2 / (2)^{1/2} V. \quad (1)$$

If the mobility is a function of V as it will be for electrons, this equation gives an average value determined by the relation

$$\int_0^{1/2n} \frac{V}{d} K \sin 2\pi n t \, dt = \int_0^{1/2n} f(v) \frac{V}{d} \sin 2\pi n t \, dt.$$

Compton's theory gives

$$f(v) = \frac{a}{[1 + (1 + BV^2)^{1/2}]^{1/2}}. \quad (2)$$

¹ H. B. Wahlin, Phys. Rev. **23**, 169 (1924); **27**, 558 (1926); **35**, 1568 (1930).

² K. T. Compton, Phys. Rev. **22**, 333, (1923).

In Fig. 1 the average values of K calculated from Eq. (1) are plotted against the field strength (V/d) in which they were determined. For very low values of the field the mobility is a constant, and over this range the values calculated from Eq. (1) are nearly exact. In fields above 2 volts/cm the mobility rises sharply. The values found for this range serve merely to illustrate qualitatively the rapid increase in the mobility.

Fig. 1.

An examination of Eq. (2) shows that according to Compton's theory one should expect a decrease in the mobility with increasing voltage due to the increased thermal velocity of the electrons. In order to account for the discrepancy between theory and experiment it is necessary to assume a very rapid increase in the electron free path in argon with increasing thermal velocity. This is in agreement with the free path determinations of Townsend and Bailey³ and others.

The results shown in Fig. 1 serve in one way as a check on Compton's theory. The equation giving the mobility as a function of the field strength (Eq. (2)) demands that for low field the mobility shall be a constant; i.e. that for low field the electrons shall be in thermal equilibrium with the gas.

Fig. 2.

The fact that the mobility is nearly a constant as V approaches zero shows that apparently the thermal velocity does not vary sufficiently to produce any appreciable change in the free path.

In Fig. 2 two typical mobility curves are presented. The curve taken at a frequency of 14,100 cycles/sec is of the same character as those found for other gases. The one taken at the higher frequency is characteristic for argon. This frequency gives two values for the mobility. The variation in the shape of the mobility curve is due to the Ramsauer effect which in argon is much more pronounced than in other gases studied.

³ J. S. Townsend and V. A. Bailey, *Phil. Mag.* **44**, 1033 (1922).

The limiting electron mobility in argon containing 1.53 percent N_2 is for low fields 59,600 cm/sec/volt/cm. The mean free path calculated from this value assuming

$$K = 0.75e\lambda/mc$$

is 0.363 cm at 1 mm pressure.

To correct for the presence of N_2 the following expression may be used

$$\frac{760}{\lambda_m} = \frac{P_n}{\lambda_n} + \frac{P_a}{\lambda_a}$$

where P_n is partial pressure of N_2 , P_a the partial pressure of argon, λ_m the mean free path at 1 mm in mixture, λ_n the mean free path at 1 mm in N_2 and λ_a the mean free path at 1 mm in pure argon. This expression was used by Townsend and Bailey with a mixture of H_2 and A and was justified by them for this case. The corrected value for the mean free path when the electrons are in thermal equilibrium with the argon atoms is (assuming $\lambda_n = 0.0996$ cm) 0.385 cm at 1 mm pressure.

In Fig. 3 the author's value of λ (indicated by X) together with Townsend and Bailey's values are plotted as a function of the thermal velocity \bar{c} . This

Fig. 3.

curve shows the prominence of the Ramsauer effect in argon, and also serves to explain the shape of the mobility curves obtained at high frequencies.

SUMMARY

The results of the determinations of the mean free paths of electrons in gases, together with the values calculated from kinetic theory, are shown in Table I.

DISPERSION AND REFRACTIVE INDEX OF NITROGEN
MEASURED AS FUNCTIONS OF PRESSURE BY
DISPLACEMENT INTERFEROMETRY

BY CLARENCE E. BENNETT

DEPARTMENT OF PHYSICS, BROWN UNIVERSITY

(Received December 15, 1930)

ABSTRACT

The Lorentz-Lorenz relation has never been satisfactorily checked by experiment for pressures above atmospheric, because of a lack of trustworthy data on the refractive indices of pure gases as functions of pressure. Such data would also be particularly valuable in the study of polar molecules on account of Maxwell's law connecting the refractive index with the dielectric constant. Due, however, to the difference between optical and electrical frequencies the refractive index must be reduced to zero frequency before Maxwell's law can be applied. This necessitates a precise knowledge of dispersion which is not available for many pure gases. In the present paper a method of measuring simultaneously the dispersion and refractive index of a gas is discussed. The method is justified on theoretical and experimental grounds and applied in a practical way to the measurement of dispersion and refractive index of nitrogen over a range of pressures and at two different temperatures with a high degree of precision.

The results show that over a seven atmosphere range the Lorentz-Lorenz relation is followed and that the dispersion is a linear function of pressure. The value of the Cauchy constant B is found to be 1.95×10^{-16} per cm of mercury pressure. The index of refraction for nitrogen is measured for three wave-lengths at 0°C and 30°C with a limiting error in $(\mu - 1)$ of one third of one percent. The dispersion information enables the values to be reduced to infinite wave-length with the result that a value for the dielectric constant is obtained which differs by less than two-thirds of one percent from that measured directly by Zahn. The values of μ under *NTP* conditions for the wave-lengths 4811Å, 5893Å, and 6362Å are 1.0002991, 1.0002969, and 1.0002967 respectively.

INTRODUCTION

THE problem of measuring the index of refraction of gases has been attacked by many observers in the past, but precise results have been obtained with only a few substances. The most accurate determinations have been made for air, an admittedly complex substance, and in practically all cases the observations have been made at atmospheric pressure. The data on air obtained by Meggers and Peters¹ with a Fabry-Perot interferometer over the whole visible spectrum range, undoubtedly represent the best work of this sort ever attempted. Trustworthy data on the index of refraction of pure gases as a function of pressure, however, were scarce at the time the present research was started. Gale² in 1902 worked on air, about the constitution of which he knew very little, up to a few atmospheres with a Jamin interferometer, and Magri³ in 1905 went up to fourteen atmospheres with air also using

³ L. Magri, Phys. Zeits. 6, 629 (1905).

a Jamin interferometer. Cheney,⁴ using pure gases, in 1927 measured the refractive indices of nitrogen, ammonia, carbon dioxide, sulphur dioxide and air over a temperature range of a few hundred degrees at one atmosphere by means of a Fabry-Perot etalon, but so far as can be ascertained, no one with the exception of Phillips⁵ who worked with carbon dioxide, has published any reliable data on pure gases at pressures higher than one atmosphere.

In the light of the Lorentz-Lorenz^{6,7} equation such information should be particularly significant. Furthermore as a result of the work of Debye⁸ and others in which dipole moments have been coordinated with dielectric constants, data on refractive index become especially valuable because of Maxwell's law connecting the dielectric constant with the refractive index. This necessitates a knowledge of the dispersion of the medium because dielectric constants are measured at very low frequencies compared with optical frequencies.

Some years ago Carl Barus⁹ made a few preliminary observations on the index of refraction of air with his displacement interferometer, as a result of which, it appeared possible to measure both refractive index and dispersion simultaneously. This work was only qualitative and no attempt was made to secure high precision, yet the experiments showed that such precision might be expected if the instrument were properly developed. It was the particular good fortune of the writer to be able to assemble an instrument of this type with the personal assistance of Professor Barus, and to adapt it for this sort of work.

DISPLACEMENT INTERFEROMETRY

The optical arrangement of the displacement interferometer is shown in Fig. 1. When the system is properly aligned so that the mirror M' is made accurately parallel to the virtual image of the mirror M as seen through the half silvered mirror HS , the interfering light beams, if viewed through the telescope T on the front of which is mounted a ruled grating, display a beautiful interference pattern consisting of black concentric oval fringes superposed on a continuous spectrum. The optical path difference necessary to produce this result is a known function of the thickness, the index of refraction, and the dispersion of the glass half silvered mirror.

These fringes are very interesting. They have been studied at length by Barus,⁹ and Birchby¹⁰ has more recently described and explained fringes of a similar nature. Like Michelson fringes they expand or contract with every

motion of the micrometer screw, but continuous motion causes the whole system to move bodily along the spectrum from violet to red as the path from the micrometer mirror to the half silver is made shorter. Using for a half silvered mirror a plate of glass 0.25 inches thick, a motion of the micrometer mirror of 0.17 mm corresponds to a shift of the fringes from the red to the blue-green region of the spectrum. This means that movements of the fringe system along the spectrum corresponding to displacements of the mirror can be calibrated with a good micrometer. Hence the instrument is particularly well suited to measure displacements greater than can conveniently be measured with a Michelson interferometer, because it is unnecessary to count fringes, yet the accuracy is about the same.

Fig. 1. Optical arrangement of a linear displacement interferometer.

The fringes are visible simultaneously in all spectrum orders and remain so even for very wide slit openings, the visibility however, being generally best for reduced illumination. When sunlight is used as a source, the dark Fraunhofer lines constitute fixed lines of reference by means of which measurements of the displacement of the fringe system can be made. Ordinarily with a carbon arc the yellow sodium line is bright enough to stand out against the continuous spectrum background and serve as a reference line.

By a geometrical consideration of the reflected and refracted rays Barus derived the fundamental relations of displacement interferometry. But let us now consider in quite an independent manner how the instrument can be used to measure the index of refraction of a gas. Suppose the interferometer to be so adjusted that the oval fringes are centered on a given spectrum line, for example the sodium *D* line, when a column of gas of length e is in one arm of the interferometer. Assume μ_1 to be the index of refraction of this gas, μ_A to be the index of refraction of the medium in which the micrometer mirror is displaced (air), and if there are any other substances in the path let their refractive indices be denoted by $\mu_2 \cdots \mu_n$.

With the gas in the path, the optical path difference from the half silver to the mirrors *M* and *N* is

$$n\lambda = \mu_1 e + F(\mu_2 \cdots \mu_n) - P \quad (1)$$

where λ is the wave-length of the spectrum line on which the fringe system is centered, $\mu_1 e$ is the optical path length of gas, $F(\mu_2 \cdots \mu_n)$ is the path length of all remaining substances in the path, and P is the optical length of the opposite path. F and P are absolutely independent of the nature of the gas in question and are not affected by evacuating the tube.

When the gas is removed from the path (by evacuation of the containing tube) and the micrometer mirror is displaced to recenter the fringe system on the given spectrum line

$$n'\lambda = e + \mu_A \Delta x + F(\mu_2 \cdots \mu_n) - P \quad (2)$$

where μ for vacuum is of course one, and Δx is the air displacement of the micrometer mirror.

The radial distance between the central spot and the first fringe ring is observed to be greater than that between any two successive rings. Hence in accordance with Cornu's principle, the fraction of a fringe shift for the change of one wave-length must be a minimum at the center of the system, i.e.

$$\frac{\partial n'}{\partial \lambda} = \frac{\partial n}{\partial \lambda} = 0.$$

Thus the fringes near the center of the configuration are relatively coarse and far apart, whereas the outermost ones are very fine and close together.

Dividing Eqs. (1) and (2) by λ , differentiating each with respect to λ , setting the resulting equations equal to zero, subtracting one from the other, and solving, we get

$$\Delta x = \frac{e \left[(\mu_1 - 1) - \lambda \frac{\partial \mu_1}{\partial \lambda} \right]}{\mu_A - \lambda \frac{\partial \mu_A}{\partial \lambda}}. \quad (3)$$

The denominator for all practical purposes is one, whence

$$(\mu_1 - 1) = \frac{\Delta x}{e} + \lambda \frac{\partial \mu_1}{\partial \lambda}. \quad (4)$$

DISPERSION

Eq. (4) shows that before the index of refraction of a gas can be determined by displacement interferometry some knowledge of its dispersion is necessary. Further considerations, however, show that the dispersion can be obtained directly with the instrument from the values of the displacement Δx taken for two different wave-lengths in the spectrum.

Consider the Cauchy dispersion relation

$$\mu = A + \frac{B}{\lambda^2} + \frac{C}{\lambda^4} + \cdots$$

The data of Meggers and Peters¹ show that for air, two arbitrary constants A and B are sufficient to represent the facts. The writer has taken these data for three different temperatures 0° , 15° , and 30°C and plotted $(\mu - 1)$ against $1/\lambda^2$ on a very large scale (a graph 50×70 cm) as shown in a

Fig. 2. Dispersion data for air plotted from observations of Meggers and Peters.

reduced photograph in Fig. 2. In each case the points lie rather well on straight lines, indicating that two arbitrary constants are sufficient to represent the data.

If now $(\mu - 1) = A + B/\lambda^2$ whence

$$\frac{\partial \mu}{\partial \lambda} = - \frac{2B}{\lambda^3}. \quad (5)$$

Then Eq. (4) reduces to

$$(\mu_1 - 1) = \frac{\Delta x}{e} - \frac{2B}{\lambda^2}. \quad (6)$$

Now writing Eq. (5) twice for two different wave-lengths λ_1 and λ_2 and subtracting the one from the other

$$(\mu_1 - \mu_2) = B \left(\frac{1}{\lambda_1^2} - \frac{1}{\lambda_2^2} \right). \quad (7)$$

For these two wave-lengths Eq. (6) gives

$$(\mu_1 - 1) = \frac{\Delta x_1}{e} - \frac{2B}{\lambda_1^2} \quad (8)$$

$$(\mu_2 - 1) = \frac{\Delta x_2}{e} - \frac{2B}{\lambda_2^2}. \quad (9)$$

Where B is assumed to be constant throughout the visible spectrum as the data of Meggers and Peters show to be true for air. Solving Eqs. (7), (8), (9)

$$B = \frac{(\Delta x_1 - \Delta x_2)}{3e\left(\frac{1}{\lambda_1^2} - \frac{1}{\lambda_2^2}\right)}. \quad (10)$$

Now consider again Eq. (6) rewritten so as to read

$$\frac{\Delta x}{e} = (\mu - 1) + \frac{2B}{\lambda^2}. \quad (6a)$$

Experiments on nitrogen which will be described later, show conclusively that Δx is a linear function of pressure when values of Δx are plotted against pressure. Therefore, since e is a constant, $[(\mu - 1) + 2B/\lambda^2]$ must be a linear function of pressure, meaning that either each term separately varies directly with pressure or that there is some involved relation connecting the two terms in such a way that their sum varies directly with pressure if separately they do not. Since $\frac{2}{3}(\mu - 1)$ is a first approximation to $(\mu^2 - 1)/(\mu^2 + 2)$ we should expect $(\mu - 1)$ to be directly proportional to pressure by the Lorentz-Lorenz relation, and so B must, therefore, be a linear function of pressure. This means that B/p is a constant which can be determined directly by the difference in the slopes of the lines $\Delta x_1/p = \text{constant}$ and $\Delta x_2/p = \text{constant}$.

Dividing Eq. (10) by p it appears that

$$B_0 = \frac{B}{p} = \frac{\left(\frac{\Delta x_1}{p} - \frac{\Delta x_2}{p}\right)}{3e\left(\frac{1}{\lambda_1^2} - \frac{1}{\lambda_2^2}\right)} \quad (11)$$

B_0 here means B per cm pressure. The B used in the previous work can now be interpreted to mean B at pressure p .

It follows then that the displacement interferometer can be used to determine the dispersion factor B of a gas, first finding B_0 from the difference in the slopes of the $(\Delta x, p)$ lines for two different wave-lengths and then multiplying by the pressure to get the value of B corresponding to that pressure. After B has been determined $(\mu - 1)$ can be determined at the same pressure by Eq. (6). The value of $(\mu - 1)$ can be reduced to its equivalent at 0° and normal pressure if it is not so measured, by assuming the Lorentz-Lorenz equation to be at least approximately true, whence

$$\frac{\mu - 1}{\rho} = \frac{\mu_0 - 1}{\rho_0} \quad (12)$$

$$\therefore (\mu_0 - 1) = (\mu - 1) \frac{760}{p} \frac{T}{273.1}. \quad (13)$$

PRELIMINARY EXPERIMENT

An interferometer with arms something over a meter long was assembled according to Fig. (1), and measurements of the refractive index of dry air

were made at atmospheric pressure using for the dispersion correction the value given by Fig. 2. The average of some twenty or more independent observations gave a resulting value for $(\mu_0 - 1)$ of 0.0002921 with a mean deviation of ± 0.0000007 . This is exactly the value given by Meggers and Peters.¹ Hence the conclusion is drawn that the above theoretical considerations have been experimentally justified.

DESCRIPTION OF THE APPARATUS

The arrangement of the apparatus is sketched in Fig. 1. A photograph of the actual set-up in the basement of the laboratory is reproduced in Fig. 3. The interferometer mirrors were made from plates of optical glass 3 inches square obtained from Bausch and Lomb. The micrometer mirror *M* was fastened to the movable table of a small Michelson interferometer which had a well-made micrometer screw about $3/16''$ diameter of 0.5 mm pitch. The

Fig. 3. Photograph of apparatus.

Michelson inteferometer was also set up so that it could be used as an auxiliary instrument as indicated in the figure, for the purpose of calibrating the screw over the range actually used, by counting Michelson fringes from an independent monochromatic source of light.

The Michelson interferometer and the two other mirrors of the displacement interferometer were mounted on independent cement piers which rested on the ground and were free from contact with the building. They extended up through the floor in the form of shafts one foot square and about three feet high.

The illuminating system consisted of an arc light, a lens and a collimator all mounted on a table. To produce a zinc spectrum for work on dispersion, the arc was loaded with pieces of zinc wire inserted into drilled carbons. The arrangement was such that a concave mirror could be substituted for the lens to make it possible to focus sunlight from a hole in the floor of the room above, upon the slit of the collimating telescope to produce a solar spectrum. The

oval fringes were observed with a 25 cm focal length telescope having a gelatin grating, with approximately 1150 lines to the inch, mounted normally in front of the objective. The arc light, the collimating telescope, the table upon which they rested, and the Michelson interferometer, were mounted upon squares of sponge rubber to minimize the effects of vibration. Even with the heavy cement piers completely separated from the building all trouble due to vibration was not completely eliminated, although with them the fringes occasionally steadied down for short intervals. Ordinarily in the day time the quiet intervals were neither as long nor as regularly spaced as in the evening, and for this reason most of the readings were taken in the evening.

The experimental refraction tube containing the gas to be experimented with, was supported in the working arm of the displacement interferometer. It was made of Shelby cold drawn steel tubing $\frac{1}{8}$ inch wall and approximately one inch bore. The ends were closed by disks of high quality optical glass, obtained from Bausch and Lomb, 1.15 inches in diameter and 0.25 inches thick, with accurately plane parallel surfaces. A second tube just like the first but containing air at room temperature and pressure was used in the

Fig. 4. Method of fastening glass ends to the experimental tube.

other arm of the interferometer to optically compensate for the experimental tube. The length of the refraction tube inside the end plates measured 100.30 cm.

The packing shown in detail by Fig. 4, was used to fasten the glass ends to the tube, and proved very satisfactory. The end of the tube *T* was carefully tinned and, while still hot, was screwed into a hot threaded sleeve *A* to form a very tight fit. *C* is a thin-walled steel cup carefully machined down to fit the glass disk *G* which is cemented into it with a thin layer *K* of de-Khotinsky cement. The steel washer *W* is also cemented to the glass, and the rim of *C* projects out beyond *G* just enough to take up the strain when *W* is pressed against it. *P* is a very thin sheet of rubber (dental dam) also cemented to *C*. This whole unit *P, C, K, G, W*, was set in place and the ring *R* was screwed in about flush with *A*. Then by means of eight equally spaced screws *S* the unit was pressed tightly up against the end of the tube *T*.

The experimental tube was mounted in a water bath, by means of which the temperature was kept uniform and constant to 0.01°C .

A small McLeod vacuum gauge was used for the purpose of registering pressures less than 0.1 mm mercury obtained with a Cenco Hyvac pump.

Pressures above atmospheric were measured with a mercury column. The lower end of this column was a length of 3/16" steel tubing welded through a hole in the plug of a commercial iron mercury flask, and just long enough nearly to reach the bottom of the container. The upper end was a glass tube fastened to a brass centimeter scale, some 350 cm long in two sections, mounted on the side of a wooden ladder just long enough to reach from the floor to the ceiling beams, and fastened rigidly at each end.

The pressure line connecting the various pieces of apparatus; the gas source, the mercury column, a dial gauge (which was included for rough work), and the experimental refraction tube was made up of 1/8" steel tubing. Connections were made by means of soldered sleeves or carefully built steel unions. Each piece of apparatus could be isolated from the rest by special high pressure steel stopcocks.¹¹

EXPERIMENTAL PROCEDURE AND OBSERVATIONS WITH NITROGEN

Water pumped nitrogen was obtained in commercial containers under about 2000 lbs. pressure, guaranteed pure except for 0.5% water and 0.5% oxygen. The oxygen was removed by passing the nitrogen through a steel tube full of sheet copper clippings maintained at a temperature of 500–600°C into an auxiliary steel tank where it was stored under a pressure of 600 lbs. The water vapor was removed by phosphorus pentoxide contained in three tin cans suspended by copper wires inside this auxiliary tank.

The nitrogen thus stored was allowed to stand a few days to become dry. The system was thoroughly rinsed out with it and observations were carried out in the following manner: A vacuum of 10^{-2} mm of mercury was obtained, and after a reading of the barometer had been taken, the temperature of the bath being kept constant at 30°C, the fringes were very carefully centered on the blue (4811A) zinc spectrum line. The reading of the micrometer was recorded, and then the screw was so turned as to cause the fringes to proceed through the spectrum to the yellow (5893A) sodium line. This process was continued to bring the fringes up to the orange (6362A) zinc line. Then a small quantity of nitrogen was admitted to the system, and after the temperature and pressure had come to equilibrium, the temperature of the room being usually several degrees below 30°, the reading of the mercury column was noted, and readings of the micrometer were made with the fringes centered upon each of the three spectrum lines. This process was continued until readings had been made at intervals of approximately one atmosphere up to the limit of the gauge, i.e. a pressure of about 475 cm of mercury above vacuum. At this pressure due allowance was made for the back lash of the screw in the opposite direction, and readings were made for settings of fringes at each spectrum line, this time in the order of orange, yellow, and blue, for decreasing pressures at intervals of approximately one atmosphere, ending with a reading for vacuum.

After several runs of this sort a very careful run was made at a temperature of 0°C obtained by packing the constant temperature bath with ice.

¹¹ F. G. Keyes and Jane Dewey, *Jour. Opt. Soc. Am.*, **14**, 491 (1927).

The observations obtained in these runs are recorded in Tables I and II.

COMPUTATIONS AND RESULTS

The calculated values in the above tables were computed from the most probable values of $\Delta x/p$ obtained from an analysis of the data by least squares. The observed values of Δx were also plotted against pressure on a paper 50×90 cm of which Fig. 5 is a reduced photograph showing graphically

Fig. 5. Experimental results for nitrogen.

the linearity of the points. Values for B_0 were computed by Eq. (11) for the ranges 4811A–5893A and 4811A–6362A at each temperature.

Range (A)	Dispersion ($B_0 \times 10^{16}$)	
	0°C	30°C
4811–5893	1.90	2.08
4811–6362	1.87	1.95
		Mean 1.95

Mean value of B (at 760 mm pressure) = 1.48×10^{-14} . Although there is a very good agreement between the two values obtained at the zero temperature, the precision of the measurements is not sufficient to detect by experiment any temperature effect. For this reason the arithmetic mean of all the B values was used in the calculation of refractive index by Eq. (6). The values of $(\mu - 1)$ thus obtained at three different wave-lengths were reduced to values corresponding to infinite wave-length, by the Cauchy relation

$$(\mu - 1)_\infty = (\mu - 1) - \frac{B}{\lambda^2} \quad (14)$$

The values at 30° were reduced to zero degrees by Eq. (13) producing the results shown in the last row of Table III. The values in parentheses were obtained by reducing the 30° data to zero degrees for purposes of comparison with the data obtained directly at 0°.

SIGNIFICANCE OF RESULTS AND CONCLUSIONS

Observation of the graph Fig. 5, and a least square analysis of the data show that the displacements Δx follow very closely a linear relation with pres-

sure. The origin lies just as well on the lines as any of the observed points. This linearity means, as was pointed out before, that the Lorentz-Lorenz relation holds, and that dispersion is a linear function of pressure for nitrogen up to seven atmospheres. Theory suggests an inverse linear dependence of dispersion on temperature although the data do not indicate it. The values of B_0 differ from the mean on the average by only 6% whereas an inverse linear temperature function would call for values at 0° to differ from values at 30° by 10%. In this connection it might be noted that Meggers and Peters data Fig. 2 show no consistent temperature effect.

On the other hand the precision of the measurements is not great enough to guarantee B_0 to better than 8%. The micrometer settings can be made to one third of one percent. At one atmosphere Δx is accurate to this degree, but as the pressure increases, so does the accuracy. Analysis shows the errors in the slopes to be less than one part in four thousand, yet due to the fact that B_0 depends on the difference between two slopes observed under different circumstances it is probably not accurate to better than approximately 8%. An error of 8%, however, in B_0 corresponds to an error of less than 0.3% in $(\mu-1)$. On the other hand a survey of the literature indicates that B_0 for a gas has not previously been recorded and that B has not been very accurately determined.

This information on dispersion enables one to reduce observations of refractive index at any wave-length to a value for infinite wave-length or zero frequency, and for this reason the results are probably of most value. It is, of course, the refractive index at zero frequency which should be compared by Maxwell's law with the dielectric constant for a gas. It will be noted that in Table III the values of $(\mu-1)_{\infty,0}$ all check to a remarkable degree, thus further emphasizing the degree of precision of the observations.

The above analysis of the data shows that the accidental errors in the results amount to less than one third of one percent. The only constant error of any consequence which affects them is the possible error in the pitch of the micrometer screw, which hitherto has been assumed to be 0.5 mm. To eliminate this uncertainty a very careful calibration of the screw was made over the range actually used by counting Michelson fringes as before described. The mercury 5461A line, filtered by screens provided by Cooper Hewitt, was

used for a source, and fringes were counted over a 2 mm range. The results of ten separate counts over a whole turn (approximately 1827 fringes per turn) indicated that the irregularities of the screw were negligible and that the actual value of the pitch was 0.499 mm in this range, making $\mu_{\infty 0}$ equal to 1.0002927 instead of 1.0002933, and limiting the absolute error to one third of one percent. As a result μ^2 is equal to 1.000585 to be compared with Zahn's¹² value of ϵ equal to 1.000581 which he estimates to be accurate to one percent in $(\epsilon-1)$. The difference between these values amounts to approximately two thirds of one percent in $(\epsilon-1)$.

Incidentally it might be observed that the values for the index of refraction at a pressure of one atmosphere and a temperature of zero degrees at the three wave-lengths are as follows, corrected for the screw error:

<i>Refractive Index of Nitrogen at 0°C and 760 mm Pressure</i>			
λ	4811A	5893A	6362A
μ	1.0002991	1.0002969	1.0002967

These values are in accord with previously published results obtained by different methods.

ACKNOWLEDGMENTS

This problem was suggested by Professor F. G. Keyes, Director of the Research Laboratory of Physical Chemistry at the Massachusetts Institute of Technology, and at the time the work was started, also Consulting Professor of Physics at Brown University. To Professor Carl Barus and Professor C. W. Miller, the writer is also indebted for assistance in various matters, particularly with reference to the displacement interferometer. The writer is, however, especially grateful to Professor A. deF. Palmer for his sustained interest and help in supervising the whole problem.

ON THE ULTRAVIOLET ABSORPTION SPECTRUM OF ACETYLENE*

BY GEORGE B. KISTIAKOWSKY

DIVISION OF CHEMISTRY, HARVARD UNIVERSITY

(Received December 26, 1930)

ABSTRACT

It is shown that the ultraviolet absorption bands reported previously do not belong to acetylene but to some impurity. In pure acetylene, bands are observed only below 2400Å. These bands are arranged into three progressions and their interpretation is proposed using information from the work on the infrared absorption spectrum of acetylene.

THE more recent investigations of the infrared absorption spectrum of acetylene have revealed a very simple structure of these bands¹ leading to the conclusion that the acetylene molecule has all four atoms in a straight line and is therefore characterised by rotational quantum levels typical of a diatomic molecule. It seemed promising to undertake a study of the ultraviolet absorption spectrum of acetylene in the hope that here also a more complete analysis could be achieved than is possible with the majority of polyatomic molecules. Not much work has been done on acetylene spectrum. Stark and Lipp² investigated the absorption spectrum in gaseous acetylene and reported bands between 2200–1900Å without giving their wave-lengths. On the other hand, Henri and Landau³ studying gaseous acetylene and using a 40 cm absorption tube found numerous bands at longer wave-lengths which they divide into three groups: bands with fine structure from 3157 to 2872Å; partly sharp, partly diffuse bands in the region 2960 to 2495Å and bands with fine structure between 2327 and 2236Å.

In the present work absorption tubes up to 2 meters length were used. As a light source a hydrogen discharge tube was employed and the photographs taken first with a medium size and later with a large Hilger El spectrograph. Acetylene was taken from a small "Prestolyte" tank and was purified⁴ by passing it slowly through a series of five Milligan wash bottles containing water, chromic acid in sulfuric acid, mercuric chloride in hydrochloric acid, copper nitrate in nitric acid and sodium hydroxide solutions, respectively. It was finally dried over phosphorus pentoxide.

Acetylene thus purified was found to be completely transparent down to 2400Å and even using plates of the most contrast no traces of the some 70 bands reported by Henri and Landau could be detected. Exposures were also made with acetylene prepared from commercial calcium carbide and only crudely purified. Here a continuous absorption was found extending from

shorter wave-lengths up to about 3200Å. It became evident that the spectrum described by Henri and Landau is due to some impurity and a further search for it was abandoned.

In the short ultraviolet a number of bands was observed. The wave numbers of the band heads will be found in Table I. Most of these bands are extremely faint and, in addition, a continuous absorption sets in at about

2300–2350Å and becomes so strong below 2250Å that not more than 5 per cent of the light of this wave-length is transmitted by a 2 meter layer of acetylene at 760 mm pressure. In view of this, no great precision can be claimed for the wave-length determinations, the error for the fainter bands being probably of the order of 5 cm^{-1} . The bands are shaded to the red and have double heads with a spacing of about 14 cm^{-1} . The resolution obtained was not sufficient to show rotational structure near the heads, but in the stronger bands (43674–43687 and 43730–43744 cm^{-1}) evidence of structure was observed some distance away. Even in this spectral region the bands reported by Henri and Landau must be attributed to impurities for, with the exception of 42961 cm^{-1} , none of them coincides with the now observed ones within less than 20 cm^{-1} . It is of course not excluded that the bands here reported are also to be ascribed to impurities. On the other hand every precaution exercised in purifying acetylene seemed not to effect them in the least.

The bands recorded in Table I can be arranged into three progressions at a distance of 1032 and 1012 cm^{-1} apart. These progressions can be described by the same equation, as will be best seen from Fig. 1 in which the wave-numbers of the shorter wave-length band heads (after subtracting from the second and third progressions 1032 and 2044 cm^{-1} , respectively) have been plotted against an arbitrary number v . A quadratic expression in v is, however, certainly insufficient to describe the progressions since they show a pronounced convergence for the lowest values of v , but for $v=5$ to 10 the bands become nearly equidistant. It is also unusual that both the first and the second progression break off abruptly after the strongest band ($v=10$). A tenta-

tive interpretation of the observed regularities is possible using information obtained from the vibration-rotation bands of acetylene. Mecke¹ has pointed out that a normal acetylene molecule possesses three modes of vibration parallel to the molecular axis, of which one is optically active in the infrared ($\nu_2 = 3312.83 \text{ cm}^{-1}$), and two transversal vibrations of lower frequencies ($\theta_1 = 729.27$ and $\theta_2 = 1328.5$). It is quite likely that the three progressions here reported are due to transitions into successive quantum states of either of the longitudinal vibrations of the excited molecule—probably ν_2 —while the bands within each progression are caused by transitions to successive quantum states of one of the transversal modes of vibration. Against this interpretation speaks mainly the abnormal intensity distribution within each progression, but perhaps this, as also the rather unusual law of binding force necessary to account for the observed spacing of the bands can be attributed to the transversal character of the vibrations involved.

Fig. 1. A plot of three progressions of the acetylene bands.

Although a calculation of the fundamental frequencies of the excited molecule is impossible at present, it can be pointed out at least that they are probably lower than those of the normal molecule, the bands being shaded to the red, thus indicating a larger moment of inertia and presumably weaker binding force in the excited molecule. Assuming that the rotational structure of the acetylene bands is similar to that of diatomic molecules and that the double band heads are due to *R* and *Q* branches, one can estimate from their separation and the known moment of inertia of the normal molecule,⁵ the moment of inertia of the excited one. One obtains thus $25.6 \pm 0.3 \times 10^{-40} \text{ gm cm}^2$ as compared with $23.509 \times 10^{-40} \text{ gm cm}^2$ of the normal molecule.

The origin of the continuous absorption, mentioned in the beginning of this note, remains uncertain. It is likely, though, that this absorption is due to residual traces of impurities, because Stark and Lipp² were able to observe absorption bands down to 1900Å.

It is a pleasant duty to thank Mr. Alfred L. Loomis for his kind permission to work in the Loomis Laboratory and for the facilities put there at my disposal.

⁵ Assuming that the head of the *Q* branch coincides with the zero line of the band, that the equation of the *R* branch is $\Delta\nu = (B' + B'')K + (B' - B'')K^2$ and that for its head $K = -B' + B''/2(B' - B'')$.

SPACE CHARGE vs. IMAGE FORCE IN THERMIONIC EMISSION

BY R. S. BARTLETT AND A. T. WATERMAN

SLOANE PHYSICS LABORATORY, YALE UNIVERSITY

(Received December 7, 1930)

ABSTRACT

This paper is a joint report on work by the two authors, preliminary to further and more detailed publication on different phases of the problems here discussed. Attention is called to certain deficiencies in the Schottky image force as an explanation of the thermionic work function, both on theoretical and experimental grounds. Evidence is advanced to show that space charge is more important than image force over most of the region in which the image force is thought to be valid. It is further shown that space charge with Fermi-Dirac statistics is able to account for observed phenomena of thermionic emission, including the effect of external fields. Numerical examples indicate some of the consequences of this point of view.

THE most commonly accepted explanation of the thermionic work function is that which attributes the major part of it to the "image" force of the electron (Debye, Schottky, Langmuir). Schottky¹ gave an analysis to show that space charge and structure effects, in the layer outside that in which the surface atomic structure of the emitting body plays an important part, were negligible compared with the image force. To do this it was necessary to estimate the electron density in this layer; this he calculated on the assumption that the image force law was correct, showing that under these conditions space charge and structure effects were negligible.

On the other hand, if the assumption is made that the potential and thereby the charge density in the above-mentioned layer is determined by space charge instead of by image force considerations then it may be shown that the space charge is more important than the image force. Thus we must look further for evidence by which to choose between the two explanations. As a numerical illustration of the difference involved, a calculation of the field intensities from these two contrasting standpoints at various distances from a plane tungsten cathode at 2300°K gives the following results in the absence of external field. E_i being the field intensity in v/cm computed from the image force, E_s that computed for the space charge field, we have, at a distance of 10^{-7} cm from the cathode, $E_i = 3.6 \times 10^6$, $E_s = 4.0 \times 10^6$; at a distance 5×10^{-7} cm, $E_i = 1.4 \times 10^5$, $E_s = 8.0 \times 10^5$; at 10^{-6} cm, $E_i = 3.6 \times 10^4$, $E_s = 4.0 \times 10^5$. Thus, for distances from the surface greater than about 10^{-7} cm, the field intensity computed from space charge considerations is greater than when computed by the image force, and this difference is accentuated as the distance from the surface increases. The concentration of electrons shows a similar behavior. The space charge treatment of course assumes a continuous distribution of electricity whereas the image force assumes the escape of only

¹ Schottky, Phys. Zeits. 15, 872 (1914).

one electron. As Schottky correctly points out, since in practice we find a situation intermediate between these two view-points it is necessary to examine which of these two extremes is most nearly approached in practice.

A reconsideration of this matter seems desirable, not only in view of the above fact, but also because the earlier work on the subject postulated a Maxwell distribution law in the electron atmosphere. Since the advent of the Sommerfeld electron theory it becomes desirable to find whether the degeneracy of the electron gas at and presumably also near the emitting surface affects the analysis. Among the chief reasons for the general acceptance of the image force explanation have been (1) the observed constancy of the work function for a given pure metal under moderate applied accelerating fields, i.e. the thermionic saturation current, (2) for pure metals the fairly accurate verification of the variation of thermionic current with stronger applied fields (Schottky effect) as computed by Schottky, (3) the estimation of a reasonable value for the work function, with the opportunity of characteristic values for different materials. Its chief drawback at the present time appears to be in its application to emission from coated filaments, i.e. in failing to account for lack of saturation and for the Schottky effect observed in these cases without complicated, rather *ad hoc*, assumptions.

It is clear therefore that before any superiority may be pointed out a space charge analysis should also lead to confirmation with experiment in the above directions. In deriving the thermionic current, extending through the Schottky effect, by use of space charge considerations alone, if Poisson's equation is combined with a Maxwellian distribution of electron velocities the results show definite lack of agreement for pure metals. But if a Fermi distribution is substituted for the Maxwellian, the calculated dependence of current on temperature and applied field is found to be in reasonable agreement with experiment. This may be taken to indicate the constancy of the work function calculated by this method, but it seems more reasonable to deal with directly observable quantities, and compare calculated with observed currents under varying conditions. Furthermore, the variation of the current with the nature of the emitter can be explained more readily by space charge than by image force. According to the latter the field becomes constant within a certain critical distance from the surface, this distance being so chosen that the total work function thus calculated agrees with the experimental value. As justification for this step it is pointed out that close to the surface structure effects would be important. Now, assuming the space charge method valid right down to the surface, different currents from different metals are explained by the different electron concentrations within the metals, and the work function comes out to be of the correct order of magnitude according to the Sommerfeld theory (i.e. $= W_a$) without further assumption. This leads, incidentally, to a simple explanation of the observed interdependence of A and b , the constants in the usual thermionic emission equation. Moreover it appears that the use of Fermi-Dirac statistics takes account, in part at least, of structure effects. For a simple calculation will show that an electron gas is degenerate when the electrons are so closely crowded that the mutual po-

tential energy of neighboring pairs is large compared with their kinetic energy of thermal agitation, and obeys classical laws when the potential energy is small. For example, in an electron gas at 1600°K for which the Fermi A is 10^{-3} , i.e. the gas nearly in the classical state, the average kinetic energy is roughly twenty times the potential.

Thus it appears that the space charge calculation based on Fermi-Dirac statistics is a more proper method of dealing with pure metals, and it may be further pointed out that the same calculation based on classical statistics, assuming a low electron concentration in the emitter, seems capable of explaining results obtained with coated filaments. This latter point is being investigated further.

Following out their preliminary investigations on this subject² the authors have carried the work further, one of them taking exclusively the problem of deducing the thermionic current under applied accelerating fields from zero to fields operative in the Schottky effect, the other treating exclusively the case of the statistical equilibrium resulting under retarding applied fields (including zero). Both deal only with the case of an infinite plane emitting surface.

The former (R. S. Bartlett) has handled the problem after the manner of Langmuir and Fry by postulating the emission of electrons with velocities distributed according to the Fermi statistics, these electrons being subject only to the space charge field, and obeying the law of continuity of current. This calculation is rendered troublesome by the necessity of graphical computation of the Fermi integrals for the region of transition from a degenerate to a classical state, and thus are not at present in a form suitable for detailed report in this communication. The general results have been mentioned above, and appear encouraging, especially in pointing the way to a single explanation of thermionic currents from zero applied field up through fields of Schottky intensity.

The latter author (A. T. Waterman) starting with Poisson's equation and the Fermi analogue $A = A_0 e^{-v\epsilon/kT}$ of the familiar Boltzmann relation, has evaluated the potential and the electron concentration at points outside the surface, where the atmosphere is in the classical state (assuming a degenerate state within the metal). In the presence of a retarding field E the solution takes different forms on either side of a critical distance, which, expressed in terms of potential difference between this distance and the surface, is $V' = 2 \log E/\beta$ where $\beta^2 = 16\pi(2\pi m)^{3/2} h^{-3} (kT)^{5/2} e^{W/kT}$ where W is Sommerfeld's W_i , the thermodynamic potential of the electrons within the body. Thus for $V > V'$ (thus including zero field), V (at distance x) $= -2kT/\epsilon \log(1 + \epsilon\beta/2kT x)$ and the number of electrons per cc, $n = kT/2\pi\epsilon^2 x^2$. For $V < V'$, $V = -kT/\epsilon(\epsilon Ex/kT - \log 4E^2/\beta^2)$ and $n = E^2/2\pi kT e^{-\epsilon Ex/kT}$. It will be noted that on the space charge conception the concentration of electrons in equilibrium with a hot body depends only upon the distance and the temperature,—in particular not upon the nature of the hot body, for distances at which the electron gas is in the classical state (roughly $> 10^{-7}$ cm). Examination as to

the above-mentioned critical distance introduced by an applied retarding field, which is a measure of the distance inside which the applied field has no appreciable effect on the electron atmosphere, results in the observation that applied retarding fields of the order existing in cold extraction currents would control the electron atmosphere extending into the region where the electron gas becomes degenerate very near the surface. A prediction of the work is that the ratio of the anode potentials which would give equal thermionic currents under zero applied field from two different emitters under otherwise identical conditions (temperature and geometry of tube) should be $V_1/V_2 = \log \beta_1 / \log \beta_2$. If Sommerfeld's electron theory is assumed, then this ratio should show appreciable difference from unity, e.g. $V_{Ca}/V_W = 0.65$; on the classical theory the ratio should always be very nearly unity, e.g. $V_{Ca}/V_W = 0.98$ in the instance quoted.

ORIGIN OF THE AXIAL ROTATION OF THE SUN

BY ROSS GUNN

NAVAL RESEARCH LABORATORY, WASHINGTON, D. C.

(Received December 24, 1930)

ABSTRACT

In earlier papers the solar atmosphere has been shown to rotate rapidly as a result of the electric and magnetic forces which act on the atmospheric ions. At the equator the ionized layers move much faster than the solar surface proper but this relative movement decreases with latitude in the manner required by observation. The fast moving atmospheric layers transfer momentum to the sun proper and its rotation is a necessary consequence of the observed atmospheric motions. The resultant torque is calculated and the angular acceleration shown to be adequate to account for the observed rotation.

THE almost universal prevalence of rapid rotation in celestial objects has been pointed out again and again by astronomers, but the origin of such rotation has been somewhat of a mystery. Celestial mechanics shows how a star may rotate faster and faster as it contracts due to condensation, but gives no clue as to the origin of the initial rotation, which must be comparable to the final value. In an important paper Jeans¹ discussed the relation of the radiation of matter to the rotation of a star and he concluded that the radiation of the star carries off angular momentum in such a way that it "generally lessens the angular momentum per unit mass of the star." He thus pointed out that the common assumption of a constant angular momentum for a radiating star is invalid. We must, therefore, for the most part, attribute the observed high rotational velocities to changes in the mean density together with an initial rotation of the star or else to some phenomena not adequately described by celestial mechanics.

In a series of papers which deal with the electromagnetic effects operating in the solar atmosphere, it has been shown² that the anomalies of the sun's apparent rotation arise from an electromagnetic drift of the ionized atmosphere and are not directly dependent on the motion of the surface of the sun proper. It was shown that the solar atmosphere rotates in the same direction as the sun proper but *much faster* and that this superposed drift results from the interaction of the atmospheric ions with the observed solar magnetic field and a radial electric field.

The sun may be thought of as a highly viscous mass of gas bound together by gravitational, radiative and electromagnetic forces in such a manner as to form a semi-rigid system. Radiative viscosity acts in such a manner as to equalize differences of rotation in different layers but Jeans¹ calculations indicate that these forces alone are incapable of equalizing the rotations in a time

¹ Jeans, Monthly Notices R. A. S. **86**, 328, 444 (1926).

² Gunn, Phys. Rev. **35**, 635 (1930); **36**, 1251 (1930).

so short as the age of the sun. The sun's observed magnetic field is asymmetric with respect to the axis of rotation and hence shells of highly conducting solar matter rotating about the geographical axis will induce electromotive forces and systems of electrical eddy currents which will strongly oppose motion relative to the magnetic field. A quantitative calculation of the electromagnetic damping forces due to axial slippage is difficult but we have seen that in regions of high electrical conductivity the forces due to radial contraction are tremendous³ and it seems probable that electrical forces contribute in an important manner to the apparent viscosity of the sun. To be sure that these forces have time to act we must examine whether the electrical time constant of the induced current circuit is sufficiently short compared to the solar age for current systems to build up. It is convenient to note that the largest time constant τ possible is the constant for the whole sun which is given by $\tau = L\Sigma$ where L is the effective inductance and Σ is the total conductivity. On making this calculation it results that τ is of the order of 10^9 years. This is very small compared to the age of the sun and we assume that inductive effects are unimportant.

On account of the high effective viscosity of the interior it seems satisfactory to assume as a first approximation that the sun is a semi-rigid body rotating on its axis at a period corresponding to the observed period of rotation of its magnetic pole. With the solar radius known it is evident that the peripheral velocity of any point on the solar surface proper can be calculated. The difference between this velocity and the velocity of the same point as determined by an earth-bound observer watching the solar atmosphere is evidently the atmospheric drift velocity. This superposed drift velocity U of the ionized atmosphere is readily determined from observation or can be calculated from²

$$u = \frac{E \times B}{B^2 \left(1 + \left(\frac{R}{\lambda} \right)^2 \right)} \quad (1)$$

where E and B are the electric and magnetic field intensities, λ the mean free path of the ions, and R the radius of the helix generated by an ion as it spirals around the impressed magnetic field. This radius is calculated from

$$R = \frac{mV}{Be} = \frac{(2mkT)^{1/2}}{Be} \quad (2)$$

where m is the mass of the ion, V the component of velocity perpendicular to B and e the ionic charge.

It is clear from Eq. (1) that the drift motion of the atmosphere drops abruptly as the ion pressure increases to such a value that the free path becomes of the order of R . Thus a more or less sharply defined transition layer exists between the atmosphere and the solar surface proper. In this critical transition region between the sun and its atmosphere there is a constant

³ Gunn, Phys. Rev. 35, 107 (1930).

interchange of momentum, and the faster moving layers transfer their momentum to the slower. At the surface of the sun the temperature is low and the radiative and electromagnetic viscosities are small compared to the molecular viscosity, so that we need only consider the forces due to the latter. The tangential force applied to the periphery of the sun by the more rapidly rotating atmosphere is

$$F = \eta u \frac{A}{S} \quad (3)$$

where η is the mean coefficient of viscosity of the transition layer, u the mean difference in velocity of the layers, A the effective area in contact and S their separation. To a sufficient approximation we may assume that in the transition layer the coefficient of viscosity is independent of the magnetic field and write

$$\eta = \frac{(3ZmkT)^{1/2}}{2(2)^{1/2}\pi\sigma^2} \quad (4)$$

where m is the mass of the hydrogen atom, Z the mean atomic weight of the ions composing the layer, k the Boltzmann constant, T the absolute temperature, and σ the kinetic theory diameter of the ions. To a sufficient approximation we may assume that the effective contact area A is a ring around the equator of width R where R is the radius of the sun and that the mean velocity difference is not appreciably different from the equatorial value. The torque Q applied to the solar mass is

$$Q = I\alpha = \frac{(3ZmkT)^{1/2}}{(2)^{1/2}\sigma^2} \frac{u}{S} R^3 \quad (5)$$

where I is the effective moment of inertia and α is the angular acceleration. Assuming that the solar density is uniform we get from Eq. (5)

$$\alpha = \frac{5(3ZmkT)^{1/2}}{2(2)^{1/2}\sigma^2} \frac{uR}{SM} \quad (6)$$

where M is the mass of the sun. Taking from earlier work $Z=3.3$, $m=1.66 \times 10^{-24}$ gm, $k=1.37 \times 10^{-16}$, $T=6,000$, $\sigma=10^{-8}$ cm, $R=7 \times 10^{10}$ cm, $M=2 \times 10^{33}$ gm, $u=5 \times 10^4$ cm/sec and $S=5 \times 10^6$ cm we find $\alpha=2.3 \times 10^{-26}$ rad/sec.²

We have seen in an earlier paper⁴ that the solar magnetic field is maintained by a system of electrical currents which flow in rings about the sun's axis and that this system of currents is not primarily related to the rotation, but to the sun's radial and axial symmetry. This circumstance suggests that the magnetic field and hence motions of the solar atmosphere have not changed in order of magnitude for a considerable portion of the sun's life, which various estimates put at 7×10^{12} years or 2×10^{23} seconds. By multiply-

⁴ Gunn, Phys. Rev. **34**, 335, 1621 (1929).

ing the angular acceleration α by the life time we find to a crude approximation that the final angular velocity of the sun should be 4.6×10^{-6} radians per second, if its initial rotation was negligibly small. The observed angular velocity, as computed from the motion of the magnetic pole is 2.3×10^{-6} radians per second. The agreement is rather better than one might expect from a calculation based on steady states.

Were allowance made for the increased radiation during the youthful period and a smaller moment of inertia used, due to the concentration of mass toward the center, then the elapsed time necessary to account for the observed rotation would be considerably reduced. This suggests that in the earlier stages of development the sun was unmagnetized and was a typical pulsating star.³ It is clear that the solar rotation can be accounted for by the mechanical drag of the solar atmosphere on the sun proper if the velocity of the atmosphere exceeds that at the surface by 0.5 km/sec. This is the precise value required to explain the anomalous rotation of the sun; this having been adequately accounted for in an earlier paper by the author. The mechanism of rotation which we have considered doubtless has universal application in all stars having a magnetic field. It seems probable that this mechanism, which constantly supplies angular momentum to stellar systems, may assist in explaining certain puzzling facts in connection with spiral nebulae and binary systems. Numerical application to other star systems seems meaningless at the present time due to lack of data, and we can only point out that most other stars will behave like the sun. Ordinary mechanics has been found inadequate to explain the rapid rotation of heavenly bodies. The present investigation shows that the rotations can be accounted for by the momentum transferred to the body proper by its own highly ionized atmosphere. We have shown previously that the motion of the solar atmosphere is controlled by the magnetic and electric fields existing in the atmospheric layers and that these fields are probably controlled by the rate of radiation of matter. We may then conclude that the rotation of all heavenly bodies is intimately related to the dissolution of matter and in a static, non-radiating universe rotating systems would not exist.

THE NATURE OF THE CONDUCTIVITY
OF INSULATING OILS*

BY KARL F. HERZFELD

DEPARTMENT OF PHYSICS, THE JOHNS HOPKINS UNIVERSITY

(Received December 23, 1930)

ABSTRACT

It has been shown in a previous paper how the methods developed in the study of conduction of electricity through gases could be applied to determine the nature of the ions present in liquids and solids. In the present paper these methods have been applied to the measurements of the space charge set up in insulating oils by a steady electric field, which were recently performed by Whitehead and Marvin. The procedure is as follows: the shape of the curve shows that the current must be considerably below three-fourths of the saturation current. It is possible to fit the curve closely by assuming the Langevin constant to be $\beta = 36 \pm 10$. From this the number of ions present in the normal state and their mobility can be calculated, which turns out to be $3.5 \cdot 10^{-6} \pm 50\%$ cm/sec per volt/cm. With the assumption that the mobility is inversely proportional to the viscosity, the mobility of these ions in water would be $1.2 \cdot 10^{-4}$ cm/sec per volt/cm or in the usual units 12. If one assumes that Lorenz's results for organic ions can be applied these ions should have approximately 110 atoms. From the boiling point of the oil one would conclude that the molecule of the oil contains about 45 atoms.

A NUMBER of papers¹ have recently appeared from the Engineering School of The Johns Hopkins University, investigating the conductivity of transformer oils. The last of these make possible an application² of Mie's³ formulas to discover the properties of the ions.

We start with the space-charge distribution⁴ in oil "B", when a potential of 1500 volts is applied between large condenser plates 2 cm apart. The distribution of potential is nearly symmetric around the center, proving that the mobility of the ions of opposite sign must be nearly equal. We are going to neglect whatever dissymmetry might be present.

Fig. 1 shows that the line is very nearly straight in the neighborhood of the center, i.e. the field very closely constant for quite a distance. It follows from this that the current must be considerably below $\frac{3}{4}$ of the saturation current and the approximate formulas have to be used which apply, according to Mie, to weak currents.

⁴ An enlarged drawing of this figure, which has been used for Fig. 1 of the present paper, has been kindly put at my disposal by Dr. J. B. Whitehead.

The next step is the calculation of β (β^{-1} is Langevin's constant). For this purpose, one has to compare the field in the center and the field near the electrodes. The field in the center is

$$h_0 = 450 \pm 10 \text{ volt/cm.}$$

The field near the electrodes is not measured directly; from the drawing it was estimated to be $h_m = 2400 \text{ volt/cm.}$ This would lead to

$$c = \beta^{\beta/\beta-1} = \frac{h_m^2}{h_0^2} = \left(\frac{2400}{450}\right)^2 = 28.5.$$

Subsequently, $c=40$ proved to be the value which suited the curve best, but calculations were also made with $c=30$ for comparison, which turn out to fit the curve appreciably less.

$$c = 40 \text{ gives } \beta = 36.3, (2\beta)^{1/2} = 8.5.$$

It turns out that it is more useful for the actual calculation to put Mie's formulas into a form different from the one that had been given previously.

Fig. 1.

Calling, as was done there, x_K the location of the bend in the graph of the field, we measure the location in the condenser relative to x_K and find for the flat (central) part⁵

$$h^2 = H^2 [1 + (c-1)(e^{-y_1} + e^{-y_2})] \quad (1)$$

$$y_1 = \frac{(c-1)(c-1-(2\beta)^{1/2})}{2\beta-c+1} \left(\frac{c-1-(2\beta)^{1/2}}{c-1} - 2 \frac{l-x}{l-x_K} \right) \quad (2)$$

in y_2 only $l-x$ has to be replaced by $l+x$.

⁵ In formula (50) of the paper cited in footnote (2) $4l^2$ should be stricken from the denominator.

With the high value of β given above the exponent is always so large that the deviation from a constant $h=H$ for the field or from a straight line $V=-Hx+V_0/2$ for the potential is negligible in the range of this formula, that is within $-x_K < x < x_K$. That means $h_0=H$, there is no change in the amount of ions in the central part. In the central part Ohm's law is preserved with the initial conductivity. In the range between the electrodes and x_K , (1) holds, but there y_1 and y_2 have a different form from the one in the central part. y_2 as before is derived from y_1 by substituting $l+x$ for $l-x$. We have

$$y_1 = + (2\beta)^{1/2} \frac{c-1-(2\beta)^{1/2}}{2\beta-c+1} \frac{l-x}{l-x_K} \left(1 + \frac{1}{2} \frac{c-1-(2\beta)^{1/2}}{2\beta} \frac{l-x}{l-x_K} \right). \quad (3)$$

But here too, with the large value of β , the coefficients are so large that $(c-1)e^{-y_1}$ is appreciable only for small values of $l-x/l-x_K$, and than e^{-y_2} with the argument $l+x/l-x_K$ is negligible. With this in mind, it is useful to measure, as Mie does, the distance from the electrode instead of the center and write

$$h^2 = h_0^2 [1 + (c-1)e^{-y_1}] \quad (1')$$

$$y_1 = (2\beta)^{1/2} \frac{c-1-(2\beta)^{1/2}}{2\beta-c+1} \frac{x}{x_K} \left(1 + \frac{1}{2} \frac{c-1-(2\beta)^{1/2}}{2\beta} \frac{x}{x_K} \right). \quad (3')$$

The subsequent procedure is as follows:

One draws a curve of h as function of x/x_K , from $x/x_K=0$ (electrode) to $x/x_K=1$ (bend) and proceeds from thereon with $h=h_0$. The problem is to determine x_K , or to put it differently, to determine l/x_K .

We accordingly integrate graphically beyond the point $x/x_K=1$, taking into consideration the scale of our drawing and changing it continuously as we go on [because $V=\int h dx = x_K \int h d(x/x_K)$], until we get to a point where $V=V_0/2=750$ volts. This must be the center. To show a few examples, we get with different assumptions for the position of the bend:

$\frac{x_K}{l}$,	$\frac{8}{12}$	$\frac{10.5}{12}$	$\frac{11}{12}$
V	680	750	765.

It seems therefore safe to say that

$$\frac{x_K}{l} = \frac{7}{8} = 0.88 \pm 0.08.$$

The points calculated with this value and $c=40$ are marked with crosses in the figure. Formula (53)⁶ gives then

$$\frac{j}{j_{\text{sat}}} = \frac{x_K}{l} \frac{(2\beta)^{1/2}(2\beta-c+1)}{(c-1)(c-1-(2\beta)^{1/2})} = 0.2 \pm 0.05.$$

⁶ See footnote (2).

We put then the current $j = 81.6 \times 10^{-11}$ amp/cm² with δ probably near unity. That makes $j_{\text{sat}} = 88 \times 10^{-11} \pm 25\%$ amp/cm² or, if we consider that j_{sat} is the total amount of charge generated per cm², that is in a cylinder of $2l = 2$ cm length, that gives the number of pairs of univalent ions, generated in 1 cc per second

$$q = \frac{j_{\text{sat}}}{2.2e} = 1.25 \times 10^8 \cdot \delta \pm 25\%.$$

Furthermore, we have

$$\beta = \frac{8\pi K_e}{\alpha\epsilon} = 40 \pm 10.$$

If we want K in cm/sec/ volt/cm instead of per est. unit/cm, we have to divide by 300. It is this number that shall be meant by K from now on.

We assume $\epsilon = 2.5 \pm 10\%$

$$\frac{K}{\alpha} = 2.8 \times 10^7 \pm 35\%.$$

Now $q/\alpha = n_0^2$ (n_0 being the equilibrium number of the ions of each sign which is present in the central part of the condenser even under the conditions of our experiment). Therefore

$$\frac{qK}{\alpha} = Kn_0^2 = 3.5 \times 10^{15}\delta \pm 50\%.$$

On the other hand, the conductivity in the central part, when Ohm's law is valid gives

$$\frac{j}{450 \cdot 2 \cdot e} = n_0 K = 1.1 \times 10^{15}\delta$$

or

$$n_0 = 3.2 \times 10^{10} \pm 50\%$$

and

$$K = 3.5 \times 10^{-6}\delta \pm 50\% \text{ in cm/sec/volt/cm.}$$

⁷ The current density was measured on March 27 and found to be 1.6×10^{-11} amp/cm²; the space charge curve was taken April 4-6, a remeasurement of current on May 2 gave 2.9×10^{-11} amp/cm², the curves in Fig. 12 (in the last paper mentioned in footnote 1) give for the initial conductivity 5.1×10^{-14} h_0 which, for 450 volt/cm, would amount to a current of 2.25×10^{-11} amp/cm². But during April a considerable manipulation with the oil makes the first given current more trustworthy. There is another fact pointing in this direction. The ratio of the initial field to the central field in the steady state should be equal to the ratio of the initial current to the steady current, if the conductivity (number of ions) remains unchanged in the central part. But in the later measurements the ratio of the currents is only 1.45 (private communication), while the ratio of the fields is $750/450 = 1.67$. This is clear if in the meantime the number of ions has increased because then one would be further from saturation and the ratio of the two fields at the time of the second current measurements would be less.

On the other hand, the measurement on March 27 (Fig. 11) points to a ratio of currents 1.7.

To get a reasonable comparison for this value, one remembers that according to Walden,⁸ the mobility of large ions in different solvents is inversely proportional to their internal friction η . Professor J. C. Hubbard, of this Laboratory, was kind enough to determine η for this oil and found it 0.35 (water 0.01), which would make the mobility in water 1.2×10^{-4} cm/sec/volt/cm or, in the usual units (multiplication with 96540 coulomb) equal to $12 \pm 50\%$.

According to Lorenz⁹ one could now estimate that an anion of mobility 12 contains about 110 atoms, an ion of mobility 18, 65 atoms.

M. F. Hamburger, of the Department of Electrical Engineering, has kindly measured the boiling point of the oil and found it to be about 290°C. Accordingly, one would estimate that the oil has molecules containing about 15 C-atoms, therefore about 45 atoms. If the ions are products of oxidation (last paper footnote 1) the anion should contain about two molecules (be the anion of an acid coming from the oxidation of a polymer of double molecular weight). The equal mobility of the action would have to be explained as due to the fact that the H^+ ion has two oil molecules (or a molecule of the above mentioned isomer) attached to it.

If the interpretation of Dr. Whitehead, that the increase in conductivity above the Ohm-value upon reversal is due to an ion of a mobility $K = 10^{-4}$ cm/sec/volt/cm is correct, this ion would turn out, with our present data, to be very quick. Multiplying namely with 10^5 (units!) and 35 (ratio of η of oil and water) we get 350 which is a speed only attained by H^+ in water. We might have to divide this by 2 or 3 as small anorganic ions move in water slower as expected, and reduce the estimated K to $1/2 \cdot 10^{-4}$. Then we could still have the mobility of a small anorganic ion.

If this is accepted, then the picture is as follows: There are present a large number of slow, organic ions which are continuously generated and move on to the electrodes where they are discharged without appreciable accumulation. They are responsible for the space charge and the long time phenomena.

Besides, there are quick, small anorganic ions which are not discharged at the electrodes, but accumulate there, without practically influencing the space charge, and are the cause of short time processes. Offhand, three origins could be imagined: (a) They are present as impurities, but are not supplemented continuously. That is impossible, because then upon reversal of the field the current would not go beyond the initial current of the original field. (b) They are generated continuously; then their number must be much smaller than the number of the slow ions, because the latter determine the space charge (β). (c) Their origin could be a secondary process on the electrodes (OH^+ ?).

POTENTIAL DUE TO A BURIED SPHERE

By I. H. WEBB

WILLIAMS COLLEGE

(Received December 16, 1930)

ABSTRACT

A series solution of the problem dealing with the electrical potential due to a buried conducting sphere is given. The general method of attack consists in finding a solution of Laplace's equation $\nabla^2\Phi=0$, subject to proper boundary conditions. The condition requiring the vanishing of the normal derivative of potential on the surface of the half space is satisfied by placing an image sphere in an upper half space. The introduction of this image sphere also introduces the complication of the interaction of the potential due to two spheres. This is handled by means of spherical harmonics and the solution of the problem is made possible by means of a special transformation in spherical harmonics.

INTRODUCTION

MANY problems of this type have arisen recently in connection with the subject of geophysics. Since the introduction of electrical methods for ore exploration, there have been numerous attempts to find some means by

Fig. 1. Buried and image sphere.

which to predict the nature and scope of irregularities in homogeneity of structure beneath the surface of the earth, when point electrodes on the surface are maintained at definite potentials.¹ In most of these attempts, cer-

¹ A. Petrowsky, Phil. Mag. [5] 31, 927 (1928); 28, 334 (1928).

tain approximations have been made. In fact, in the more complicated problems, approximations must be made. The present problem of the sphere is worked out, making no approximations, as a first step toward finding out the allowable approximations which may be made in the more complicated problems, e.g. a buried ellipsoid or cube.

Assume a sphere of radius a and conductivity σ_1 buried in an infinite half space of conductivity σ_2 (see Fig. 1). At the center of the sphere, locate the common origin of a set of cartesian coordinates x, y, z and a set of polar coordinates ρ, θ, ϕ . Place an electrode at the common point $P_0(h/2, 0, c)$ and $P_0(\rho_0, \theta_0, \phi_0)$. Note that $\phi_0 = \pi/2$. The potential due to the electrode alone is $I/4\pi r\sigma_2$ in which r is the distance from P_0 to any point P and I is the current. It is desired to find the potential at every point in space due to the buried sphere S . Designate by u and U the inside and outside potential, respectively, due to the sphere alone. Then the functions u and U must satisfy Laplace's equation

$$\nabla^2 \Phi = 0, \quad (1)$$

at all points in space, and are further subject to the conditions:

$$k \frac{\partial u}{\partial \rho} - \frac{\partial U}{\partial \rho} = - (k - 1) \frac{\partial U_e}{\partial \rho}, \quad \rho = a, \quad (2)$$

$$u = U, \quad \rho = a, \quad (3)$$

$$U = 0, \quad \rho = \infty \quad (4)$$

and

$$\frac{\partial \Phi}{\partial x} = 0, \quad x = h/2, \quad (5)$$

in which U_e denotes the potential due to the electrode and k represents the ratio of conductivities σ_1/σ_2 . Condition (2) results from the well-known equation:

$$k \frac{\partial \Phi}{\partial n_1} + \frac{\partial \Phi}{\partial n_2} = 0$$

in which Φ is the total potential and n_1 and n_2 are the normals pointing into the regions whose conductivity is σ_1 and σ_2 respectively. In the above equation

$$u + U_e = \Phi,$$

inside the sphere, while

$$U + U_e = \Phi$$

outside the sphere. Then since

$$\frac{\partial}{\partial n_1} = - \frac{\partial}{\partial \rho},$$

while

$$\frac{\partial}{\partial n_2} = \frac{\partial}{\partial \rho},$$

the last equation becomes

$$-k \left(\frac{\partial u}{\partial \rho} + \frac{\partial U_e}{\partial \rho} \right) + \left(\frac{\partial U}{\partial \rho} + \frac{\partial U_e}{\partial \rho} \right) = 0,$$

from which Eq. (2) follows at once. The complication which arises in the solution of the above problem is due to the boundary condition (5). In order to satisfy this condition, an image sphere S_i is placed in the upper half space, which is imagined filled with material of conductivity σ_2 . Then, from symmetry, the normal derivative of potential will vanish on the boundary

$$x = \frac{h}{2}.$$

It may be seen that the problem can be viewed as either one in which a single sphere S is situated in an infinite half space, subject to the boundary condition (5), or a problem in which two spheres S and S_i , (S_i being the image in plane MN of S), are situated in an (whole) space. In the problem which includes the image sphere, the boundary condition (5) is automatically satisfied while at the same time, the complication arises that the interaction between the two spheres must be taken into account. Analytically, this results from the fact that, when the image sphere is included, the applied potential consists not only of U_e , the potential due to the electrode, but also U_i , the potential due to the image sphere. This new potential will be called U_a . According to the uniqueness theorem, the solution of the problem with the image sphere will also be a solution of the problem in hand, since such a solution satisfies Laplace's equation and boundary conditions (2), (3), (4) and (5). The solution of the problem, using the image sphere is the one here given.

The following solutions of Laplace's equation may be written immediately

$$u_1 = \sum_{m=0}^{\infty} \left(\frac{\rho}{a} \right)^m Y_m(\mu, \phi), \quad (6)$$

$$u_2 = \sum_{m=0}^{\infty} \left(\frac{a}{\rho} \right)^{m+1} Y_m'(\mu, \phi), \quad (7)$$

in which $Y_m(\mu, \phi)$ stands for the ordinary spherical harmonic and μ for $\cos \theta$. Because of condition (4) and because the potential of the sphere must be finite at $\rho=0$, u_1 and u_2 are chosen as u and U , the inside and outside potentials respectively. If the coefficients A_{nm} and B_{nm} , in the above expressions, can be so chosen that u and U satisfy all the boundary conditions, the solution of the problem will have been found.

Eqs. (6) and (7) satisfy Laplace's equation, condition (4), and will satisfy condition (3) provided the coefficients in (6) and (7) be set equal, making

$$Y_m(\mu, \phi) \equiv Y_m'(\mu, \phi).$$

The next step is to apply condition (2). Before this is possible, a suitable expression for U_a must be found. U_a consists of two parts

$$U_a = U_e + U_i, \quad (8)$$

a part U_e due to the electrode and a part U_i due to the image sphere S_i . From symmetry, the potential at any point P due to sphere S_i is the same as the potential at point P_i due to sphere S , where² P_i is the image of P in the plane MN , i. e.,

$$U_i(P) \equiv U(P_i) = \sum_{m=0}^{\infty} \left(\frac{a}{\rho_i}\right)^{m+1} Y_m(\mu_i \phi_i). \quad (9)$$

Thus the expression for the potential U_a , at P , can be written,

$$U_a = \frac{I}{4\pi\rho_0\sigma_2} \sum_{m=0}^{\infty} \left(\frac{\rho}{\rho_0}\right)^m L_m(\mu_0, \phi_0, \mu, \phi) + \sum_{m=0}^{\infty} \left(\frac{a}{\rho_i}\right)^{m+1} Y_m(\mu_i, \phi_i), \quad (10)$$

in which L_m is a Laplacian, a special form of the spherical harmonic Y_m . Since $\phi = \phi_i$, ϕ_i may be replaced by ϕ . Hereafter D will be written for the constant term $I/4\pi\sigma_2$. The first member of Eq. (10) is the part of the potential due to the electrode, and the second member is the part due to the image sphere S_i . The coefficients in the second member of (10) are identical with the coefficients in the expressions (6) and (7) for the potential of the sphere S . The boundary condition (2) will be employed for determining the values of these coefficients which appear in (6), (7) and (10). This will be accomplished by substituting for u , U and U_a their values from (6), (7) and (10) in Eq. (2) and equating coefficients of like tesseral harmonics. Before this is possible, however, U_a must be expressed as a sum of tesseral harmonics with arguments μ and ϕ whose coefficients contain (besides the constants A_{nm} and B_{nm} to be determined) successive powers of ρ . The first term of (10) is already essentially in the desired form. The second term of (10) is at present, however, expressed in terms of ρ_i , μ_i and ϕ . It will be expressed, as desired, in terms of ρ , μ and ϕ by the establishment of a relationship of the type:

$$\sum_{m=0}^{\infty} \left(\frac{a}{\rho_i}\right)^{m+1} Y_m(\mu_i, \phi) = \sum_{m=0}^{\infty} f_m(\rho') Y_m(\mu', \phi), \quad (11)$$

and subsequently replacing ρ' and μ' by their values in terms of ρ and μ . When the second term of (10) has been thus transformed, the solution of the problem is then found at once by comparing on the two sides of Eq. (2) coefficients of like tesseral harmonics.

Now a relationship between tesseral harmonics, which makes possible a transformation of type (11), has been found. This relationship is

$$\frac{P_m^n(\mu_i)}{\rho_i^{m+1}} = \frac{(-1)^{m-n}}{(m-n)!} (1 - \mu'^2)^{n/2} \frac{\partial^{m-n}}{\partial h^{m-n}} \frac{1}{h^n} \frac{\partial^n}{\partial \mu'^n} \sum_{k=n}^{\infty} \frac{\rho'^k}{h^{k+n+1}} P_k(\mu'), \quad (12)$$

² The subscript i is used throughout to refer to image points.

in which the quantities θ' and θ_i are related as shown in Fig. 1. Differentiating with respect to μ' and h , the result is

$$\frac{P_m^n(\mu_i)}{\rho_i^{m+1}} = \sum_{k=n}^{\infty} \frac{(m+k)!}{(m-n)!(n+k)!} \frac{\rho'^k}{h^{m+k+1}} P_k^n(\mu') = \sum_k \alpha_{knm}. \quad (13)$$

For the special case $n=0$, (13) reduces to the form,²

$$\frac{P_m(\mu_i)}{\rho_i^{m+1}} = \sum_{k=0}^{\infty} \frac{(m+k)!}{m!k!} \frac{\rho'^k}{h^{m+k+1}} P_k(\mu') = \sum_k \alpha_{k0m}. \quad (14)$$

Substituting (13) and (14) in the second member of (10) one obtains

$$U_a = \frac{D}{\rho_0} \sum_{m=0}^{\infty} \left(\frac{\rho}{\rho_0} \right)^m L_m(\mu_0 \phi_0 \mu \phi) + \sum_{m=0}^{\infty} \left[A_{0m} \sum_k \alpha_{k0m} + \sum_{n=m}^{\infty} (A_{nm} \cos n\phi + B_{nm} \sin n\phi) \sum_k \alpha_{knm} \right].$$

By an interchange of indices m and k , one finds

$$U_a = \frac{D}{\rho_0} \sum_{m=0}^{\infty} \left(\frac{\rho}{\rho_0} \right)^m L_m(\mu_0, \phi_0, \mu, \phi) + \sum_{m=0}^{\infty} \left[\sum_k A_{0k} \alpha_{m0k} + \sum_{n=m}^{\infty} \sum_k (A_{nk} \cos n\phi + B_{nk} \sin n\phi) \alpha_{mnk} \right], \quad (15)$$

which is the desired result. It is now possible to apply the boundary Eq. (2). The values of u , U and U_a to be substituted in Eq. (2) have been given above. This boundary Eq. (2) involves the first derivative of u , U and U_a with respect to ρ . The second member of (15) for U_a , gives the potential in terms of ρ' and μ' at point P_i , due to the sphere S . From symmetry it may be seen, however, that if ρ' and μ' be replaced by ρ and μ , the second member of (15) will then give the potential at point P , due to the sphere S_i . If now the values of u , U and U_a be substituted in Eq. (2), ρ set equal to a , and coefficients of like tesseral harmonics equated, the following sets of linear equations result:

$$\alpha_m A_{nm} = K_{nm} \left(\frac{a}{\rho_0} \right)^m - \sum_{k=n}^{\infty} a_{nkm} A_{nk}, \quad (16)$$

$$\alpha_m B_{nm} = K_{nm} \left(\frac{a}{\rho_0} \right)^m - \sum_{k=n}^{\infty} a_{nkm} B_{nk}, \quad (17)$$

$$(n = 1, 2, \dots, \infty), (m = n, n+1, \dots, \infty), \\ (n = 0), (m, k = 1, 2, \dots, \infty),$$

in which

$$\alpha_m = \left[\frac{(k+1)}{(k-1)} + \frac{1}{m(k-1)} \right], \quad (18)$$

² See Whittaker and Watson, *Modern Anal.* 4th. Ed., p. 400, Ex. 7.

$$K_{nm} = \frac{2D}{\rho_0} \left(\frac{a}{\rho_0}\right)^m \frac{(m-n)!}{(m+n)!} \cos n\phi_0 P_m^n(\mu_0), \quad (19)$$

and

$$a_{nkm} = \frac{(m+k)!}{(m+n)!(k-n)!} \left(\frac{a}{h}\right)^{m+k+1}. \quad (20)$$

It should be noted that these results, for each value of n , are an infinite set of linear equations. The different sets are identical in form, however, and so it will be necessary to demonstrate the possibility of solution for only one of the sets. For simplicity, the set (16), for which $n=0$, is chosen, and it will be shown by an argument due to von Koch⁴ that this system of equations has a unique bounded solution for the A_{0k} . In the argument, α_m will be replaced by its minimum value unity. If the argument holds for this value of α_m , it will hold for all possible values of α_m . (It may be noted that the dependence of α_m upon m is only slight.) Eqs. (16) may then be written:

$$a_{1m}A_{01} + a_{2m}A_{02} + \cdots + (1 + a_{mm})A_{0m} \cdots = K_m \left(\frac{a}{\rho_0}\right)^m \quad (21)$$

where,

$$(m = 1, 2 \cdots \infty).$$

In order to change to von Koch's notation, replace the unknowns $A_{01} \cdots A_{0k}$ by $x_1 \cdots x_k$, etc. and write Eq. (21) as

$$a_{i1}x_1 + a_{i2}x_2 + a_{i3}x_3 + \cdots + (1 + a_{ii})x_i \cdots = K_i \left(\frac{a}{\rho_0}\right)^i, \quad (22)$$

in which

$$(i = 1, 2 \cdots \infty).$$

Divide (22) by $(1 + a_{ii})$ and set

$$\begin{aligned} \frac{a_{ik}}{1 + a_{ii}} &= -b_{ik}, \\ b_{ii} &= 0, \\ \frac{K_i}{1 + a_{ii}} \left(\frac{a}{\rho_0}\right)^i &= c_i. \end{aligned} \quad (23)$$

Then

$$\begin{aligned} b_{ik} &< \frac{(i+k)!}{i!k!} \left(\frac{a}{h}\right)^{i+k+1}, \\ c_i &< K \left(\frac{a}{\rho_0}\right)^i, \end{aligned} \quad (24)$$

⁴H. von Koch. Jahres bericht der Deutschen Mathematiker Vereinigung 22, 285-291 (1913).

in which K is the upper limit of K_i , namely D/ρ_0 . Eqs. (22) become,

$$x_i - \sum_{k=0}^{\infty} b_{ik} x_k = c_i, \quad (25)$$

$$(i = 1, 2 \dots \infty).$$

Let

$$x_k = x_k^{(1)} + c_k,$$

substitute and obtain

$$x_i^{(1)} = \sum_{k=1}^{\infty} b_{ik} x_k^{(1)} + \sum_{k=1}^{\infty} b_{ik} c_k + c_i^{(1)}.$$

Let

$$x_k^{(1)} = x_k^{(2)} + c_k^{(1)},$$

and so on, continuing this process of successive approximations indefinitely. Using the notation

$$b_{ik}^{(2)} = \sum_{v=1}^{\infty} b_{iv} b_{vk}$$

$$b_{ik}^{(3)} = \sum_{v=1}^{\infty} b_{iv}^{(2)} b_{vk}, \quad \text{etc.,}$$

then according to von Koch's argument, the series

$$x_i = c_i + c_i^{(1)} + c_i^{(2)} + \dots,$$

i.e.

$$x_i = c_i + \sum_{k=1}^{\infty} b_{ik} c_k + \sum_{k=1}^{\infty} b_{ik}^{(2)} c_k + \sum_{k=1}^{\infty} b_{ik}^{(3)} c_k + \dots, \quad (26)$$

is absolutely convergent and represents the unique bounded solution of the system (25), provided $\sum_{k=1}^{\infty} |b_{ik}| < 1$ for all values of i and provided $c_i < K$ a fixed constant. The first of these conditions is fulfilled, provided $a/h < 1/2$, as may be seen from the following summation,

$$\sum_{k=1}^{\infty} b_{ik} = \sum_{k=1}^{\infty} \frac{(i+k)!}{i!k!} \left(\frac{a}{h}\right)^{i+k+1} = \left[\left(\frac{a}{h-a}\right)^{i+1} - \left(\frac{a}{h}\right)^{i+1} \right]. \quad (27)$$

The second condition is fulfilled, as from (24)

$$c_i < K \left(\frac{a}{\rho_0}\right)^i$$

where

$$\frac{a}{\rho_0} < 1$$

and

$$K \leq \frac{D}{\rho_0}.$$

The first five equations of the system (22) for the special case

$$\frac{a}{h} = \frac{1}{2}, \quad \frac{a}{\rho_0} = \frac{1}{2}, \quad K_i = K,$$

will be written down;

$$\left. \begin{aligned} 1.125x_1 + 0.187x_2 + .125x_3 + .078x_4 + .047x_5 \cdots &= \frac{1}{2}K \\ .187x_1 + 1.187x_2 + .156x_3 + .117x_4 + .082x_5 \cdots &= \frac{1}{4}K \\ .125x_1 + .156x_2 + 1.156x_3 + .136x_4 + .110x_5 \cdots &= 1/8K \\ .078x_1 + .117x_2 + .136x_3 + 1.136x_4 + .123x_5 \cdots &= 1/16K \\ .047x_1 + .082x_2 + .109x_3 + .123x_4 + 1.123x_5 \cdots &= 1/32K \end{aligned} \right\} (28)$$

The calculated values of x_1 and x_2 , using the first four terms of formula (26), are

$$\begin{aligned} x_1 &= .3716K, \\ x_2 &= .1456K. \end{aligned}$$

It is very laborious, however, to use formula (26) and it has been found that the values of the unknowns x_k may be found more easily by solving the first of the Eqs. (28) for x_1 , retaining only the first term; using this value in the second equation to obtain an approximate value of x_2 by retaining the first two terms only; then correcting the value of x_1 , by substituting the value found for x_2 in the first equation and so on. By this method, using three of the equations in three of the unknowns, it is found that

$$\begin{aligned} x_1 &= .3725K, \\ x_2 &= .1458K, \\ x_3 &= .0475K, \end{aligned}$$

in good agreement with the values as calculated by the formula (26). It should be noted that the values of the coefficients fall off rapidly in the present case. If the ratio of $a/h < 1/2$ or $a/\rho_0 < 1/2$, the convergence will be still more marked.

All that has been said in regard to Eqs. (16) may be said of the infinite set of Eqs. (17). The convergence, as n grows, becomes more rapid. For n greater than five, the A_{nk} and B_{nk} can be found to an accuracy of about two percent by making the approximation in (16) and (17)

$$A_{nm} = \frac{1}{\alpha_m} K_{nm} \left(\frac{a}{\rho_0} \right)^n,$$

$$B_{nm} = \frac{1}{\alpha_m} K_{nm} \left(\frac{a}{\rho_0} \right)^m.$$

For n less than five, and $a/h = 1/2$, the values of the coefficients A_{nk} and B_{nk} can be found with an accuracy of the order of one percent by solving the first five equations, in the first five unknowns, of the infinite sets of Eqs. (16) and (17).

The expression for the total potential, due to the buried sphere and the electrode, at all points without the buried sphere is

$$\begin{aligned} \Phi = \sum_{m=0}^{\infty} \left(\frac{a}{\rho} \right)^{m+1} Y_m(\mu, \phi) + \sum_{m=0}^{\infty} \left(\frac{a}{\rho'} \right)^{m+1} Y_m(\mu', \phi) \\ + \frac{D}{\rho_0} \sum_{m=0}^{\infty} \left(\frac{\rho}{\rho_0} \right)^m L_m(\mu_0, \phi_0, \mu, \phi), \end{aligned} \quad (29)$$

in which the coefficients in each of the spherical harmonics $Y_m(\mu, \phi)$ and $Y_m(\mu', \phi)$ have the values found by solving the sets of linear Eqs. (16) and (17) for given values of a/h and a/ρ_0 .

The first and third members of Eq. (29) are expressed in terms of ρ , θ and ϕ . The second member is expressed in terms of ρ' , θ' and ϕ . If actually there existed the two spheres S and S_i , then the first and second members of Eq. (29) would express the potential due to the spheres S and S_i respectively. If, as is the case here, there is only the buried sphere S in the infinite half space, which is bounded by the plane MN , then the first two members of (29) are necessary for expressing the potential due to the buried sphere alone. The second member of (29) simply serves to accommodate the boundary condition expressed by Eq. (5).

NUMERICAL COMPUTATION

As an example, the potential $(\Phi - U_e)$ will be computed for a point on the surface of the half space directly above the center of the sphere. The potential will be computed for various depths of the sphere and for the ratio of conductivity, k , of the two media equal to ten. The calculation will be made first by means of approximation formulae described below, and finally by means of the exact formula (29). An electrode of radius a_1 , at which a current I is being introduced, is placed at the point whose cartesian coordinates are $(h/2, 0, (3)^{1/2}a)$. The potential is calculated for the point whose cartesian coordinates are $(h/2, 0, 0)$. It will be assumed that the current is removed at some electrode so far distant from the buried sphere, that its influence upon the sphere may be neglected. It should be mentioned, however, that if the second electrode were not so situated, the potential of the buried sphere, under the influence of this second electrode, could be computed by means of the formula (29) and this potential added to the potential calculated for the first electrode.

First approximation. As a first order approximation to the potential, the field due to the electrode is considered uniform over the buried sphere and

equal to its value at the center of the sphere, and the interaction between the buried and image sphere is entirely neglected. The potential at all points without the buried sphere then is given by the expression

$$\begin{aligned} \Phi - U_e = & \left(\frac{a}{\rho}\right)^2 [A_1 \cos \theta + (A_{11} \cos \phi + B_{11} \sin \phi) \sin \theta] \\ & + \left(\frac{a}{\rho'}\right)^2 [A_1 \cos \theta' + (A_{11} \cos \phi + B_{11} \sin \phi) \sin \theta'], \end{aligned} \quad (30)$$

in which the coefficients have the values

$$A_1 = \frac{D}{\rho_0} \frac{(1-k)}{(k+2)} \frac{a}{\rho_0} \cos \theta_0,$$

and

$$\left. \begin{matrix} A_{11} \\ B_{11} \end{matrix} \right\} = \frac{D}{\rho_0} \frac{(1-k)}{(k+2)} \frac{a}{\rho_0} \left\{ \begin{matrix} \cos \phi_0 \\ \sin \phi_0 \end{matrix} \right\} \sin \theta_0.$$

Second approximation. As a second order approximation to the potential, the field over the buried sphere due to the electrode will again be considered uniform but the first order cross effect due to the interaction of the two spheres will be taken into account. By first order cross effect is meant that the field, due to sphere S_i , is considered uniform over the buried sphere S and equal to the value it has at the center of the sphere S . Such a formula can be obtained by applying boundary condition (2) and then dropping all terms containing $(a/\rho_0)^2$ and $(a/h)^4$ and higher powers of these ratios. If this be carried out, the resulting expression for the potential is identical with Eq. (30), but the coefficients have the values:

$$A_1 = \frac{D}{\rho_0} \frac{(1-k)}{[(k+2) + (a/h)^3(k-1)]} \frac{a}{\rho_0} \cos \theta_0,$$

and

$$\left. \begin{matrix} A_{11} \\ B_{11} \end{matrix} \right\} = \frac{D}{\rho_0} \frac{(1-k)}{[(k+2) + (a/h)^3(k-1)]} \frac{a}{\rho_0} \left\{ \begin{matrix} \cos \phi_0 \\ \sin \phi_0 \end{matrix} \right\} \sin \theta_0.$$

Third approximation. As a third order approximation, the field over the buried sphere due to the electrode will be considered uniform so that terms in $(a/\rho_0)^2$ and higher powers may be dropped. However, the field due to sphere S_i , will no longer be considered uniform over sphere S . That is, terms in $(a/h)^4$ and higher powers will be retained. The formula found under these conditions is:

$$\Phi - U_e = \sum_{m=0}^{\infty} \left(\frac{a}{\rho}\right)^{m+1} Y_m(\mu, \phi) + \sum_{m=0}^{\infty} \left(\frac{a}{\rho'}\right)^{m+1} Y_m(\mu', \phi),$$

in which the coefficients must be determined from the infinite sets of equations of the type (22). Since terms in $(a/\rho_0)^2$ are to be neglected, the right sides of Eqs. (22) after the first are to be set equal to zero.

The values of the potential $(\Phi - U_e)$ as calculated by these three approximate formulae and finally from the exact formula (29) are shown in Fig. 2.

Fig. 2. Potential curves. (a) first approximation; (b) second approximation; (c) third approximation; (d) actual.

To obtain the total potential Φ simply add to the values on the curve, the constant term due to the electrode,

$$U_e = I/4\pi\sigma_2(3)^{1/2}a = M/(3)^{1/2}.$$

This last equation serves to define M , which occurs in the data. In order that the data may be readily put into practical units, the following calculation is to be noted. The potential due to the electrode is

$$U_e = D/r,$$

where r is the distance from the electrode. If, in particular, $r = a_1$, a_1 being the radius of the electrode,

$$U_e = I/4\pi\sigma_2 a_1$$

or

$$I = (U_e)_{a_1} 4\pi\sigma_2 a_1.$$

Therefore, M in the above data becomes

$$M = a_1/a (U_e)_{a_1},$$

and since $(U_e)_{a_1}$ is the potential of the electrode in volts, M will also be in volts.

From the curves, it is clear that any of the approximate formulae are sufficiently accurate for computing the potential, due to the buried sphere, in cases where the depth of the center of the sphere is greater than three times the radius of the sphere. In the region for which $h/2$ is less than a , only the exact formula can be used with any degree of accuracy.

In conclusion, I should like to express my sincere thanks to Professor Warren Weaver of the University of Wisconsin for his helpfulness and interest in the above problem.

MAGNETIC SUSCEPTIBILITIES AND IONIC
MOMENTS IN THE PALLADIUM AND
PLATINUM GROUPSBY ALBERT N. GUTHRIE AND L. T. BOURLAND
PHYSICS LABORATORY, UNIVERSITY OF ILLINOIS

(Received December 15, 1930)

ABSTRACT

Susceptibility measurements have been made on Ru, Rh, Pd, Os, Ir, and Pt and some of their compounds over a range of temperatures by means of an improved Curie balance.

Pd and Pt are found to follow approximately a Curie-Weiss law. Ru, Rh, Os, and Ir are found to have paramagnetic susceptibilities which increase with temperature.

RuCl_3 and IrO_2 are found to follow a Curie-Weiss law which gives for the ion Ru^3 a moment of 9.8 Weiss magnetons per mole and for Ir^4 13.8. The spectroscopically predicted value for each ion is 29.4. The paramagnetic susceptibility of Rh_2O_3 is found independent of temperature while that of RuO_2 increases rapidly with temperature. RhCl_3 is found to have an unmeasurably small susceptibility over the temperature range investigated. IrCl_3 and PtCl_2 are diamagnetic with susceptibilities independent of temperature.

THE determination of ionic magnetic moments in the Pd and Pt groups, by susceptibility measurements on compounds of these elements, is of particular interest in connection with the Hund method¹ of predicting these moments from spectroscopic theory. Hund² has employed his method for the moments of the trivalent rare earth ions and obtained remarkable agreement with the measured values of several investigators. In the case of the ions of the iron group, the elements Sc to Ni of the periodic table, the method has been unsuccessful. Laporte and Sommerfeld³ calculated the moments to be expected for the iron group ions in two cases, infinite separation and zero separation of the J -levels of the ground multiplet predicted by the Hund method. Several of the measured values are found to lie outside of these limits. Bose⁴ has pointed out that the measured moments of the iron group ions are best explained by assuming that they are due to the spin of the electrons alone, the orbital moments being ineffective. Stoner⁵ has called attention to the striking difference in the structures of the rare earth and iron group ions, and the effect that this difference should be expected to have on the ions with the conditions under which their moments are measured. In the iron group ions the incompleting group of electrons which gives the ion its mechanical and magnetic moments is that of highest total quantum number. In the rare

⁵ E. C. Stoner, *Phil. Mag.* **8**, 250 (1929).

earth ions this group of electrons is not that of highest total quantum number. The interaction between the paramagnetic ion and surrounding ions and molecules will presumably effect primarily the electrons in the group of highest total quantum number; in the iron group ions the electrons responsible for the magnetic moment, in the rare earth ions electrons that are not responsible for the magnetic moment. In general this interaction is a strong orbital interaction while the spin moments are left relatively free. In a qualitative way this is an explanation of the apparent ineffectiveness of the orbital moments in the iron group ions and their almost complete effectiveness in the rare earth ions.

There exist few data on the susceptibilities of the elements of the Pd and Pt groups from which ionic moments can be calculated. Bose and Bhar⁶ have made measurements at room temperature on some chlorides and complex salts of some of these elements and have calculated ionic magnetic moments assuming that the susceptibilities of the compounds follow the Curie law. Cabrera and Duperier⁷ made measurements on RuCl_3 , RhCl_3 , PdCl_2 , OsCl_2 , IrCl_3 , and PtCl_2 over a range of temperatures from about 20°C to 100°C . They found that RuCl_3 approximately followed a Weiss law which gave a moment for Ru^3 of 12.9 Weiss magnetons. The susceptibilities of the other chlorides were found to remain constant or increase with temperature.

For this investigation the compounds RuCl_3 , RuO_2 , RhCl_3 , Rh_2O_3 , IrCl_3 , IrO_2 , and PtCl_2 were obtained from the American Platinum Works, Newark, N.J. These compounds were prepared with special regard for purity by Dr. S. Streicher of their chemical laboratory.

Through the kindness of the Bureau of Standards samples of the six metals Ru, Rh, Pd, Os, Ir, and Pt of very great purity were made available for a new determination of their susceptibilities. Several investigators have measured the susceptibilities of these metals but the results have been in very poor agreement.

DESCRIPTION OF APPARATUS

The susceptibility measurements were made by means of a Curie balance. In this apparatus the usual mechanically operated torsion head was replaced by an electrically operated one. The ease and speed of making measurements with this arrangement far surpasses that attainable with the usual mechanical types. In Fig. 1 is shown a sketch of the essential parts of the electrically operated torsion head. A coil of small copper wire, *A*, wound on a flat, hard rubber spool is suspended by a fine wire, *B*, with its plane parallel to a magnetic field produced by two fixed coils, *C*, carrying a current. To the coil *A* is attached the suspension, *D*, which supports the balance arm and to which is applied the torque to overcome the force on the sample. A plane mirror, *E*, is attached to the coil *A* and the twist in the suspension *D* is read from it by means of a telescope and scale placed about one meter away. In order to fix the axis about which the coil *A* rotates suspension guides, *F*, are em-

⁷ B. Cabrera and A. Duperier, *C. R.* **185**, 414 (1927).

ployed. These guides consist of thin brass strips attached to the box which supports the balance and pierced with small holes through which the suspensions pass. The coil *A* is damped by means of vanes *G* suspended in stanolax. A current, which is controlled so as to give the proper torque to the suspension, is carried through the coil *A* by means of long thin spirals of wire which do not hinder the coils free rotation. The other parts of the balance are of the usual design.^{7a}

The apparatus was calibrated by making measurements on distilled water, using as its susceptibility with respect to air at 20°C and 76 cm pressure the value -0.749×10^{-6} .

Fig. 1. Sketch of the essential parts of the electrically operated torsion head.

The inhomogeneous magnetic field was furnished by a Dubois electromagnet with its pole pieces set at an angle of about twelve degrees with a line joining their centers. The field strengths obtainable were in the range 1400 to 6400 gauss.

The samples were heated by means of a nichrome resistance furnace. A junction of a Cu-constantan thermocouple was mounted so as to occupy the same relative position in the furnace as the sample on which measurements were being made. The other junction of the thermocouple was kept in a bath of ice and water. Temperatures were read by means of a D'Arsonval galvanometer in the thermocouple circuit. A galvanometer deflection of one mm corresponded to a temperature change of about 2.5°C. The thermocouple was calibrated by means of the boiling points of well-known substances.

EXPERIMENTAL RESULTS

In Tables I, II, III, are given the results of measurements on the various substances indicated.

The susceptibility of Rh was found to decrease with increasing field strengths. At room temperature the change was from 1.60×10^{-6} at 1420 gauss to 1.20×10^{-6} at 6390 gauss. This variation was assumed to be due to ferromagnetic impurities and the method first used by Honda⁸ was used to calculate the susceptibility of Rh from these measurements.

^{7a} The modification of the Curie balance as used by Foëx was considered but calculation showed that the torsion method could be made more sensitive for our measurements.

In Fig. 2 are plotted the values of $1/\chi$ for Pd, Pt, RuCl_3 and IrO_2 as a function of temperature.

Fig. 2. Values of $1/\chi$ for Pd, Pt, RuCl_3 and IrO_2 plotted as a function of temperature.

DISCUSSION OF RESULTS

Pd and Pt are found to follow approximately a Curie-Weiss law, the deviation being accounted for by an underlying diamagnetism independent of temperature. From purely formal theory, it would be expected that the diamagnetic component of the susceptibility would be greater for Pt than for Pd but the experimental results indicate the opposite.

Ru, Rh, Os, and Ir are found to have paramagnetic susceptibilities which increase with temperature. This is, of course, inconsistent with Langevin's theory.

RuCl_3 and IrO_2 are found to follow a Curie-Weiss law. For the former the equation is:

$$\chi = \frac{2340}{T + 37} \times 10^{-6} \text{ c.g.s./gram}$$

and for the latter

$$\chi = \frac{4310}{T + 4025} \times 10^{-6} \text{ c.g.s./gram.}$$

These results give for the magnetic moment of the Ru^3 ion 9.8 Weiss magnetons per mole, and for the Ir^4 ion 13.8. The predicted normal state for both ions is 6S which gives 29.4 Weiss magnetons per mole for the moments. In the iron group, good agreement between measured and predicted moments has been found for all ions with predicted S normal states. In these groups, there is no agreement whatever and the behavior of some of the compounds is such

that no moments can be determined from measurements on them. If the susceptibility does not follow a Curie-Weiss law, there is no theory which will give the elementary magnetic moments.

A deviation from the Curie-Weiss law is predicted for compounds containing a paramagnetic ion with other than an S normal state due to the increase with temperature of the number of excited ions with moments differing from that of the ions in their normal state. With an S normal state there are no excited ions at ordinary temperatures. In these researches only the compounds containing the paramagnetic ion with a predicted S normal state are found to follow a Curie-Weiss law but the deviations of the other compounds are opposite to (excepting RuO_2) and much greater than can be accounted for by the theory.

The behavior of those compounds which do not follow a Curie-Weiss law is not due to a permanent chemical or physical change due to heating for at room temperature the susceptibilities are found to be the same after as before heating.

The disagreement between the measured and the spectroscopically predicted ionic moment may be due to error in prediction of the normal state. Hund's rule, combined with present ideas of the electronic arrangement in atoms and ions, predicts for Ru^3 and Ir^4 a 6S normal state. In the same way the prediction for the normal state of the Pd atom is a 3F . The atomic spectrum of Pd has been analysed by Beals, Beckert and Catalan, and McLennan and Smith.⁹ They all have concluded that the normal state for the Pd atom is a 1S which means that the Pd atom in its normal state has zero magnetic moment. That the moment of the Pd atom is zero in its normal state has been verified by Copley and Guthrie¹⁰ by the molecular ray method.

The question of the validity of Hund's rule in the wave mechanics has been examined by Slater.¹¹ He has found that the wave mechanics gives the same normal state as Hund's rule although their predictions differ higher up in the spectrum.

The interpretation of the magnetic moment determined from susceptibility measurements on compounds as the true moment of the paramagnetic ion seems not to be well founded. The ion in chemical combination, surrounded by other ions and molecules, must be a different thing from the ion with which the spectroscopist deals in the Zeeman effect. Therefore, in spite of some past successes it appears hopeless to expect always to find agreement between these two.

The writers wish to express their appreciation to Professors E. H. Williams and Jakob Kunz for their encouragement and advice during the progress of this work.

CHANGES IN ELECTRICAL RESISTANCE DUE
TO MAGNETISM AND HARDNESS

BY S. R. WILLIAMS AND RICHARD A. SANDERSON

DEPARTMENT OF PHYSICS, AMHERST COLLEGE

(Received December 19, 1930)

ABSTRACT

A series of twenty-two rods or strips of nickel, to which had been imparted different degrees of hardness by cold rolling, had their resistance measured when subjected to a longitudinal magnetic field. There were eleven degrees of hardness, two samples for each degree. The longitudinal magnetic field increased the resistance in all cases.

The different degrees of hardness did not vary the specific resistance of the nickel, but it did cause a large variation in the change of resistance due to a magnetic field. The measurements were carried out at a constant temperature of 35°C.

IN HIS summary to Part I of an extensive study of the electrical conductivity in strong magnetic fields, Kapitza¹ says, "It has been shown that the physical change produced in a conductor by hardening and annealing has a strong influence on the phenomenon of change of resistance. The influence of the impurities is also very marked and was studied."

Kapitza has brought together as fine a collection of the elements for study in strong magnetic fields as has ever been assembled, but his greatest difficulty was in procuring these samples in a pure state. It has been pointed out² that very worthwhile results may be obtained by comparing magnetic phenomena in the same specimen, even though the purity of the sample may not be vouched for.

Some years ago there was begun in this laboratory a study³ of a series of nickel rods or strips, twenty-two samples in all, with eleven degrees of hardness in the series. The rods were given different degrees of hardness by cold rolling to various degrees of reduction. The rods were all of the same original heat and had the same chemical analysis, which is herewith given: copper, 0.16%; nickel, 98.8%; iron, 0.56%; sulphur, 0.008%; silicon, 0.06%; carbon, 0.09%; manganese, 0.23%.

While these rods could not be considered as pure nickel, yet they could be said to be identical specimens so far as their chemical constitution was concerned. It was, therefore, possible to study the effect of different degrees of hardness on the electrical conductivity of a definite material when magnetized longitudinally.

The rods came in flat strips and were furnished through the courtesy of the International Nickel Company. There were, originally, eleven strips, 91

cm long, 4.8 cm wide and 0.61 cm thick, all annealed to the same degree. Ten of these were then given the percentage cold reduction shown in Table I.

TABLE I.

Strip number	1	2	3	4	5	6	7	8	9	10	11
Percentage reduction	0	9.7	18.9	28.9	29.5	50.0	59.5	69.0	79.0	89.1	93.3

Each one of these eleven strips was then cut in two, longitudinally, and given a common length of 58 cm. This made a total of twenty-two specimens in all. The cross-sectional dimensions of the completed strips are given in Table II. They are the averages of ten to twelve readings taken along the length of the rods with a micrometer caliper. The two sets of strips were numbered;

$$A_1, A_2, A_3, \dots, A_{11}$$

and

$$B_1, B_2, B_3, \dots, B_{11}$$

wherein the rods *A* and *B* with the same subscript formed one of the eleven original strips.

Strip number	1	2	3	4	5	6	7	8	9	10	11
Scleroscope hardness	17	27	31	35	40	43	45	47	50	51	49

The resistance was measured between two fiducial marks 51.8 cm apart on each rod. The measurements were made by means of a Kelvin double bridge. The complete outfit was one manufactured by Leeds and Northrup Company and found to be most satisfactory. The bridge was made sensitive enough to indicate easily a change of resistance less than 0.000001 ohm. Higher sensitivity created more difficulty in making observations.

In Fig. 1 is shown the arrangement of apparatus. The longitudinal magnetic field was obtained by means of a solenoid, *S*, one meter long. The internal diameter of free space was 5.5 cm. There were 6025 turns which gave a constant of 75.3 gauss per ampere, both by calculation and by experimental test. In order to keep the strips at a constant temperature while being tested, they were placed in an oil bath. The container for the oil consisted of a copper trough, *TT*, passing through the solenoid and insulated from it by a coating of shellaced cloth. By means of brass gas-pipe fittings this trough was connected with a rectangle *G*, of $\frac{3}{4}$ inch brass pipe. The pump, *P*, kept the oil in continuous circulation around the rectangle. This pump consisted of a propeller blade inside of a tube and driven by the small motor, *M*. Transformer oil was used for circulating in the trough. Inasmuch as heat was

Fig. 1. Arrangement of magnetizing solenoids and constant temperature bath.

slowly given up to the system by the solenoid, it seemed best to keep the temperature of the bath somewhat above that of the room. A temperature of 35° C, was chosen as a suitable point from which the bath would always be cooling off. The moment it got below 35°C, the thermostat would turn on more gas to the burner, located under one end of trough, and keep the temperature up at 35°C. The bath did not vary over 0.2 degrees during the measurements. This kept the temperature sufficiently constant for making comparable resistance measurements. The temperature of the bath was determined by a sensitive, calibrated mercury-in-glass thermometer. Sometimes it was found that manual control of the gas was helpful. The thermostat for controlling the gas supply at the burner, *L*, which heated the bath, was a simple mercury-in-glass device. All the values for resistances, given in this paper, are for the temperature of 35° C, unless otherwise stated.

As found by other investigators,⁴ the resistance of nickel is increased when magnetized longitudinally. This was true for all of the twenty-two specimens examined. The effect of hardening may best be studied in Fig. 2, where for

⁴ W. E. Williams, *Phil. Mag.* 4, 430 (1902); 9, 77 (1905).

the field strength of 75.3 gauss the changes in resistance per ohm is plotted against hardness numbers. The effect of increasing the hardness is to decrease the change in resistance produced by the magnetic field. Fig. 2 is also

Fig. 2. Change in resistance per ohm for the different nickel strips at a field strength of 75.3 gauss.

of interest in comparison with a curve published in a paper⁵ presenting the relation between the change in length due to a magnetic field and the hardness of this same set of strips. This curve is shown in Fig. 3 with a field strength of 58.8 gauss.

Fig. 3. The changes in length for the different nickel strips at a field strength of 58.8 gauss.

The most rapid change in length and in resistance comes in the first few reductions. In some way or another the changes in resistance due to a magnetic field are very closely related to the changes in length due to a magnetic field. There seems to be a common mechanism operating in both effects.

In Fig. 4 is shown the way in which the change in resistance per ohm varies with increasing magnetic field. Curve 1 is the average of the values for the two rods, A_1 , and B_1 , while curve 2 is the average for the two rods, A_4 and B_4 . This figure represents the greatest difference obtained in the series of strips, due to differences in hardening. It confirms in a very marked way the results obtained by Kapitza, i.e., that hardness plays a very important rôle in this effect.

⁵ Williams, Trans. A. S. S. T. p. 885 (1926).

The various values of dr/R in the curves represent the average of at least eight observations. Demagnetization of the rods occurred between each reading. This was accomplished by sending a decreasing a.c. through the solenoid.

In getting the changes in resistance due to magnetism and hardness, it was also easy to find the specific resistance of these strips. The values obtained are given in Table IV, and which are the averages of the *A* and *B* series. Three

Fig. 4. Change in resistance per ohm as magnetizing force increases.

sets of values are given which were taken by different observers using different methods and about two years apart. The first set is by Mr. Lusk of the Rawson Electrical Instrument Company. Mr. Lusk checked his results by two entirely different methods. The second set is by Mr. G. K. Schoepfle, a former graduate student in this department. The third set is furnished by the junior author of this paper.

This set of readings seemed rather astonishing at first because as one crushes the nickel strips by rolling, and therefore the crystals comprising

TABLE IV.

Strip number	Lusk	Specific resistance Schoepfle	Sanderson
1	0.00001012	0.00001083	0.00001099
2	.00000993	.00001081	.00001102
3	.00000993	.00001035	.00001093
4	.00000995	.00001085	.00001089
5	.00001000	.00001060	.00001086
6	.00000995	.00001071	.00001082
7	.00001000	.00001055	.00001079
8	.00001008	.00001070	.00001071
9	.00001032	.00001090	.00001076
10	.00001033	.00001051	.00001079
11	.00001038	.00001102	.00001073

the strips, it would suggest the possibility that the specific resistance would also be changed in a corresponding manner. *The specific resistance appears to be constant.*

The values given by Lusk were obtained about five years ago and at room temperature. The values by Schoepfle were obtained about two years later and also at room temperature. In all probability there had been some aging process going on in the meantime. To release local strains set up in the rods at the time they were cut and machined into shape, they were annealed for one hour in an oil bath at 304°C. This process took place about seven years before the readings were taken for this paper.

It was also possible with this equipment to determine the temperature coefficient of the strips. This was not worked out completely, but it was carefully measured on the rods, A_1 and A_4 , those rods which had the widest variation of dr/R for a given magnetic field. Measurements were made at 35°C and at 85°C. This gave A_1 a temperature coefficient of 0.0042 and A_4 the value of 0.0043, indicating that there was little or no change in the temperature coefficient due to difference in rolling.

Although hardening by cold rolling did not change the specific resistance of this series of nickel strip, yet it did affect the change in resistance due to a magnetic field. This seems to be the most significant fact emerging from the results of this investigation,—no change in specific resistance due to varying hardness, but a decided change in the variation of resistance with magnetic field.

Attention should be called to the excellent paper by McKenhan⁶ which has appeared since these results were obtained.

⁶ McKeehan, Phys. Rev. 36, 948 (1930).

THE ROLES OF DISCRETE AND CONTINUOUS THEORIES IN PHYSICS*

BY ARTHUR RUARK

UNIVERSITY OF PITTSBURGH

(Received December 4, 1930)

ABSTRACT

The differential character of the principal equations of physics implies that physical systems are governed by laws which operate with a precision beyond the limits of verification by experiment. This appears undesirable, from an axiomatic standpoint.

Postulates of real, finite and rational description.—We may safely assume that all results obtained experimentally can be described by using real and finite functions of real, finite and rational variables. It appears desirable, therefore, to use the calculus of finite differences in formulating the results of our experiments. In dynamics, the use of this calculus yields terms corresponding to the fact that the configuration is known only when we observe it and must be arbitrary at intermediate times. For example, if a "uniformly moving particle" is observed once a second, we find experimentally that

$$\Delta^2 x / \Delta t^2 = 0,$$

whence

$$x = Ft + G.$$

Here F and G are *arbitrary* Fourier series having the period Δt . The general difference equations of dynamics are formulated. The Lorentz transformation is reinterpreted, relativistic difference equations of motion and of light propagation are set up, and geodesics in a discrete manifold are discussed.

Extensions of these ideas to electrodynamics are outlined.

I. INTRODUCTORY

IT IS often said that while the fundamental equations of physics must be capable of describing every feature of our experimental results, at the same time they must not introduce extraneous or unobservable features. On the basis of this criterion, many branches of physics are not in a satisfactory position. Broadly speaking, the difficulties to which we refer originate in the use of mathematical concepts which are unsuited to the description of our experimental knowledge, and which introduce complications having no counterparts in nature.

Let us begin with an example. Consider, on the one hand, the information we obtain by performing an experiment once, or at most, only a few times. Usually, this information consists of a table of related numerical data. Consider, on the other hand, the statistical knowledge we obtain by correlating the results of a very large number of similar experiments. We draw curves and calculate averages, and finally, we may attempt to represent our results in an idealized fashion, by writing empirical equations. Up to this point the

* A preliminary account was given before the American Physical Society in February 1929. See Phys. Rev. 33, 637 (1929).

procedure is beyond criticism, if we keep in mind the experimental basis of our equations, but when we carry the idealization process one step further, and derive differential equations from the empirical ones, we introduce conceptual difficulties. A differential equation connotes much more than the data from which it arises; herein lies its strength and,—unfortunately,— its weakness. For instance, Newton's equations imply that a dynamical system is governed by laws operating with a precision beyond the limits of detection by experiment. If, at a time t , we know the position and velocity of a body, these equations predict its condition at the time $t+dt$, but in order to verify the prediction, one would be obliged to distinguish between two positions, x and $x+dx$, by making two measurements separated by an infinitesimal time interval. But as a matter of fact, we have no desire to find the condition after the time dt ; we wish to predict the state, within limits, after a finite time interval, and this we do by integrating the equations of motion. Each coordinate may then be expressed as a continuous function of the time, and we may calculate the configuration at *any* time, that is, at an "infinite number of instants." The information yielded by the equations is much in excess of what we can test experimentally. No one will deny the great practical value of Newton's equations, and clearly, the point we wish to emphasize is this: from an aesthetic and logical standpoint, it is desirable to have available a mathematical algorithm which makes it possible for us to summarize precisely the information obtained from a series of measurements, without excess and without deficit. It is our aim to show how this may be accomplished with the aid of the calculus of finite differences.

II. CRITIQUE OF THE USE OF INFINITESIMAL ANALYSIS IN PHYSICS

THE PRINCIPLE OF REAL AND FINITE DESCRIPTION

Most of the purposes we have in mind may be accomplished by adopting a set of postulates which, for brevity, will be collectively designated as the principle of real and finite description. For our present purpose¹ we may state the postulates as follows:

All results obtained experimentally can be described in terms of real and finite functions of real and finite variables. These functions need only be defined for discrete values of their independent variables. Both the functions and their independent variables need only assume rational values.

As an illustration, we consider a series of experiments on the motion of a single atom, or on a small number of atoms. The principle of real and finite description indicates clearly that our numerical results should not be discussed by means of continuous analysis. But if the series of experiments were to be extended indefinitely, until observations had been made on a great many

¹ For the sake of simplicity, we shall speak as though a measurement consisted in assigning a definite number x_0 to a variable at a definite time, t_0 . The real situation is that we know x lies in the range $x_0 \pm x_0$ when t lies in the range $t_0 \pm \Delta t_0$. Thus we may say that x is an "indefinite function" of the "indefinite variable" t . It is easy to devise an algebra for dealing directly with the possible connections between such variables; but these matters will be postponed to a later occasion.

individuals, and over the entire ranges of the independent variables, then we would have the material necessary for building up a continuous, statistical theory,—in fact, a branch of wave mechanics. The situation in regard to the motion of a macroscopic body is quite similar. On the basis of a small amount of experience with its motion, we should not write a continuous law. (The true status of the laws of motion is connected with Ehrenfest's theorem, and is discussed in section V.) In the light of these ideas, the use of continuous analysis in physics can be clearly understood. Continuous laws should be introduced only when we deal with statistical results, obtained from vast numbers of experiments.

While the situation in regard to the use of infinitudes in physics is generally unsatisfactory, an exception must be made in the case of wave mechanics, where it is required that the wave functions shall be finite, continuous and single-valued at all real points of the coordinate space used by Schrödinger. The validity of these conditions has sometimes been questioned on the ground that, where the wave function ψ is zero, $1/\psi$ is infinite and there does not seem to be any reason why we should keep ψ from becoming infinite, rather than $1/\psi$. The writer feels that this criticism is invalid, for the square of the absolute value of ψ is measurable, indirectly at least, and therefore must not become infinite for real, finite and rational values of its variables. How ψ behaves for irrational values of its variables is none of our concern.

Again, it may be objected that in wave mechanics integrals extending over the entire ranges of the coordinates x , y and z (from $-\infty$ to $+\infty$) are constantly used with valuable results. Just as in the case above, this appears undesirable since we should think of the coordinates as measurable quantities, and should therefore limit them to finite values. Since in many problems the ψ -function approaches zero very rapidly for large values of the coordinates, it will usually occur that the values of matrix components will be little affected by restricting the range of integration to exclude infinite values, and the practical consequences of the theory will be unaltered. Even in scattering problems, where sinusoidal wave trains are used to represent incident beams of particles or protons, it would be better physics to speak of these trains as having their origin at a great, but finite, distance from the scattering center. Further, it appears desirable to use wave equations which are modified to take account of general relativity. It appears plausible from astronomical evidence that our four-dimensional space-time is limited in extent, and if this is the case, integrals of the type $\int \psi^* f \psi dv$ would naturally be extended only over a finite range. Furthermore, from our present stand-point, it is obvious that we should not treat the electron or the proton as point-singularities at which the electromagnetic and gravitational forces become infinite. Indeed, all such artificial mathematical difficulties are excluded by strict adherence to our postulates.

The situation in regard to the use of imaginaries in physics also requires comment. It is generally recognized that the introduction of $\exp i\omega t$ in vibration problems is merely a mathematical artifice, but many a physicist would feel surprise at the proposal to replace the quantum condition, $pq - qp =$

$\hbar/2\pi i$, by an equation which is free of the imaginary unit. However, from an axiomatic and aesthetic standpoint, imaginaries should be excluded from any discussion of fundamental physical questions, and this can always be done by rationalizing our equations, even when we are dealing with quantities which do not commute. (In the present instance we may use $(pq - qp)^2 = -\hbar^2/4\pi^2$ or $(pq - qp)(pq - qp)^* = \hbar^2/4\pi^2$. Then, in solving any specific problem, we get the Heisenberg matrices and their imaginary conjugates. In practice, this doubling of the solution will introduce no difficulties, and may even be advantageous.)

After these explanatory remarks we are ready to apply the principle of real and finite description to dynamics and electromagnetic theory. We shall find that when we apply it in dynamics we are naturally led to equations of finite differences, replacing the differential equations of motion. The solution of these difference equations brings in *arbitrary* functions which reduce to known constant values only at times when the configuration of the system is actually observed. This corresponds to the fact that we are not able to state the configuration of the system, except at the instants of observation. We proceed at once to amplify these statements.

III. THE DIFFERENCE EQUATIONS OF DYNAMICS

Let us analyze the information obtained by an experimental study of a body moving along the x -axis. For the moment we pass over difficulties arising from errors of observation and assume that the observer can determine times and distances with any desired precision. The result of a set of position measurements will be a table showing the values of x at each instant of observation, such as the following:

$$\begin{aligned} t_1, t_2, t_3, \dots, t_n; \\ x_1, x_2, x_3, \dots, x_n. \end{aligned} \quad (1)$$

With a view to simplicity, suppose the intervals between successive observations have a constant duration, Δt . This restriction is unnecessary, and later we shall remove it. Perhaps the most natural method of analyzing the data is to study the difference coefficients of the series of x -values. Writing $x_2 - x_1 = \Delta x_1$, $\Delta^2 x_1 = \Delta x_2 - \Delta x_1$, etc., we form the table (2).

x_1	$\frac{\Delta x_1}{\Delta t}$	
		$\frac{\Delta^2 x_1}{\Delta t^2}$
x_2	$\frac{\Delta x_2}{\Delta t}$	
		$\frac{\Delta^2 x_2}{\Delta t^2}$
x_3	$\frac{\Delta x_3}{\Delta t}$	

(2)

$$\begin{array}{ccc} x_4 & & \\ \vdots & \vdots & \vdots \\ \vdots & \vdots & \vdots \\ \vdots & \vdots & \vdots \end{array}$$

Let us suppose we find that

$$\frac{\Delta x_i}{\Delta t} = \text{constant}, \quad i = 1, \dots, n-1, \quad (3)$$

and

$$\frac{\Delta^2 x_i}{\Delta t^2} = 0, \quad i = 1, \dots, n-2. \quad (4)$$

From our present standpoint, such a motion will be defined as uniform, and the constant value of $\Delta x_1/\Delta t$ is *defined* as the velocity. Either one of the relations (3) and (4) enables us to construct the original table of x -values,² but in order to attain a degree of generality equivalent to that provided by the equation $d^2x/dt^2=0$ we shall deal with (4). Taken as they stand, the Eqs. (3) and (4) state a regularity of the data and say nothing about the values of $\Delta x/\Delta t$ and of $\Delta^2 x/\Delta t^2$ at instants which lie outside the period covered by the experiment. Further, they say nothing about the values of $\Delta^2 x/\Delta t^2$ for times intermediate to the instants of observation. They contain nothing more than the isolated facts revealed by the experiment, and we must recognize the element of hypothesis introduced when we use them as a basis for prediction. The most natural method of generalizing (4) is to write

$$\frac{\Delta^2 x}{\Delta t^2} = 0, \quad (5)$$

and to consider this equation, provisionally, as applying to *any* series of observations like the above, obtained at time intervals Δt and extending over a finite time. Now, the general solution of (5) is not identical with the general solution of $d^2x/dt^2=0$. In fact, it is

$$x = Ft + G, \quad (6)$$

where F and G are trigonometric series of period Δt ,³ let us say

$$F = A_0 + A_1 \sin 2\pi \frac{t}{\Delta t} + A_2 \sin 4\pi \frac{t}{\Delta t} + \dots + B_1 \cos 2\pi \frac{t}{\Delta t} + \dots, \quad (7)$$

the expression for G being similar. The coefficients in these series are arbitrary constants, except for one restriction. We require that F shall reduce to the observed velocity v , and G to the observed initial value of x , let us say x_0 , whenever t is a multiple of Δt . The coefficients in (7) are *not* Fourier coefficients which cause the series to represent the function $x_0 + vt$, in the interval

² In using equation (3) to reconstruct the x -values, we must specify x at one of the instants of observation, let us say t_1 ; and in using (4), we must specify one value of x and one of $\Delta x/\Delta t$.

³ Boole, *Finite Differences*, reprint by Stechert, p. 80.

from $t=0$ to $t=\Delta t$. On the contrary, when an arbitrary choice of the form assumed by x between observations has been made, they are the Fourier coefficients of that form, and the series will generally be infinite. However, the series may contain only a finite, but very great, number of terms, if we specify the values of x at only a finite number of instants. The latter type of choice is in fact the only type which is in agreement with the principle of real and finite description. With these understandings, Eq. (6) completely reproduces the experimental results. At intermediate times, when the system is not under observation, the arbitrary trigonometric terms come into play, which means that the position of the system is not known.⁴ The state of affairs is illustrated by Fig. 1, in which the solid line represents the classical motion, while the dotted curve shows a path which might possibly be represented by (6) and (7). The dotted curve might even have a finite number of disconti-

Fig. 1.

nuities in each interval Δt . When the specified set of observations is completed, we have no *physical evidence* which excludes the possibility of such a curve as the dotted one in Fig. 1. Of course, we could have taken additional observations, at the times $\Delta t/2$, $3\Delta t/2$, etc., let us say, obtaining an equation similar to (6). Under these circumstances, however, the state of our knowledge is different, for now the periodic function x must have the same values as the function $vt+x_0$, whenever t is a multiple of one-half the original Δt ; at all other times it is arbitrary. The number of observations at times between t_1 and t_n cannot be increased indefinitely; therefore the Eqs. (5), (6) and (7), since they yield the observed data only and nothing more, represent a closer approximation to our experimental knowledge of the motion than the corresponding differential equation and its solution. However,

⁴ In a paper entitled "The Limits of Accuracy of Physical Measurements," Proc. Nat. Acad. Sci. 14, 322 (1928), the writer has shown that there are definite natural limitations on the accuracy with which we can measure a coordinate or specify a time, quite independent of all considerations of experimental skill. If we are dealing with a free particle of mass m , we have $\Delta x_{\min} = h/mc$ and $\Delta t_{\min} = h/mc^2$. It is interesting to note that if the time interval between observations is reduced to the order of Δt_{\min} , the first trigonometric term in (7) has a frequency of the order mc^2/h ; that is, the frequency of the matter waves for a particle of mass m .

(6) still suffers from several defects: (1) it definitely prescribes the value of x at instants lying outside the range t_1 to t_n , although the observations were made only within that range; (2) it is scarcely arbitrary enough at intermediate times, for the trigonometric terms represent a periodic function; (3) it is assumed that the observations are equally spaced. In removing these defects, we may as well speak of a general system, exposed to forces of any kind whatever. Let all the coordinates, q_1, \dots, q_r , be observed at the instants t_1, t_2, \dots, t_n . We desire to construct a set of functions $q_1(t), q_2(t), \dots$ which will reduce, at the observation times, to functions which adequately represent the observed values of the coordinates and which will be arbitrary at all other times. The solution is immediate.⁵

We need only write down the polynomials obtained by applying Lagrange's method of interpolation, let us say

$$q_1 = f_1(t, c_1, c_2, \dots), \quad q_2 = f_2(t, c_1, c_2, \dots), \quad (8)$$

where the c 's are the constant coefficients of the various powers of t . We replace these constants by any functions of t which are *entirely arbitrary except that they must reduce to the experimental values c_1, c_2 , etc., at the instants of observation*. We shall call any such function $A(t)$, or simply A . The Eqs. (8) are now replaced by

$$q_1 = f_1(t, A_1, A_2, \dots), \quad q_2 = f_2(t, A_1, A_2, \dots). \quad (9)$$

In these equations we have a faithful picture of experimental facts. It is necessary, however, to reconsider the concept of mass, since we naturally desire to use it as soon as we consider accelerated motions. In order to obtain a definition of inertial mass suitable for use in the finite difference equations of dynamics, we must describe a procedure by which a number may be assigned to the mass of a body, without any mention of instantaneous velocity, which is a differential coefficient. When we neglect the dependence of mass on velocity, the original definition of Newton is quite satisfactory. That is, if two freely moving bodies collide head on, their masses are inversely as the changes of velocity which they experience. Since the velocity measured is $\Delta x/\Delta t$ rather than dx/dt , we see that the value of a mass, resulting from such an experiment, can be formulated entirely in terms of finite difference coefficients and a constant; namely, the number assigned to the mass of a standard body.

The construction of the Eqs. (8) is especially simple when the time interval between observations is constant. Just as in the illustration of the uniformly moving particle, we are led to finite difference equations. From the standpoint of the principle of real and finite description, these equations, or their integrals (in the sense of the calculus of finite differences), expressed in the form (9), are the true laws of motion.

If, for the moment, we suppose there are no experimental errors, and that the observations are consistent with Newton's laws, we can easily see what the finite difference equations will be. This supposition is made only for pur-

⁵ Boole, reference 3, p. 39.

poses of discussion, and implies no recession from the principles laid down in section II. The general difference equation for any problem of particle dynamics, Δt being constant, is obtained by noting that $m\Delta^2x/\Delta t^2$ is the time mean of the time mean of the force, taken over the interval Δt . We may verify directly that

$$m \frac{\Delta^2 x}{\Delta t^2} \equiv \frac{1}{\Delta t^2} \int_t^{t+\Delta t} \int_t^{t+\Delta t} m \frac{d^2 x}{dt^2} dt dt \equiv \frac{1}{\Delta t^2} \int_t^{t+\Delta t} \int_t^{t+\Delta t} F_x dt dt,$$

or,

$$m \frac{\Delta^2 x}{\Delta t^2} \equiv \bar{\bar{F}}_x, \quad (10)$$

where the bar denotes a time mean over the interval mentioned. This equation, and two similar ones, constitute a formulation of the laws of motion, to which we should doubtless be led if, in all cases, we were to carry through a process like that which led us to Eqs. (3), (4), and (5). In general the right member of (10) will depend on Δt as well as on t , because the upper limits of the integrals contain Δt . The analogue of (10) in curvilinear coordinates is very complicated. While the writer has found it possible to make considerable progress in working out a theory for second order difference equations analogous to the transformation theory of ordinary dynamics, the results are so involved as to be of little interest. Therefore, we content ourselves with stating Eq. (10).

IV. RELATIVITY DYNAMICS

In discussing special relativity from the standpoint of the principle of real and finite description, we meet at once with a kinematic problem; namely, the relation between the coordinates in different systems of reference. Whenever we pass to a new system of dynamical variables, the transformation equations themselves should be in accord with the principle. In other words, they may contain difference coefficients, but they should not contain derivatives. It is satisfying to note that the Lorentz transformation may be interpreted in such a way that it obeys this criterion. If the moving system of reference, x', y', z', t' , has velocity $V(=Bc)$ parallel to the X -axis of the observer's system, x, y, z, t , this transformation takes the form

$$x' = k(x - Vt), y' = y, z' = z, t' = k\left(t - \frac{Vx}{c^2}\right), k = 1/(1 - B^2)^{1/2}. \quad (11)$$

On the usual theory, V represents the *instantaneous* velocity of the moving axes, dX/dt , but for the present purpose a different definition is needed. We may suppose the two sets of axes are attached to isolated bodies between which there is no detectable interaction. If then we find experimentally that $\Delta X/\Delta t$ is a constant V , we *postulate* that the Eqs. (11) hold true, and with this understanding they contain no derivatives. Quite similarly, c represents the quotient of a *measured* distance travelled by a light beam between two stations, and the *measured* time required for its journey. In accordance with the spirit of this paper, c must therefore be expressed as a difference quotient.

If we assume, *momentarily and for purposes of discussion only*, that the relativistic differential equations of motion are valid, the difference equations of motion for a rapidly moving particle may be obtained very easily. The relativistic equations of motion are

$$\frac{d}{dt}(mv_x) = F_x, \text{ etc.} \quad (12)$$

where $m = m_0/(1 - \beta^2)^{1/2}$ and $\beta c = v$. If the square of the element of arc in a four-dimensional space is written as

$$ds^2 = c^2 dt^2 - dx^2 - dy^2 - dz^2,$$

(12) may be rewritten in the form

$$m_0 c \frac{d^2 x}{ds^2} = F_x \frac{dt}{ds}. \quad (13)$$

Suppose now that the observations are uniformly distributed along the world line of the particle, so that we have $\Delta s = \text{constant}$, in place of the former assumption, $\Delta t = \text{constant}$. We proceed just as we did in obtaining (10) with the result

$$m_0 c \frac{\Delta^2 x}{\Delta s^2} = \overline{F_x \frac{dt}{ds}},$$

where the right member denotes

$$\frac{1}{\Delta s^2} \int_s^{s+\Delta s} \int_s^{s+\Delta s} F_x \frac{dt}{ds} ds ds.$$

There is a way of expressing the law of light propagation without recourse to infinitesimals or to integrals. Since, in the theory of special relativity, the law is $ds^2 = c^2 dt^2 - dx^2 - dy^2 - dz^2 = 0$, we replace this by

$$\Delta s^2 = c^2 \Delta t^2 - \Delta x^2 - \Delta y^2 - \Delta z^2 = 0. \quad (15)$$

In general relativity also, the law of light propagation may be taken as $\Delta s = 0$.

It is much more difficult to formulate an analogue for the geodesic law $\int ds = 0$, which applies to the free motion of a particle. If we follow the most obvious course and assume that the law should take the form

$$\Delta s = \text{an extremum}, \quad (16)$$

we at once encounter a question of interpretation.

On the one hand, we may assume that we are dealing with a continuous space-time manifold, even though our measurements are discontinuous in character. On this basis Δs means a finite interval between adjoining observations, marked off along a geodesic line, where the word geodesic is taken in its ordinary sense. The significance of (16) is then simply that of a theorem deducible from Einstein's law of motion.

On the other hand, we may suppose that the space-time manifold is simply a discrete aggregate of observed point events, analogous to a two or three dimensional network, like a crystal lattice. The problem of defining a geodesic in such a lattice is not an easy one, as Silberstein has pointed out in his "Theory of Relativity." He suggests that the "shortest distance" between two points a and b in such a lattice (Fig. 2) should be defined as the smallest number of steps which will carry one from a to b . As to the concept of a step, it is necessary to think of the lattice points as joined by a network of lines. A step is then defined as the transition from a given point to its neighbor on one of these lines. In Figs 2a and 2b we have indicated two different methods of drawing such line-networks and it is obvious that the shortest distance depends to a great extent on the nature of these lines. Further, even with such a simple point lattice and network of lines as that shown in Fig. 2a, the paths

Fig. 2.

which correspond to shortest distances are not unique. Thus, the two paths $a, c, d \dots b$, and $a, c', d' \dots b$ both involve the same number of steps, and both may be considered as geodesics between a and b for the particular network shown. Although the shortest distance has a definite value, the path which must be traversed in order to achieve the journey in this shortest distance is not uniquely determined, save in special cases. After all, we should expect that some feature like this would emerge when we deal with discrete quantities.

In view of the existence of a limit to the accuracy with which a coordinate can be measured,⁶ we should expect that the concept of shortest distance has an indefinite meaning in the atomic domain. The contribution of the present discussion is to show that a similar difference exists even for macroscopic measurements, as soon as we abandon the idea of a continuous background for the description of events.

V. DISCUSSION OF EHRENFEST'S THEOREM

In sections II and III we emphasized that Newton's laws of motion should be interpreted statistically,—that our knowledge of a single body can never be extensive enough to justify us in supposing it follows the laws of motion exactly. There is a theorem of wave mechanics discovered by Ehrenfest,⁷

⁶ Ruark, reference 4.

⁷ Ehrenfest, *Zeits. f. Physik.* 45, 455 (1927); Ruark and Urey, *Atoms Molecules and Quanta*, p. 652, McGraw-Hill, 1930.

which throws further light on this situation. Let ψ denote the wave function for a particle, so that $\psi\psi^*dv$ is the probability for the particle to have its coordinates in the element dv of the coordinate space. Then the x -component of the center of gravity of the probability distribution is given by $X = \int \psi^* x \psi dv$, provided the wave function is so normalized that $\int \psi^* \psi dv = 1$, and the theorem may be stated as follows:

$$m\ddot{X} = \int \psi^* \left(-\frac{\partial V}{\partial x} \right) \psi dv. \quad (17)$$

The expressions for \ddot{Y} and \ddot{Z} are similar, and V is the potential energy. Now let us consider a wave packet, having a very small extension compared with any distance in which the potential energy changes appreciably. In evaluating (17), we may use the value of $-\partial V/\partial x$ at the *centroid* of the packet, in every element of the integral, and the result is

$$m\ddot{X} = \left(-\frac{\partial V}{\partial x} \right)_x \int \psi^* \psi dv = \left(-\frac{\partial V}{\partial x} \right)_x. \quad (18)$$

On the basis of an outworn interpretation of wave dynamics, the individual particle is thought of as a wave packet, and $|\psi|$ as the amplitude of the waves. If this were correct, Ehrenfest's theorem would replace the ordinary law of motion, and it would appear foolish to use finite difference equations in describing the motion of a particle. But, on the probability interpretation, the meaning of Ehrenfest's theorem is this: We consider a great number of similar experiments, in each of which a single particle moves along the x -axis, and if we measure the x -coordinate of each particle at a definite instant, we obtain the distribution of $\psi\psi^*$ appropriate to that instant. At any future time the distribution can be calculated from the wave equations and we have a picture of the *statistical* behavior of the particles at that time. In other words, the wave equations enable us only to follow the time changes of the probability distribution; and there is room for uncertainty in the motion of the individual particles. Only the centroid obeys the approximate law of motion (18). Now, from a knowledge of the probability distribution obtained by a great number of experiments on individual isolated particles, we can draw no definite conclusions as to the motion of the centroid of a great number of particles, bound together in a rigid body and set in motion all together. This remark should make it clear that there is nothing in Ehrenfest's theorem which contradicts the conclusions of sections II and III.

VI. DIFFERENCE EQUATIONS IN ELECTRODYNAMICS

The use of difference equations in electromagnetic theory arises naturally from our discussion of mechanics. Details will have to be reserved for a later occasion, but the leading ideas will be indicated here. To begin with, the electromagnetic field is *defined* entirely in terms of dynamical measurements. For our present purpose, the forces between charged bodies, magnets, and conductors carrying currents, are the fundamental things. We may employ

a small test body carrying a charge e , to map out a field of electric force. Again, if the test body is endowed with a "velocity" $\Delta s/\Delta t$, chosen to suit our convenience, a field of magnetic force may be studied. Thus we obtain the distribution of six quantities, $E_x, E_y, E_z, H_x, H_y, H_z$, which might be called components of electric and magnetic intensity if the names were not preempted by analogous entities incapable of being measured, and defined in terms of the behavior of infinitesimal test bodies. The quantities E_x, \dots, H_z are defined by the very processes used in measuring them. There is no implication that they obey Maxwell's equations. Indeed, they do not, because, from the usual standpoint, they represent average values of the field intensities, measured by a finite test body and not by a mathematical abstraction. These quantities may well be referred to as the *physical* field intensities. Their properties are simply the properties of numbers which fit a modified Lorentz equation,

$$eF \equiv e \left(E + \frac{1}{c} [vH] \right). \quad (19)$$

In this equation v means $\Delta s/\Delta t$ rather than ds/dt ; e is measured by experiments whose interpretation requires no use of infinitesimals and eF_x is a force measured, let us say, by readings on the scale of an actual spring balance, or by equating it to the value of $m\Delta^2 x/\Delta t^2$ for the test body. The field equations obeyed by the physical field intensities may now, in principle, be found by trial. They involve the properties of the test body as well as those of the bodies producing the field—a point which is important in itself. The same consideration applies in mechanics but was not emphasized in section III, for the sake of simplicity.

VII. CONCLUSION

In conclusion, this paper serves to introduce a method of talking consistently about the results of experiments, and attention may be directed again to the refinements hinted at in the first foot note. The writer's aim has been to show how physical facts can be formulated by the use of difference calculus, that is, essentially with the aid of rational numbers. Considering the almost universal use of idealized concepts such as infinitesimals and irrationals, it seemed worth while to examine the possibilities of proceeding otherwise, and the results may be summarized in a broad sense, as follows: a method has been outlined by which we can describe experimental results mathematically, without any implications concerning the state of a system at times when it is not being observed, or concerning the causal connections customarily implied by the use of continuous analysis.

The writer wishes to thank Doctors Hutchisson, Muskat, Rashevsky and Worthing for helpful discussions.

LETTERS TO THE EDITOR

Prompt publication of brief reports of important discoveries in physics may be secured by addressing them to this department. Closing dates for this department are, for the first issue of the month, the twenty-eighth of the preceding month; for the second issue, the thirteenth of the month. The Board of Editors does not hold itself responsible for the opinions expressed by the correspondents.

Nuclear Spin

On the basis of measurements by Rasetti¹ of the Raman effect in N_2 , Heitler and Herzberg² have suggested that the electron in the nucleus has lost not only its spin, but also its power to determine what the statistics of the nucleus shall be. (One could say, perhaps, that the electrons in the nucleus behave as if they had no spin and obey, therefore, the Bose-Einstein statistics, just as photons do.) The purpose of the present note is to point out that the assumption that the protons alone contribute to the resultant spin is sufficient to explain all the known facts. Furthermore, it may be that there is a building-up principle analogous to that of the outer electrons, although the evidence^{3,4} is insufficient to show exactly what this would be.

TABLE I. Building-up process.

Element	P	Z	I	Protons added	Spins added
H	1	1	1/2		
He	4	2	0	3	(+ -) -
Li	7	3	3/2	3	+++
C	12	6	0	5	---(+ -)
N	14	7	1	2	++
O	16	8	0	2	--
F	19	9	1/2	3	(+ -) +

The table gives in the last two columns the number of protons and spins, respectively, which must be added to the element in the row above to give the element in the row itself.

Thus, if we suppose that each additional proton contributes a spin of $\pm \frac{1}{2}$ to the resultant (which is the simplest assumption), the elements may be ordered as shown. Starting with He^4 , $I=0$, three parallel spins will produce Li^7 , $I=3/2$, and five more, two forming a pair, can result in C^{12} , $I=0$. Two additional parallel spins give N^{14} , $I=1$; two more, opposite in direction to the first two, O^{16} , $I=0$; and three more, two forming a pair, can yield $I=\frac{1}{2}$ for

F^{19} . The value of nuclear spin for Na^{23} is in doubt, but if we assume $I=5/2$, then, by interpolation, Ne^{20} should have $I=1$ and Ne^{22} , $I=2$. One would also expect, since $I=0$ for C^{12} and S^{32} , a value of $I=1/2$ for B^{11} and P^{31} .

The difficulty mentioned by Goudsmit for the cadmium spectrum also disappears, if one adopts the above hypotheses. The value of $I=1/2$ may be attributed to Cd^{111} or Cd^{113} , but there exist no criteria for choosing between the two isotopes. (Perhaps both give a hyperfine structure.)

It seems, therefore, that the experimental evidence to date indicates the validity of the rule that even numbers of protons imply integral values for I , and odd numbers half-integral values. This is true for Mn, Br, Pr and Bi.

One would expect aluminium, phosphorus, chlorine, potassium, scandium, vanadium, cobalt, copper, gallium, arsenic, and other elements with isotopes having only odd numbers of protons to have half-integral values for the nuclear spin.

It remains an open question as to whether or not the orbital angular momentum of the protons plays a rôle, and also whether or not closed shells of protons exist, as do closed shells of extra-nuclear electrons. If there are such closed shells of protons, then this might provide the explanation of inverted hyperfine structure, the inversion being due to the absence of a proton from such a shell.

The Cathode-Ray Tube in X-Ray Spectroscopy and Quantitative Analysis

Under this title the Journal of the American Chemical Society has published a paper by us in the January number. A Coolidge tube was used, having a soldered aluminum window 6 mm in diameter and operated continuously at 0.2 m.a. and 85 kv D.C. Experiments were made with metal targets placed above the window and cooled with a jet of hydrogen. For the recording of the relative intensities of the $K\alpha$ doublet, primary attention was given to a method involving the application of an ionization chamber and an amplifying set. The latter made use of the new FP54 tube (Metcalf and Thompson, *Phys. Rev.* **36**, 1489 (1930)). The smallest measurable grid current was $8.7 (10)^{-16}$ amps. With a copper target and 0.4 mm slits, the peak of the $K\alpha$ doublet gave a net deflection of 90 cm with an accuracy of 0.5 cm on a scale 2.6 m distant, corresponding to an ionization current of $3 (10)^{-13}$ amp.

The loss in electron velocity in passing through the window agreed with the Thomson formula. For molybdenum and iron the intensity was found to vary as the square of the difference between the electron velocity and the exciting voltage. This relationship held up to the maximum velocity employed, amounting to four-fold the exciting voltage for the case of molybdenum and eleven-fold for iron. Experiments as yet unreported are

being made on titanium and calcium and the exponent has been found to be 1.3 for the voltage range extending from ten to sixteen-fold the exciting voltage. The exponent accordingly decreases less rapidly with increase in voltage than has been observed in similar experiments with x-ray tubes.

Curves showing the relation between chemical composition and the relative intensities of the unresolved $K\alpha$ doublets were obtained for copper-nickel and iron-nickel alloys—the latter representing the case in which the intensity of radiation from one constituent is increased as the result of excitation by the other.

Other experiments were carried out, using photographic recording by means of a Seemann spectrometer. For a molybdenum target, a 1° oscillation of the crystal and a slit width of 0.05 mm, a density of the $K\alpha_1$ line amounting to 0.4 was obtained by an exposure of sixteen minutes. Analyses by this method were made on silver-cadmium and tin-antimony alloys and the results were confirmed by chemical examination.

The Hyperfine Structure of Ionized Lithium

The hyperfine structure of the low 3P state of Li^+ is of the same order of magnitude as the triplet separation itself. One might expect large deviations from the interval rule for hyperfine splitting, corresponding to large contributions of one triplet level to the perturbed eigenfunctions of another. Since the Li^+ hyperfine structure has not yet been explained conclusively,¹ we have estimated the effect of these deviations on the calculated positions of the components. The resulting corrections are, however, small, and are not sufficient to give a better agreement than obtained by Güttinger.

Our method is simply to consider the transition between the extreme cases wherein the hyperfine splitting is either small or large com-

pared to the triplet separation. The coefficients of general equations for the levels were determined by use of the vector model in the extreme cases, and by using the usual identification of the lines for the isotope Li_6 . The nucleus was considered as coupled only to the $1s$ electron in the 3P . About 6 percent was subtracted from the coupling constant as determined from the 3S , due to the interaction with the $2s$ electron there.² This correction alone has some effect on the results of Güttinger, as is indicated in the third column of the table.

In the case of $i=1\frac{1}{2}$, one of the coefficients of a cubic equation cannot be determined, and is represented by x in Table I. Its order of magnitude should be one-tenth cm^{-1} . Its evaluation would be intricate, but no value

An Attempt to Detect Axiality of X-Ray Emission

J. Stark¹ has recently reported that fluorescent *K*-series x-rays are not emitted with equal intensity in all directions from certain crystals, and that these x-rays are at least partially plane-polarized. In the case of γ - γ -dibromoanthracene, a monoclinic crystal of needle-like habit with the *b*-axis parallel to the length of the needle, he found about 20 percent more bromine *K*-radiation in directions 90° from the *b*-axis than in a direction 10° therefrom. The scattering of this radiation by aluminium indicated that it was polarized with the electric vector parallel to the *b*-axis. These effects are so important from the theoretical side that independent confirmation seemed desirable. This note reports an unsuccessful attempt to detect differences in the intensity of zinc *K*-radiation emitted in different crystallographic directions from a zinc crystal.

Zinc was chosen because the axial ratio for its hexagonal crystals, $c/a=1.86$, is so much

greater than that (1.63) to be expected in a close-packed arrangement of spheres that it is reasonable to suppose the atomic axes are not free to rotate about axes in the (001) plane. This is one of the criteria suggested by Stark for selecting materials likely to show the new effect. His objection to the use of metals, that the atoms therein are presumably free to rotate, does not therefore seem valid with respect to zinc.

The primary x-rays used were from a tungsten target tube operated at 55000 volts (peak) or from a molybdenum target tube operated at 44000 volts (peak). The zinc monocrystalline plate, 0.4 cm thick was rotated about its normal into various azimuths while its secondary radiation in a fixed direction 90° from the primary beam was measured by balancing its ionization with that of part of the primary beam. The absorption coefficient of the secondary radiation was found to be that of zinc *K*-radiation, indicating that the scattered radiation at 90° was negligible in comparison with the fluorescent. The normal to the plate was found by Laue and rotation

¹ Stark, Ann. d. Physik [5] 6, 637-662 (1930).

photographs to lie at 20° from the hexagonal axis of the crystal, so that if θ is the angle between the normal and the axis of the principal ionization chamber the angles between this axis and the hexagonal axis of the crystal vary between $\theta + 20^\circ$ and $\theta - 20^\circ$ during the rotation of the specimen. For the three settings tested, θ was 52° , 62° and 77° . In no case was the variation in observed intensity as much

as one percent. We conclude that at least as regards intensity the effect reported by Stark is unimportant in zinc.

Rotational Fine Structure in Raman Spectra

In recording the rotation spectrum of a molecule by scattered light one of the major difficulties is the very great intensity of the unmodified line as compared with those lines arising from changes in rotational energy. Long exposures tend to broaden the strong line and obliterate the weaker ones which lie very close to it. An ingenious arrangement employed by Rasetti (*Zeits. f. Physik* 66, 646 (1930)) is partially effective in overcoming this handicap. He introduced mercury vapor into the spectrograph to absorb from the scattered light those unmodified frequencies which arise from the normal state of the atom. The observations are thus practically confined to $\lambda 2537$ as parent line. Even this expedient is not wholly successful, since $\lambda 2535$ is superposed upon the rotation pattern and appears very intense in comparison with it.

Recently Manneback (*Zeits. f. Physik* 62, 224 (1930)) has computed the relative intensities and polarizations for Raleigh and Raman scattering of lines with and without rotational

displacements. He shows that if the incident light is plane polarized and the scattered light is observed in a plane normal to the electric vector, the rotation lines are almost completely depolarized. Since the unmodified line is not depolarized, this suggests the introduction of a Nicol prism between the camera and the scattering chamber. Any convenient source and any frequency for the incident line could then be used, and not only the parent line but also neighboring lines scattered without change in frequency would be eliminated. In all probability the background illumination would also be materially lessened. With this improvement in contrast considerably smaller total exposures should prove adequate, and the necessary time might not be much extended, even though the illumination would be considerably fainter.

Biological Effects of Gamma-Rays

In connection with the development in various laboratories of x-ray tubes operating at voltages of the order of a million volts, the question of adequate protection of those engaged in the work against the very penetrating gamma-rays emitted by such tubes has become of considerable importance. It has seemed valuable to perform some experiments with highly filtered gamma-rays from radium in order to ascertain the dangers from exposure to the penetrating radiation, which may be considerable in amount, passing through whatever shielding may be used around the tube. Estimates doubtless might be made from previous work, but for comparison it appeared desirable to have data on exposures to gamma-rays from radium from which all soft components were similarly filtered out.

A group of 63 white rats (with known antecedents) has been exposed to the radiation from 6 grams of radium filtered through one mm of platinum, one mm of brass, 16 mm of lead, and 5 mm of celluloid at a distance of 41 mm to the nearest side of the rat. For four additional rats the celluloid was omitted. The rats were put in celluloid boxes 47 mm high placed above and below the radium box. The radium was spread out over a surface of 3 by 10 cm area to give more uniform exposure. With this large source-area and distance, the exposure was reasonably similar throughout the whole body of the rat. In addition, 16 rats were exposed to 2.5 grams of radium at the same distance but with the lead filter removed; for eight of this group the celluloid was also omitted. This group of 16 thus re-

ceived approximately the same exposure to the hard components of the radiation but with the addition of that amount of soft gamma-radiation which penetrated the platinum and brass. The celluloid was used in order to reduce the beta-ray intensity to about the level corresponding to the rate of beta-ray production in the tissues. Exposure-times were varied from one-half minute to 17 hours in a roughly geometric progression. The 2.5 grams without the lead filter should give an "erythema dose" in about four hours at the average distance of 6 cm according to ordinary clinical data.

All rats died which were exposed six hours and longer to the 6 grams of radium with filters. With a 16-hour exposure, death ensued in three or four days, due at least in part to injury to the gastro-intestinal tract. With six-hour exposures the rats showed similar but less severe gastro-intestinal symptoms from which all recovered in about three days but died one to three weeks later from a progres-

protective measure for those working with high-voltage tubes. Breeding experiments are in progress, and the evidence so far indicates that the sterility dose approximates the lethal dose under these conditions. Abnormalities have to date appeared only in the litter of one female fertilized four weeks after a three-hour exposure.

To provide a suitable index of the total exposure of investigators working with high-voltage tubes, a series of Eastman extra fast (CC) dental x-ray films was enclosed in a lead cassette having walls 6.9 mm thick, and this cassette was exposed in the mid-position of the rat (6.2 cm to the film) for periods of 10^{-3} to 10^{-1} lethal exposure-time as determined for the rats. An exposure of 1×10^{-3} lethal dose gives a point just at the lower end of the straight portion of the density-log exposure-curve, that is, 7×10^{-4} lethal dose gives a density which is easily confused with fog due to development, whereas 3×10^{-3} gives a very obvious blackening of the film. Densities as

Fraction of lethal exposure-time	Percent transmission incident film	Percent transmission emergent film	Average T	Density = $\log_{10} 1/T$
None	100	100	1.00	0.0
0.00005	100	100	1.00	0.0
0.0001	83	97	0.90	0.045
0.0003	65	83	0.74	0.13
0.0007	46	64	0.55	0.26
0.001	33	45	0.39	0.41
0.003	9.5	12	0.11	0.96

sive anemia affecting both red and white blood-cells. One of the six rats exposed to three hours died from a similar anemia after 11 days. The lethal exposure lies thus between three and six hours, or about four hours. Two of four rats exposed 2.5 hours to 2.5 grams of radium without the lead filter died from anemia after 19 and 37 days. The lethal exposure for these conditions is thus about three hours.

Blood-counts were made on 66 rats before and 0, 1, 3, 7, 14, 21, and 35 days after exposure. The minimum exposure which showed an appreciable effect on the blood-count was approximately 20 minutes for the rats exposed to the 6 grams with filters. Since a single massive dose is the most favorable for detecting a change in blood-count and since ten times this exposure is above the lethal dose, blood-count observations alone are not a satisfactory

measured on a photoelectric photometer for the two films in each plaque are given below. The plaque was exposed as labeled with the "black paper toward tube" (radium).

For these film-exposures 2.5 grams of radium were used with the 16-mm lead filter (in addition to the cassette), and 12 hours was taken as the lethal exposure-time.

BOOK REVIEWS

Vorlesungen über Wellenmechanik. A. LANDÉ. Pp. 132, figs. 15, Akademische Verlagsgesellschaft, Leipzig 1930. Price RM 9.50.

This small volume represents the lectures delivered at Ohio State University during the academic year 1929–30. In general character it is more of a *Handbuch* than a self-sufficient introductory treatise. The number of topics touched upon is surprisingly large, but the treatment of the individual items is correspondingly shortened.

After a brief introduction on the general foundations of atomic theory there is a section on the dualism of the wave and corpuscle viewpoints, and one on the uncertainty principle. The treatment is along the usual lines, but the compactness of the material is so great as to detract very considerably from its value. The third section on quantum statistics gives a treatment of the Bose-Einstein method but only a mention of that of Fermi.

The major portion of the book is of course devoted to Schrödinger's equation and its solution. Only the simplest cases are discussed, but no attempt is made to give actual methods of solution, results only being stated. One may call attention to the treatment of the Pauli principle and the symmetry properties of wave functions, which is rather more carefully stated than is usual. The last section on the relativistic wave equation contains a paragraph on Dirac's electron theory and even one on quantum electrodynamics. Perhaps one of the best uses of this book will be as a guide in the development of more detailed lecture notes.

E. L. HILL

Handbuch der Astrophysik. Band II, Erste Hälfte. Edited by G. EBERHARD, A. KOHL-SCHUTTER AND H. LUDENDORFF. Pp. 430, figs. 51. Julius Springer, Berlin, 1929. Price bound RM 69.

The importance of photometry in astrophysical work is well illustrated by the fact that this volume of 430 pages forms but a half of the section of the *Handbuch* which is to be devoted to this subject. The first and longest chapter deals with photometric theory. The photometry of the stars, and of self-luminous bodies in general, is rather summarily treated, for example, nothing is said about the measurement of the brightness of the sun relative to the stars, or of the comparison between the astronomical standard of light (expressed in stellar magnitudes) with the terrestrial standard (meter-candles). On the other hand, the photometry of diffusely reflecting bodies—the moon, the planets, Saturn's rings, the zodiacal light, etc., and the extinction of light in the earth's atmosphere are discussed in great detail, with the inclusion of important investigations by the author (Professor E. Schoenberg) some of which are new, while others have been difficult of access. This complete monograph, accompanied by extensive tables should be of much value to all workers in this field. There are few references, however, to work of later date than 1922, and it is to be regretted that no mention is made of Danjon's work on the earth-shine upon the moon, or of Hubble's on the illumination of nebulae by neighboring stars.

The chapter on spectro-photometry (by Dr. A. Brill) deals with a subject so new that it is largely an account of the methods employed by individual investigators. These are clearly presented and the summary is brought up to the end of 1927—including some of the modern work on the contours of individual spectral lines.

A short chapter on colorimetry (by K. Bottlinger) contains an admirable survey of the meaning of color-indices and related magnitudes, and a critical discussion of the methods and results of observation up to 1926. The final chapter on photoelectric photometry, (by H. Rosenberg) contains a thorough discussion of photoelectric and selenium cells. The latter have been practically abandoned in favor of the former, which are of ever-increasing importance. He justly remarks that their introduction into observatories has doubtless been delayed by the unfamiliarity of astronomers with the details of delicate electrical equipment, and his full descriptions of instrumental design and wiring should be of real aid here.

HENRY NORRIS RUSSELL

THE PHYSICAL REVIEW

NOTE ON THE STATISTICS OF NUCLEI

BY P. EHRENFEST AND J. R. OPPENHEIMER

CALIFORNIA INSTITUTE OF TECHNOLOGY, PASADENA

(Received December 23, 1930)

ABSTRACT

From Pauli's exclusion principle we derive the rule for the symmetry of the wave functions in the coordinates of the center of gravity of two similar stable clusters of electrons and protons, and justify the assumption that the clusters satisfy the Einstein-Bose or Fermi-Dirac statistics according to whether the number of particles in each cluster is even or odd. The rule is shown to become invalid only when the interaction between the clusters is large enough to disturb their internal motion.

I. INTRODUCTION

THE band spectra of symmetric diatomic molecules show certain striking differences from those of asymmetric molecules. For when the two nuclei of the molecule are identical, the intensity of the individual lines of a band, instead of varying smoothly from line to line, alternates more or less markedly. This alternation may in most cases be understood¹ with the help of a simple rule, but in the case of the N_2 molecule, the theoretical prediction seems to disagree with experiment, in that it leads us to expect those band-lines to be the more intense, which are in fact weaker. In this paper we do not propose to resolve this disagreement; we shall only try to give as direct a derivation as possible of the rule which plays the cardinal part in obtaining the theoretical prediction. For it seems that, in spite of the frequent citations of this rule, no explicit derivation of it from Pauli's exclusion principle has been published. In giving this derivation we shall have to investigate the conditions under which the rule is valid, and the degree of approximation to which it may be expected to hold.

The rule may be stated:

R. "If we have two nuclei, each built up of n electrons and m protons, and if the nuclei are in the "same inner state," then not all the molecular states which would be possible for an asymmetric molecule will be found to occur;

if $n+m$ is $\begin{cases} \text{even,} \\ \text{odd,} \end{cases}$ only those states $\begin{cases} S \\ A \end{cases}$ will occur for which the wave function $\begin{cases} \text{remains unchanged} \\ \text{changes its sign} \end{cases}$ when we interchange the "coordinates" of the nuclei.

¹ See the comprehensive report by R. S. Mullikan, Transactions of the Faraday Society 25, 611 (1929).

When the nuclei are in different states, the molecule behaves like an asymmetric molecule."

Since we may expect the nuclei to be in their normal state, we should be able by this rule to predict the weight of the states S and the weight of the states A if we knew the degree of degeneracy g of the normal states of the nuclei. Thus there will always be $\frac{1}{2}g(g-1)$ states S and $\frac{1}{2}g(g-1)$ states A possible; if n plus m is even, there will be g states S , if n plus m is odd, g states A , also possible. The relative weights of the states S and A will therefore be

$$\begin{aligned} (g+1)/(g-1) & \text{ if } n+m \text{ is even} \\ (g-1)/(g+1) & \text{ if } n+m \text{ is odd.} \end{aligned} \quad (1)$$

If we ascribe the degeneracy of the normal state of the nuclei to the spatial degeneracy of an angular momentum $sh/2\pi$, then these ratios become

$$\begin{aligned} (s+1)/s & \text{ for } n+m \text{ even} \\ s/(s+1) & \text{ for } n+m \text{ odd.} \end{aligned}$$

From this we see that, since $n+m$ is odd for the nitrogen nucleus, the states A should have a greater weight than the states S . According to the assertions of band spectroscopists, the electronic wave functions of the normal state of the N_2 molecule are symmetric in the coordinates of the nuclei, and there is no resultant electronic angular momentum parallel to the molecular axis. If we accept these assertions, we are led to expect a greater weight for states of odd rotational quantum number than for those of even quantum number; and it is this expectation which is not confirmed by experiment.

Our problem is now so to refine the expressions "internal state" and "interchange the coordinates of the nuclei" in our rule R , that we can derive the rule from the exclusion principle.

II. WAVE PACKETS FOR A SYSTEM OF TWO CLUSTERS

We shall consider first the following preliminary problem: Suppose that we have a system containing $2n$ electrons and $2m$ protons. Suppose further that for any group of n electrons and m protons we could write down a complete set of wave functions u_k for the stationary states k ; how then, using any two of these wave functions u_k and u_l , can we build up a wave packet for the whole system which satisfies the exclusion principle for all the electrons and all the protons in the system? Only when the particles of the system do not interact at all will these wave packets represent the stationary states of the whole system; but with the help of these packets, by linear combination, we shall be able to build up wave functions which do represent stationary states for any interaction energy of the particles. The functions u may for instance represent states of a nucleus, or an atom, or a molecule, or even some aperiodic motion of the n plus m particles; for this preliminary problem we need to make no assumption about them; but we shall see later that only when the functions u represent very stable configurations: i.e. very tight binding of the particles,—can we deduce any significant results; and so we shall call any group of n electrons and m electrons a cluster.

Let the cartesian coordinates, referred to a fixed axis system, and the component of spin in a fixed direction, of the j th electron be x_j ; similarly let the coordinates and spin of the i th proton be y_i . Let us split up each of the functions u into two functions, a function T_s which depends only on the coordinates of the center of gravity of the cluster, and a function ψ_σ which depends on the relative coordinates of the particles, and on the spin variables:

$$u_k(x_1 \cdots x_n, y_1 \cdots y_m) \rightarrow T_s(x_1 \cdots x_n, y_1 \cdots y_m) \psi_\sigma(x_1 \cdots x_n, y_1 \cdots y_m) \\ = T_s(\alpha) \psi_\sigma(\alpha)$$

$$u_l(x_{n+1} \cdots x_{2n}, y_{m+1} \cdots y_{2m})$$

$$\rightarrow T_t(x_{n+1} \cdots x_{2n}, y_{m+1} \cdots y_{2m}) \psi_\tau(x_{n+1} \cdots x_{2n}, y_{m+1} \cdots y_{2m}) = T_t(\beta) \psi_\tau(\beta)$$

We write α for the arguments $(x_1 x_2 \cdots x_n, y_1 y_2 \cdots y_m)$ and β for the arguments $(x_{n+1} x_{n+2} \cdots x_{2n}, y_{m+1} y_{m+2} \cdots y_{2m})$

Since T depends only on the sum of the coordinates of the electrons, and the sum of the coordinates of the protons, and does not involve the spins at all, it must remain unchanged when we make an arbitrary permutation of the arguments x of u among themselves or of the arguments y of u among themselves. On the other hand u must be antisymmetric in its arguments x and in its arguments y , since otherwise it could not represent a stationary state for the cluster allowed by the exclusion principle. Thus ψ must be antisymmetric in the x 's and in the y 's. Let now P be an operator which makes an arbitrary permutation of the x 's and an arbitrary permutation of the y 's in any function of $x_1 \cdots x_{2n}, y_1 \cdots y_{2n}$, and let p be the order of the permutation P . Then the functions

$$F_{st, \sigma\tau} = \frac{1}{(2n)!(2m)!} \sum (-)^p P \{ T_s(\alpha) T_t(\beta) \psi_\sigma(\alpha) \psi_\tau(\beta) \} \quad (2)$$

satisfy the exclusion principle, if the summation be taken over all the $(2n)!(2m)!$ permutations P . There are only $r = (2m)!(2n)!/(m!)^2(n!)^2$ different terms in this sum, since by the antisymmetry of the ψ 's, all of the terms in which the arguments of T_s (and therefore also of T_t) are the same have just the same value. If we define a distribution by the symbol $(x_j \cdots, y_i \cdots | x_f \cdots y_g \cdots)$ in which the arguments of T_s are to the left, those of T_t to the right, of the line, and in which the order of the arguments to the left and to the right is indifferent, then we can write

$$F_{st, \sigma\tau} = \frac{1}{r} \sum' (-)^p P \{ T_s(\alpha) T_t(\beta) \psi_\sigma(\alpha) \psi_\tau(\beta) \} \quad (3)$$

where now the summation is taken only over the r different distributions. Now in $F_{st, \sigma\sigma}$ with $\sigma = \tau$, we can combine the term with the distribution

$$(x_j \cdots y_i \cdots | x_f \cdots y_g) \quad (4)$$

with that with the inverted distribution

$$(x_f \cdots y_g \cdots | x_j \cdots y_i).$$

This second term may be derived from (4) by n plus m interchanges, and will therefore appear in the sum with the same sign as (4) if n plus m is even, and with the opposite sign if m plus n is odd. We may therefore write, with $\theta = (-1)^{m+n}$

$$F_{st,\sigma\sigma} = \frac{1}{r} \sum'' (-)^p P \{ \psi_\sigma(\alpha) \psi_\sigma(\beta) [T_s(\alpha) T_t(\beta) + \theta T_s(\beta) T_t(\alpha)] \} \quad (5)$$

where now the summation is taken over the $r/2$ different sets of arguments in the ψ_σ 's. When $\tau \neq \sigma$, we have instead,

$$F_{st,\sigma\tau} = \frac{1}{r} \sum'' (-)^p P \{ \psi_\sigma(\alpha) \psi_\tau(\beta) T_s(\alpha) T_t(\beta) + \theta \psi_\sigma(\beta) \psi_\tau(\alpha) T_s(\beta) T_t(\alpha) \}$$

which we may write

$$F_{st,\sigma\tau} = \frac{1}{2r} \sum'' (-)^p P \{ [\psi_\sigma(\alpha) \psi_\tau(\beta) + \psi_\sigma(\beta) \psi_\tau(\alpha)] [T_s(\alpha) T_t(\beta) + \theta T_s(\beta) T_t(\alpha)] + [\psi_\sigma(\alpha) \psi_\tau(\beta) - \psi_\sigma(\beta) \psi_\tau(\alpha)] [T_s(\alpha) T_t(\beta) - \theta T_s(\beta) T_t(\alpha)] \} \quad (6)$$

From (5) we see that $F_{st,\sigma\sigma}$ is $\begin{cases} \text{symmetric} \\ \text{antisymmetric} \end{cases}$ in s and t when $m+n$ is $\begin{cases} \text{even,} \\ \text{odd,} \end{cases}$

and, from (6), that for $\tau \neq \sigma$, $F_{st,\sigma\tau}$ has, for $n+m$ either even or odd, both a symmetric and an antisymmetric part, neither of which vanishes identically. These properties of the wave packets F will make it possible to deduce our rule.

III. SYMMETRY OF WAVE FUNCTIONS FOR A SYSTEM OF TWO CLUSTERS

We should expect that these symmetry properties in s and t would persist in the stationary wave functions built up from the F 's whenever the interaction of the two clusters was too small appreciably to distort the internal configuration of the clusters. In this paragraph we shall have to find the wave functions ϕ for the stationary states of the system of two clusters. We shall see that, when certain matrix components of the interaction energy of the particles may be neglected, the ϕ 's do in fact have the same symmetry in s , t as the corresponding wave packets F ; and we shall see further that the conditions under which we may neglect these matrix components are just those in which the interaction of the clusters does not greatly disturb their internal motion.

Let E be the energy of the system, and H the Hamiltonian; it will in general be given us as an operator on a function of the x 's and the y 's, and it will be 'impartial' to all x 's and 'impartial' to all y 's. The wave equation for $\phi(x_1 \cdots y_{2m})$ will be

$$(H - E) \phi = 0 \quad (7)$$

Since ϕ must satisfy the exclusion principle, and since our original u 's formed a complete set of functions, we may expand ϕ as a linear function of the F 's:

$$\phi = \sum_{\substack{(\sigma, \tau) \\ \sigma \neq \tau}} \sum_s \sum_t a(st, \sigma\tau) F_{st, \sigma\tau} + \sum_{\sigma} \sum_{(s, t)} a(st, \sigma\sigma) F_{st, \sigma\sigma}. \quad (8)$$

Here the summation $\sum_{\sigma \neq \tau}^{(\sigma, \tau)}$ is to be taken over all pairs (σ, τ) with $\sigma \neq \tau$, and $\sum_{(s, t)}$ over all pairs (s, t) . We now introduce that part of the irreducible matrix for H which belongs to the term system satisfying the exclusion principle:

$$(st, \sigma\tau | H | s't', \sigma'\tau') = \int dV \tilde{F}_{st, \sigma\tau} H F_{s't', \sigma'\tau'}. \quad (9)$$

The integration $(\int dV \dots)$ is to be taken over the whole domain of all the coordinates, and is to include a summation over the two values of all the spin variables. With the help of this matrix we may write the wave equation for the a 's which is equivalent to (8):

$$\sum_{\substack{(\sigma, \tau) \\ \sigma \neq \tau}} \sum_s \sum_t (s't', \sigma'\tau' | H | st, \sigma\tau) a(st, \sigma\tau) + \sum_{\sigma} \sum_{(s, t)} (s't', \sigma'\tau' | H | st, \sigma\sigma) a(st, \sigma\sigma) = E a(s't', \sigma'\tau'). \quad (10)$$

By (5), (6) we have

$$F_{st, \sigma\tau} = \theta F_{ts, \tau\sigma}$$

and

$$a(st, \sigma\tau) = \theta a(ts, \tau\sigma). \quad (11)$$

Suppose now that we may set

$$(st, \sigma\tau | H | s't', \sigma'\tau') = 0 \text{ for } (\sigma, \tau) \neq (\sigma', \tau'). \quad (12)$$

We shall have later to see under what circumstances, and to what approximation, (12) is legitimate; but if we accept it, then we see that (10) reduces to a series of independent equations, one for each pair of values of (σ, τ)

$$\begin{aligned} \sigma = \tau: \sum_{(s, t)} (\sigma\sigma, s't' | H | \sigma\sigma, st) a(\sigma\sigma, st) &= E a(\sigma\sigma, s't') \\ \sigma \neq \tau: \sum_s \sum_t (\sigma\tau, s't' | H | \sigma\tau, st) a(\sigma\tau, st) &= E a(\sigma\tau, s't') \end{aligned}$$

For each such pair of values (σ, τ) we thus get a set of solutions $a(st)$; for σ

$= \tau$ these will be $\begin{cases} \text{symmetric} \\ \text{antisymmetric} \end{cases}$ in s and t when $m+n$ is $\begin{cases} \text{even;} \\ \text{odd;} \end{cases}$ for $\sigma \neq \tau$ both

symmetric and antisymmetric functions are possible. If we define the "state" of the cluster by the σ 's, then this result is fully equivalent to the rule (R) given at the beginning of this paper. We may see this directly in the following way: for the quantum numbers s, t , we may take directly the value of the components of the total momenta of the two clusters; if we introduce the center of gravity coordinates of the two clusters, X, Y by the conditions

$$\begin{aligned} sX - Xs &= \hbar/2\pi i; & sY - Ys &= 0; \\ tY - Yt &= \hbar/2\pi i; & tX - Xt &= 0; \end{aligned} \quad (13)$$

then we get the transformation functions:

$$(st/XY) = e^{-2\pi i/h(sX+tY)}. \quad (14)$$

The wave functions for the stationary states of the whole system are then given as functions of X, Y by

$$\sum_{s,t} a(st, \sigma\tau)(st/XY). \quad (15)$$

For $\sigma = \tau$, these must be $\begin{cases} \text{symmetric} \\ \text{antisymmetric} \end{cases}$ in X and Y when $n+m$ is $\begin{cases} \text{even;} \\ \text{odd;} \end{cases}$ for $\sigma \neq \tau$ they may have either symmetry.

We have now only to consider the conditions for the validity of (12). If the states σ, τ of the isolated clusters are degenerate, then the matrix elements of H corresponding to transitions between such degenerate states—states in which the isolated clusters have the same internal energy,—may be made to vanish by choosing suitably the u 's which give the stationary states of the clusters. The terms

$$(st, \sigma\tau | H | s't', \sigma'\tau')$$

in which the states (σ, τ) and (σ', τ') correspond to different energy levels of the clusters, will, since the original u 's were chosen to make the internal energy of the isolated clusters a diagonal matrix, represent the matrix components of the interaction and interchange energy of the particles in one cluster with those in the other; and if the particles in the cluster are very tightly bound together, these energies will be very small compared to the energy differences of two stationary states σ, σ' of the isolated cluster. The terms which were neglected in (12) therefore, will give in this case only very small correction terms to the a 's of the order of the ratio of the interaction energy of the two clusters to their proper energy; in general these correction terms will be neither symmetric nor antisymmetric in s and t , so that only for very stable clusters may we expect a rule like (R) to hold: for the two identical *atoms* of a symmetric molecule no such rule as (R) holds, since here the interaction energy of the atoms is of the same order of magnitude as their proper energy. Even in this case, of course, the exclusion principle for the electrons and protons reduces the number of possible stationary states; but here we cannot say just what states are excluded by investigating only the symmetry of the corresponding wave functions in the coordinates of the center of gravity of the clusters, but must study in detail the symmetry of the functions in the coordinates of all the elementary particles. The importance of the rule (R) arises from the circumstance, that in the dynamical treatment of most atomic and molecular problems we do not need to know anything about the structure of the nuclei, except that they are stable: we may treat them as point charges, with, in some cases, a spin s which gives a proper intrinsic degeneracy. And whenever this is so, we may use a rule like (R) to determine what states of the system survive the exclusion principle.

THE INTENSITY OF X-RAYS REFLECTED FROM PLATINUM, SILVER, AND GLASS

BY HIRAM W. EDWARDS

UNIVERSITY OF CALIFORNIA AT LOS ANGELES

(Received January 7, 1930)

ABSTRACT

The intensity of a monochromatic beam of x-rays reflected from platinum, silver, and glass mirrors was measured for angles of incidence varying from 0.75 to 1.25 times the critical angle. Radiation having a wave-length of 0.69\AA was obtained by reflection from calcite. Values of the intensity of the reflected beam calculated by Thibaud's modification of Fresnel's equation were found to be in good agreement with experimental values obtained from platinum. Experimental results obtained from silver and glass mirrors do not agree quantitatively with the theoretical values. No explanation for the lack of concordance is offered.

LINNIK and Laschkarew¹ have observed that the intensity of x-rays ($\lambda = 1.537\text{\AA}$) totally reflected from an iron mirror does not fall off abruptly at the critical angle when increasing the glancing angle of incidence. Forster² attributed this lack of sharpness to an absorption effect in the reflecting medium. He attempted to derive an expression from the Fresnel reflection equations to express the intensity of the reflected x-ray beam in terms of the critical angles. Although Forster made an error in the derivation of his equation, the curves which he gave to show the effect of the absorption upon the intensity-glancing angle of incidence relation are in agreement with the curves, published later by Schon³ and also with those given by Thibaud.⁴

Dershem⁵ gave the relative intensities of the K_{α} line of carbon ($\lambda = 44.6\text{\AA}$) reflected from glass for angles of incidence varying from 1° to 8° . Thibaud⁴ shows that Dershem's results are qualitatively in agreement with the values calculated by his (Thibaud's) extension of the Fresnel reflection equation.

The writer is not aware of any attempt having been made to check, quantitatively, the Fresnel equation of the intensity of reflected radiation in the x-ray region. In order to make a quantitative test three materials, platinum, silver, and glass, were selected. Platinum was chosen because of its relatively high absorption coefficient, silver and glass because of their low absorption coefficients. While the absorption coefficients of silver and glass are both low, the two materials are unlike in having relatively widely separated critical angles and are otherwise optically different.

APPARATUS

The apparatus was arranged as shown in Fig. 1. The x-radiation was produced by a water cooled tungsten tube operated at 50,000 volts. The x-ray beam was defined by two slits, S_1 and S_2 , each about 0.4 mm wide and about 80 cm apart. The x-ray beam was directed against a calcite crystal oriented so that a monochromatic beam ($\lambda = 0.69\text{\AA}$) was reflected. The tube voltage was sufficiently high to excite radiation up to a wave-length of 0.25\AA and consequently a second monochromatic beam of $\lambda = 0.345\text{\AA}$ would be reflected from the calcite crystal along with the first. It is thought that the presence of the radiation of shorter wave-length did not appreciably alter the intensity measurements under consideration. If one assumes that the critical angles of the two radiations are proportional to the square of the wave-lengths, the critical angle of the shorter wave would be 0.25 of that of the longer wave, hence in the region investigated the intensity of the shorter wave must be very small as may be readily shown.

Fig. 1. Arrangement of apparatus.

The mirror under investigation was mounted on a spectrometer table and carefully placed parallel to the x-ray beam reflected from the calcite. The distance from the crystal to the mirror was approximately 27 cm. The axis of rotation of the spectrometer table was very nearly tangent to the surface of the mirror and approximately in the center of the incident beam. Both platinum and silver mirror were sputtered on pieces of glass (2×4.5 cm) which were flat within 0.5 of a wave-length of yellow light. The platinum mirror was opaque to visible light and thick enough to have a critical angle equal to that calculated by the Lorentz dispersion formula. The silver mirror would transmit about 5 percent of the visible light incident normally and not thick enough to give its maximum critical angle for this wave-length used. Three glass mirrors were used, all flat to within half a wave-length of yellow light.

It was found expedient to use a third slit S_3 in the optical system. This was placed very close to the mirror and served to limit the radiation to a very narrow beam the width of which was less than the length of the mirror multiplied by the smallest glancing angle of incidence used. By this arrangement all of the beam passing through the slit would strike the mirror surface and hence maintain an incident beam of constant intensity. At the same time the arrangement eliminated annoying scattered radiation which would have been present had any portion of the beam been permitted to pass by the mirror unreflected. Radiation scattered from the reflected beam caused no trouble.

The intensity of the reflected beam was measured by absorption in an ionization chamber and the rate of accumulation of charge on the string of a string electrometer. The sensitivity of the instrument was not determined but remained constant during any single series of observations. The front end of the ionization chamber was 65 cm from the center of the mirror.

The voltage across the x-ray tube was maintained constant within 1 percent. Filament current in the tube was practically constant.

The angle of incidence of the radiation upon the reflecting mirror was determined for a single position of the mirror by evaluating the particular reading of the tangent screw on the spectrometer table from measurements made photographically. For this purpose the slit S_3 was opened sufficiently to permit some of the radiations to pass by the mirror unreflected. The film was placed 63 cm from the mirror. Because of this comparatively short distance the angle could not be determined with an accuracy greater than about 3 percent.

RESULTS

In the case of reflection of x-rays from metals or from glass it is necessary, because of the absorbing nature of the reflecting medium, to replace the ordinary index of refraction n , ($n = 1 - \delta$), by the complex quantity n' where,

$$n' = (1 - \delta) - iK$$

and

$$K = \mu\lambda/4\pi$$

in which μ is the absorption coefficient and λ the wave-length.

Starting with the above expression and the Fresnel equation for the ratio R/I of the amplitude of the reflected wave, parallel to the plane of incidence, to that of the incident wave,

$$\frac{R}{I} = \frac{n \cos i - \cos i'}{n \cos i + \cos i'}$$

where i and i' are the angles of incidence and reflection measured from the normal to the surface, Thibaud⁴ derived the following expression for the ratio (A) of the intensity of the reflected to that of the incident beam:

$$A = \frac{(1+m)^2 + 2(m^2 + a^2)^{1/2} + 2(1+m)(2(m^2 + a^2)^{1/2})^{1/2} \cos \phi/2}{(1+m)^2 + 2(m^2 + a^2)^{1/2} - 2(1+m)(2(m^2 + a^2)^{1/2})^{1/2} \cos \phi/2} \quad (1)$$

in which m is defined by the equation $\theta = (1+m)\theta_m$ where θ is the glancing angle of incidence, and θ_m is the critical angle. The other quantities are defined by the relations:

$$a = K/2\delta \quad \theta_m^2 = 2\delta \quad \tan \phi = -\frac{a(1-\delta)}{m - a^2\delta}$$

The following tables give the values of the constants used in calculating the intensities of the reflected rays.

TABLE I.

Mirror	μ	a	θ_m (radians)	$\delta \times 10^6$	$\lambda \times 10^8$
Platinum	2295.	0.078	0.00400	8.00	0.69
Silver	258.	.015	.00305	4.65	.69
Glass	17.4	.004	.00153	1.18	.69

The experimental and calculated values of the intensity of the x-rays reflected from the three materials are shown graphically in Fig. 2. Experimental observations are indicated by small circles and the calculated values are shown by small crosses.

Fig. 2. Intensity of reflected x-rays.

The glancing angle of incidence is expressed in radians. Relative intensities are given in terms of the intensity of the incident beam taken at unity.

Because of the deviation of the calculated values from those obtained experimentally in the case of glass and silver, separate curves have been drawn to show the variation of intensity as determined experimentally and by computation.

Three different samples were used in obtaining reflection curves from glass and all yielded curves which were similar in form to that given in Fig. 2. The index of refraction was not the same in the three samples. The variation in δ was not large ($\delta = 1.18$ to 1.50×10^{-6}) and would have no appreciable effect upon the character of the intensity curve anyway. It was difficult to obtain a reliable value for the absorption coefficient because of the necessarily great thickness of the glass. Values of the absorption coefficient obtained from thinner pieces of glass which appeared to have the same composition did not differ from 17.4 by more than 10 percent.

The character of the experimental curve of reflected intensities from glass suggests that the coefficient of absorption should be considerably larger than

17.4. Although theoretical curves were drawn for which larger values of a were assigned none could be found from Eq. (1) which duplicated the form of the experimental curve, although the "fit" was much closer than that indicated in the figure. It is possible, however, that the absorption coefficient of the surface layer, that in which the phenomenon of reflection takes place, is greater than the average value of the glass as a whole. Undoubtedly deviations of the surface from being optically flat would alter the form of the curve. The most nearly flat specimen used, however, gave no appreciably different result from the poorest mirror.

The results from the silver mirror show a better agreement between theory and experiment than those obtained from glass.

Here also the experimental results indicate a larger absorption coefficient than that measured. The silver film was not sufficiently thick to give a critical angle equal to that which would have been obtained with a thicker film.⁶ This factor would seem to give a smaller coefficient of absorption rather than a larger one.

The results shown for platinum indicate good agreement between experimental and theoretical results. Just why there should be an agreement in this case and not in the other two is not clear. The writer plans to continue the investigation and hopes to be able to find an explanation for this behavior.

INTENSITY MEASUREMENTS IN THE
SPECTRUM OF MANGANESE*

BY RAYMOND S. SEWARD

PHYSICAL LABORATORY OF STANFORD UNIVERSITY

ABSTRACT

Relative intensity measurements have been made for the lines of twenty-five multiplets of manganese, containing about one hundred and fifty lines in all. All but three of these were of Mn I. None of the Mn II multiplets measured were found to contain lines of abnormal intensity. On the other hand, at least eight multiplets of Mn I contain lines which are clearly anomalous. These eight multiplets contain a large number of the strongest lines of the spectrum. All involve terms derived from the term a^4D of Mn II and are of the inverted type with wide separations between the sub-terms. There seems to be regularity in the departure from normal intensities which can best be described by graphs in which the calculated intensities are plotted against the measured intensities on double logarithmic paper. In these plots, the satellites often assume a regular pattern above or below the main diagonal lines.

The total relative intensities of seventeen of these multiplets have also been measured. After reasonable excitation corrections have been applied, the agreement of their intensities with the theoretical values is as close as is to be expected. The measurements on the quartet triad of this group are the most reliable.

INTRODUCTION

THE elements of the iron group present complex spectra which are at present in the process of analysis.¹ A number of intensity studies have been made upon elements of this group, chiefly by Frerichs² at Bonn, by Harrison and co-workers³ at Stanford, and by Ornstein and Bouma⁴ at Utrecht.

The element manganese stands at the center of the iron group. Its maximum multiplicity is eight, which is the largest attained in this group. It is expected that departures from the Russell-Saunders or LS coupling which predominates in elements on the left side of the periodic table will gradually increase as the atomic number of the element in the group becomes greater, and at the same time departures from the normal intensity formulas will increase. Hesthal has found a greater fraction of anomalous lines in the multiplets of chromium ($Z=24$) than has Harrison in titanium (22), while the work of Ornstein and Bouma indicates still greater departures for cobalt (27) and nickel (28). The element manganese ($Z=25$) thus takes an interesting intermediate position in this connection.

Considerable work has been done on the analysis of the spectrum of Mn I and a less amount on that of Mn II. The analysis of Mn I given by McLennan and McLay⁵ and unpublished data furnished by Dunham of Mt. Wilson Observatory have been used in the present study. Material for Mn II has been taken from recent articles by Russell⁶ and by Duffendack and Black.⁷ The assignments of terms to definite electron configurations as given by Russell⁸ and by Hund⁹ is used.

The aim of the present investigation has been to secure accurate intensity determinations of as many lines of the spectrum of manganese as is practicable in order that the information may be available for reference in connection with atomic problems.

Fig. 1. Energy level diagram of the spectral terms of Mn I and Mn II.

Some features of the manganese spectra are summarized in Fig. 1, which is an energy level diagram of the spectral terms. They are classified according to multiplicity, there being quartet, sextet, and octet terms of Mn I and quintet and septet terms of Mn II. The separations of sub-terms are not shown. Symbols for electron configurations where known are written in front of the term symbols. Lines are drawn between terms to indicate multiplets. These are identified by numbers written in circles drawn on the lines, the larger numbers being assigned to the shorter wave-lengths. Intersystem transitions are represented by dotted lines.

Multiplets 27, 28, and 31 constitute a quartet triad, while multiplets 32, 36, and 40 make up a sextet triad. All six multiplets are due to *sp* electron

jumps and constitute two related super multiplets. Russell has shown that similar *sp* jumps are responsible for important triads in other members of the iron group.¹⁰ All of the eight terms involved in these supermultiplets are inverted and will be referred to as the inverted system of terms, while most of the other terms of Mn I are normal. It is in members of this supermultiplet that the most interesting intensity results were found in the present study.

EXPERIMENTAL PROCEDURE

The method of photographic photometry of spectral lines used in the present study has been described thoroughly in an article by G. R. Harrison.¹¹ The general method of procedure will not be given, but only special details noted.

The source used was an arc whose cathode consisted of a purified carbon rod into a cavity of which had been introduced finely pulverized manganese. For the anode a silver rod was used, as this gave a more steady arc than a second carbon rod, there being no serious overlapping of the silver lines with those of manganese.

Some spectrograms on each plate were exposed with an arc run at atmospheric pressure, while for others the pressure was reduced to from 10 to 20 cm of mercury. Currents of from 0.5 to 3.0 amperes were employed in order to give variable conditions of self-reversal and excitation and to bring out the strong and weak lines at the best intensities for measurement.

The source used for calibration in the ultraviolet was a mercury arc in quartz operated by a 110 volt storage battery, while in the visible a gas-filled 6 volt, 20 ampere tungsten lamp with a ribbon filament was used. As a standardizing source for much of the ultraviolet as well as all of the visible, a "black body" electric furnace with quartz window operated at about 2400°C was employed (see page 290 of reference 9), the intensities for various wavelengths being determined by Wien's Law.

For varying the intensity during calibration, neutral wire screens were used whose transmitting power had been previously determined by thermopile readings.

The spectrographic arrangement, as in previous studies, was of a modified Paschen type. The lens for focusing the source on the slit was a quartz fluorite achromat of 2.5 cm aperture and a focal length remarkably constant at about 25 cm for all wave-lengths encountered. The grating was a concave reflector of about 35 feet radius, containing about 85,000 lines, 5900 per cm, the dispersion in the first order being about 1.67 Å. per mm. This grating is remarkably free from ghosts, has intense first and second order spectra, and is in general excellent for intensity work.

The plates used, except for the region $\lambda\lambda$ 5300–6000, were the Eastman 36 brand. To secure measurable spectrograms for the green and yellow regions with the same exposure times as were used for the more actinic regions, panchromatic plates sensitized with ammonia were employed. Such plates, while

¹⁰ See reference 1.

¹¹ G. R. Harrison, J.O.S.A. 19, 267 (1929).

comparatively sensitive, are apt to become fogged and mottled. Their contrast was found much greater than desired, and the measurements made by their use are not so reliable as the others.

Self-reversal seems to have been reduced to a negligible amount in most cases, as indicated by a 45° slope to the "self-reversal curve" for a multiplet.¹² Exceptions in which self-reversal corrections were added are noted in the discussion of results.

Six sets of plates were secured, two of which covered the entire available spectrum ($\lambda\lambda$ 2500–6000). From 12 to 18 measurable spectra were obtained on

Fig. 2. Calculated and measured intensities for Multiplet 21 ($a^6D - y^6P$).

each plate. The results (recorded in the Table of Results) were obtained by averaging what were considered the most reliable determinations. It was impossible to measure accurately the weaker lines in certain exposures and in others the stronger lines were too black for accurate determination. But from 20 to 60 determinations were made for all but a few inaccessible lines.

RESULTS AND DISCUSSION

Intensities within multiplets. The intensities of the lines making up a given multiplet may be determined with much greater accuracy than is possible when lines of different multiplets are compared, because excitation conditions

¹² In a self-reversal curve, the measured intensities are plotted against the calculated intensities on double logarithmic paper. For an explanation of such curves see p. 401 of the first reference cited in reference 3.

are similar for the various lines, and the plate sensitivity generally does not differ greatly for the lines being compared.

The results of the relative intensity measurements for the individual multiplets are found in column 5 of the Table of Results; the corresponding calculated intensities appear in column 4; while the results obtained by Freichs for five multiplets which he measured appear in column 6. In all cases the intensity is expressed in percent of the strongest line. For convenience in testing the Sum Rule, the sums of the line intensities from a given upper state and of those having a given lower state have also been determined. These appear in the same column as the line intensities. Column 3 gives the term or transition distinguishing the sum or line.

Fig. 3. Calculated and measured intensities for Multiplet 27 ($a^4D - z^4F$).

The measurements for the most interesting individual multiplets will now be discussed, following the order of decreasing wave-length.

Multiplet 21 ($a^6D - \gamma^6P$; $\lambda\lambda$ 5540-5340). Besides lying in a region to which the ordinary photographic emulsion is insensitive, this multiplet covers a wide wave-length range in which the sensitivity of the panchromatic plate has a number of maxima and minima. It was also necessary to use exposures which were not favorable to complete removal of self-reversal. In obtaining the tabular values, self-reversal corrections were applied in some cases. The results indicate that lines *b* and *f* are abnormally weak. The multiplet is of interest in that its upper state belongs to the normal system of terms, while its lower state belongs to the inverted system. The calculated and measured intensities are shown graphically in Fig. 2.

Multiplet 23 (a^6S-z^8P ; $\lambda\lambda$ 5432-5395). The two lines in this intersystem multiplet are fairly strong. Although there is no theoretical relation known between the intensities of such lines, the present measurements illustrate that the lines of largest J values are the strongest, and that the intensities follow qualitatively rules similar to those for lines in normal multiplets.

Multiplet 25 ($a^4D_3-z^6F_4$, $a^4D_4-z^6F_5$; λ 5000) and *Multiplet 45* (a^6S-z^4P ; λ 3220) gave similar results.

Multiplet 27 (a^4D-z^4F ; $\lambda\lambda$ 4766-4671). A large number of very consistent determinations were made on multiplet 27 in which self-reversal graphs showed a uniform slope of 45° , indicating the vanishing of this effect. The averaged values taken from the Table of Results are plotted in Fig. 3. A

Fig. 4. Calculated and measured intensities for Multiplet 28 (a^4D-z^4D).

large number of similar graphs for the individual exposures showed an almost identical structure. While the four brightest lines are seen to have intensities very close to their calculated values, this is not the case for the first order satellites, line c being much too bright, line d less so, while line e is too weak. The wide divergence of lines c and e which are of nearly equal calculated intensity, is most striking.

Multiplet 28 (a^4D-z^4D ; $\lambda\lambda$ 4502-4415). This multiplet is a second member of the triad to which multiplet 27 belongs. It is also one of the five manganese multiplets measured by Frerichs. As in the previous case, a large number of consistent determinations was made. The plot of the calculated and measured intensities on double logarithmic paper is shown in Fig. 4.

Both groups of satellites show very striking departures from the normal, being too bright by varying amounts. There are eight lines of fairly nearly equal calculated intensity in this multiplet, so that departures from the normal intensity could not very well be explained by self-reversal, even if some were present. An excitation correction would not tend to lessen the departures of the lines, since the lines which are too bright do not have a common upper state.

Multiplet 29 ($z^6P - e^6D$; $\lambda\lambda$ 4462–4455). This is the most satisfactory example of a multiplet belonging to the normal system of Mn I as distinguished from the inverted system. All the lines except *t* and *u* were resolved. The

Fig. 5. Calculated and measured intensities for Multiplet 31 ($a^4D - y^4P$).

determinations showed excellent consistency and agreement with the calculated values. Frerichs obtained similar results.

Multiplet 31 ($a^4D - y^4P$; $\lambda\lambda$ 4312–4235). Multiplet 31, plotted in Fig. 5, is the third member of the quartet triad. As in the case of multiplet 28, the first order satellites are too bright; also lines *c* and *e* of nearly equal calculated intensities differ widely in measured intensities. The two second order satellites appear somewhat too bright and of more nearly equal intensities than their calculated values, although these lines were too weak for best determination. Frerichs obtained similar results in this case also.

Multiplet 32 ($a^6D - z^6D^0$; $\lambda\lambda$ 4084–4018). This is the first member of the sextet triad belonging to the *sp* inverted supermultiplet. Fig. 6 shows some

of the satellites too weak as compared with the main diagonal lines. This is in contrast to the corresponding DD^0 quartet multiplet 28, in which the corresponding lines were too intense. Lines j and k were not resolved completely. Their sum was measured, and then this value was distributed to the two lines in a ratio equal to the apparent intensities given when they were partly resolved. The position of these two individual lines is not known exactly, but their sum is not so great as the calculated value of the sum. This is another case in which departure from calculated values could not be explained by self-reversal, since a number of lines of nearly equal calculated intensities give radically different measured values.

Fig. 6. Calculated and measured intensities for Multiplet 32 ($a^6D - z^6D^0$).

Multiplet 36 ($a^6D - z^6F$; $\lambda\lambda$ 3844–3776). When conditions were best for removal of self-reversal, cyanogen bands were apt to develop in the position occupied by multiplet 36. In order to resolve two pairs of interesting lines, it was also necessary to work in the second order. For these reasons, exposures in which some self-reversal remained were used in calculating the intensities, a small correction being applied to correct for the effect. The plot of the intensities as shown in Fig. 7 would be very similar if this correction had not been applied, except that the slope of the curve would be less. The departures from normal intensities are in this case the clearest and most regular of any so far encountered. The first order satellites are all clearly too weak as compared with the main diagonal lines. Since the lines are too weak, there

is no possibility of explaining their deviations by laps with unidentified lines. The two second order satellites *f* and *i* seem to have the order of their intensities inverted, though the data so far as this is concerned are not conclusive.

Multiplet 40 (a^6D-x^6P ; $\lambda\lambda$ 3629-3577). This multiplet completes the *sp* sextet triad and is the last member of one of the supermultiplets arising from the a^5D term of Mn II. Measurements were possible in which self-reversal was apparently completely eliminated, and a large number of determinations gave nearly identical results. Of the first order satellites, line *d* is much too intense, line *e* slightly so, and line *f* is apparently about normal. The second order satellites *g*, *h*, *i* seem to be abnormally bright; these latter form a line in Fig. 8 which has much less slope than the main diagonal line.

Fig. 7. Calculated and measured intensities for Multiplet 36 (a^6D-x^6F).

Multiplet 42 (a^5D-z^5P ; $\lambda\lambda$ 3497-3442). This was the only complex multiplet of Mn II available for measurement. All measurements gave excellent agreement with the calculated values.

Multiplet 44 ($a^6D-y^6F^0$; $\lambda\lambda$ 3260-3209). Because of its comparative weakness, this multiplet, like its prototype number 36, was measured from exposures which had some self-reversal. The plot of its intensities shown in Fig. 9 is almost a reproduction of that for number 36, except that line *f* is a little depressed. Although the departure from normal intensities by the first order satellites is of the same type as in number 36 the amount of this departure is somewhat less. The second order satellites seemed to be stronger than their calculated values.

Fig. 8. Calculated and measured intensities for Multiplet 40 ($a^6D - x^6P_4$).

Fig. 9. Calculated and measured intensities for Multiplet 44 ($a^6D - y^6F^0$).

Multiplet 46 (z^8P-f^8S ; $\lambda\lambda$ 3178-3148). Multiplet 46 gave very close agreement with the calculated values. It is the second member of a sharp series following a Rydberg formula, multiplet 26 being the first member.

Multiplet 47 (a^6D-w^6P ; $\lambda\lambda$ 3082-3044). This has the same final state as has number 40. While the upper state has not been assigned to any electron configuration, it has normal intensities or nearly so (Fig. 10), and does not show anomalies analogous to those in number 40.

Fig. 10. Calculated and measured intensities for Multiplet 47 (a^6D-w^6P).

Multiplet 49 (z^8P-f^8D ; $\lambda\lambda$ 2940-2914). Measurements indicated the normal intensity ratio between lines b and a . Line c was a little strong, probably due to a lap.

In summarizing the line intensities within multiplets, it may be stated that most of the anomalous lines, if not all of them, were in multiplets whose terms, one or both, were derived from the a^5D term of Mn II. The departure from normal intensities shown in graphs of Figs. 2 to 10 are of a regular nature in some cases at least. It is always possible to draw a straight line which passes through or near each point representing a main diagonal spectral line. Such lines can also be drawn through some of the satellite points, but the latter line is usually broken in the middle. One may proceed along this broken line in the shape of a V with the J values (subscripts) increasing or decreasing in regular sequence. Lines l_{11} , j_{22} , h_{33} , e_{44} , and b_{55} of multiplet 36 illustrate this regularity. It seems probable that this regular departure is caused by some perturbation factor which is usually negligible but which assumes significant values in the present case.

Relative intensities of the multiplets. Intensities for different multiplets, even when related, depend greatly on excitation conditions; so that measurements obtained under one set of conditions may not be compared directly with those obtained under another set. The figures for relative line and multiplet intensities given in column 7 of the Table of Results are based mainly on measurements made under fairly uniform conditions; namely, a current of 1.0 ampere and a pressure of 18 cm of mercury. Figures for each exposure were worked out separately and reduced to a common standard before finding the average figure which appears in column 7.

To obtain the intensities for infinite excitation as given in column 9, it was necessary to find the equivalent temperature. For this purpose the theoretical intensities of the members of the *sp* supermultiplet were employed.

The numbers 14, 10, 6, 15, 21, 9 are the intensities of multiplets 27, 28, 31, 32, 36, and 40 respectively as calculated by formula. The calculated intensities for the lines in each multiplet were first adjusted so that their sums were proportional to these numbers. The proper ν^4 correction was applied for each line, and the results placed in column 8 of the Table of Results.

If the multiplets may be brought to their calculated intensities by excitation correction, the equation $\log_{10} R = 0.625 \Delta\sigma / T$ must have a common temperature solution. R is the factor required to bring the relative intensity of a line, or group of lines of common upper state, to the value for infinite excitation, and $\Delta\sigma$ is the difference in term values of the upper state in question and that of a line used as a standard.

In seeking the common solution of the above equation, the following procedure may be followed. The ratio I_m/I_c (measured intensity)/(calculated intensity) for each line group of common upper state is determined. The factor R_m by which each of these I_m/I_c values must be multiplied to make it equal to the value for the standard is next found. Finally the logarithms of these R_m values are plotted as ordinates and the corresponding $\Delta\sigma$ values as abscissas. In case these points all lie on a straight line, the intensities are normal, and the equivalent temperature may be found from the slope of this line; i.e., $T = 0.625 \Delta\sigma / \log_{10} R$. In practice, a straight line which passes through as many such points as possible is drawn, the equivalent temperature and the corresponding excitation factors for different states being taken as determined by this line, the corrected measured intensities thus coming out greater or less than their calculated values according as their plotted points lie below or above the line.

In the present case, the first four multiplets had intensities which approximated their theoretical values quite closely, the equivalent temperature being between 5000 and 6000A. On the other hand, multiplets 36 and 40 had intensities which were much too small. These multiplets occur at wave-lengths about 3800A and 3600A respectively. It was thought that the apparent anomaly might be due to small J/I standardization values resulting from the action of scattered light. To test this point the values obtained when a filter was used which transmitted only ultraviolet light were tried for the members of the sextet triad, the quartet members being in a region not transmitted by

this filter. In this case the three multiplets showed fair alignment, although the calculated temperature tended to be a little less than in corresponding exposures for the quartet triad.

The measured intensities corrected for infinite excitation as recorded in column 9 of the Table of Results were obtained by first determining the relative intensities of the four multiplets of longest wave-length; then the relative intensities of the three short wave multiplets were determined from two exposures using the filter as just described. The two determinations were then tied together by multiplet 32 common to both sets. The intensities of other short wave multiplets in column 8 were also raised to correspond to these new determinations, the procedure being equivalent to a new standardization. From the preceding statements, it may be inferred that the determinations for the long wave-lengths are most reliable, and that it will be desirable to make further measurements in the ultraviolet in which more reliable standardizations for this region are available. This does not, however, affect the validity of line measurements in multiplets.

No total multiplet intensities for wave-lengths less than 3400A have been given, as intensity values for standardizing are not available at this time.

The approximate multiplet intensities as recorded in column 7 have also been written on Fig. 1, which may be used as a convenient means of studying the multiplet intensities as a whole. The values for the high upper states will be increased, of course, for higher equivalent temperatures or decreased for lower equivalent temperatures than that of the source here employed. It may be noticed that the sextet and quartet triads furnish a large part of the total radiation. Multiplet 41 in the octet system is very intense. Multiplet 34, furnishing the *raies ultimes*, while of very respectable intensity, is nevertheless surpassed by some of the others in total intensity. The comparatively small intensity of multiplet 21 as compared with that of number 40 with the same lower state and higher upper state is of interest. It may be recalled that number 21 has its lower state in the inverted system of terms and upper state in the normal system. Its comparative weakness may be connected with this fact. Multiplet 20, on the other hand, is much more intense than number 33 which has the same lower state. In this case, both the upper states, as well as the lower state, are of the normal type.

The present work has been made possible by the use of the equipment developed by Dr. George R. Harrison in the Stanford Spectroscopy Laboratory. To him and to the other workers in the same laboratory, who have furnished invaluable help and shown a fine spirit of cooperation, the writer wishes to acknowledge his sincere appreciation.

TABLE OF RESULTS. *Summary of intensity measurements.*

Explanation

- Column 1—Number of multiplet; distinguishing letter for each line.
- Column 2—Approximate wave-length of the line.
- Column 3—The transition for the spectral line or the term common to a line sum. Landé quantum numbers are used for the Mn I multiplets or for those of even multiplicity. Sommerfeld quantum numbers are used for Mn II multiplets. The first kind of quantum number is changed into the second by the subtraction of a half unit.

Column 4—Calculated intensity in percent of the strongest line.

Column 5—Measured intensity in percent of the strongest line.

Column 6—Intensity in percent of the strongest line as measured by Frerichs.

Column 7—Measured intensities reduced to a common standard (equivalent temperature about 5500 A, current 1.0 ampere, pressure 18 cm of Hg).

Column 8—Calculated intensities for six related multiplets reduced to a common standard.

Column 9—Measured intensities corrected for infinite excitation.

RAMAN SPECTRA OF SOME ORGANIC HALIDES

BY CLAUD EDWIN CLEETON WITH R. T. DUFFORD
THE UNIVERSITY OF MISSOURI, COLUMBIA, MISSOURI

(Received December 29, 1930)

ABSTRACT

Raman spectra obtained by helium excitation from nineteen organic compounds, CHCl_3 , CH_3Br , CH_3MgBr , CH_3I , CH_3MgI , $\text{C}_2\text{H}_5\text{Cl}$, $\text{C}_2\text{H}_5\text{Br}$, $\text{C}_2\text{H}_5\text{I}$, $\text{ClCH}_2\text{CH}_2\text{Cl}$, $\text{BrCH}_2\text{CH}_2\text{Br}$, CH_3CHCl_2 , CH_3CHBr_2 , $\text{C}_2\text{H}_2\text{Cl}_4$, $\text{C}_2\text{H}_2\text{Br}_4$, C_6H_6 , $\text{C}_6\text{H}_5\text{N}$, $\text{C}_6\text{H}_5\text{CH}_2\text{Cl}$, $\text{C}_6\text{H}_5\text{Cl}$, $\text{C}_6\text{H}_5\text{Br}$, five of which have not been reported on before, are described and discussed. It is shown that in many cases the observed frequencies can be expressed in terms of four assumed fundamentals (five in the cyclic compounds), two of which are not observed, and which may prove to be illusory. The bearing of such theory as is available is discussed.

THE Raman* spectra of a number of simple organic compounds containing carbon, hydrogen, and halogen (chlorine, bromine, or iodine) atoms are described and discussed in this paper. The work was begun as part of a systematic study of a number of physical properties of the class of compounds known as Grignard reagents, which are formed in anhydrous ether solution when the halogen compounds just mentioned react with magnesium to form compounds of the type R-Mg-X . Raman spectra from two such compounds are described below. At the time the work was started, only a few of the organic halides had been reported on; but since then, various workers have reported the Raman spectra of a great many of them, as will be noted below, and some steps have been made toward theoretical interpretation of the spectra.

EXPERIMENTAL ARRANGEMENTS

In almost every case, the results reported by others have been obtained using light from a mercury arc, usually unfiltered, following an early scheme suggested by Wood.¹ The advantage of intense exciting light, which this method possesses, is compensated to a large extent by the serious overlapping of the Raman patterns from the numerous exciting lines, which leads to difficulty and error in identifying the exciting line responsible for certain displaced lines. Matters can be improved somewhat by using appropriate filters, as Wood has shown. The results in the present paper are free from such uncertainty, since they were obtained by helium excitation, using a helium spiral surrounding the "resonance" tube, and a tube of Corning red ultra

* No attempt is made to give here a complete bibliography of all the hundreds of papers that have appeared on the subject since the discovery of the effect was announced by C. V. Raman, *Indian Jour. of Physics* 2, 387 (1928). Such bibliographies are available elsewhere; e.g., S. Bhagavantam, *Ind. Jour. Phys.* 5, 237 (1930), A. S. Ganesan, *Ind. Jour. Phys.* 4, 281 (1929), and the Symposium on Molecular Spectra, *Trans. Faraday Soc.* 25, 611-949 (1929).

¹ R. W. Wood, *Phil. Mag.* (7) 6, 729 (1928).

glass as a filter. This method is also due to Wood.² While the method has not the advantage of the high intensity obtainable from the newer helium arc,^{3,4} it does have, in common with this apparatus, the great advantage that there is only one exciting line, $\lambda 3889$, and almost no helium lines coming through the filter to confuse the Raman pattern. Further, this exciting line has a shorter wave-length than many of the mercury lines used. As shown by Ornstein and Rekveld,⁵ the intensity of the Raman lines increases at least approximately with the fourth power of the exciting frequency. Besides the consequent gain in strength of the Raman lines, there is the added advantage that the displaced lines occur at wave-lengths near the sensitivity maximum of the photographic plates.

The first exposures were made using a "resonance" tube about an inch in diameter and twelve inches long. It was soon found that better results were obtained with a smaller tube, about 1 cm in diameter and 10 cm long, with a smaller filter and helium spiral; less power was required, too, and smaller quantities of the substances to be investigated. The spectra were photographed with a specially reconstructed single prism glass spectrograph of considerable speed, which has been described elsewhere.⁶ For measurement, images of the spectra were projected, using a magnification of about forty diameters, on a screen on which a scale of wave-numbers had been worked out, using a large number of reference lines. With this scale, wave-number differences could be read off with an accuracy of about 5 cm^{-1} in the case of the sharpest lines. Many of the Raman lines are too broad, however, to permit reading as accurately as this.

DISCUSSION OF RESULTS

In discussing Raman spectra, the quantity of primary interest is the amount by which a given line differs in frequency (or more usually, in wave-number) from the exciting line. Since the arrangements used permitted this quantity to be read directly, it is recorded in the tables that follow. In the tables, compounds of similar structures are grouped, for convenience in comparing their spectra. Intensities are indicated by numbers in parentheses following the observed wave-number shifts.

While measurements could be checked to about 5 cm^{-1} , it by no means follows that the results obtained by different observers will check as closely as this. In some cases the agreement is better, but in a considerable number, the disagreement is several times as large. There is very great need now for more accurate results than have been given in most of the investigations so far published. A single table is included to show the extent to which agreement is found in typical cases. In many cases the agreement is worse, owing to difficulty in identifying lines. Beyond this, it has seemed unnecessary to

republish all the results of other investigators; but references are given to all such work as is known to the writers.

In studying the Raman spectra of organic halides, one of the writers (C. E.C.), who made the wave-number measurements, discovered the existence of certain apparent regularities, the more important of which are indicated in the tables that follow. It would appear from these that it is possible to express the frequencies found in the Raman spectra of each of the aliphatic halides as combinations or overtones of four fundamental frequencies, of which usually two must be assumed to exist without being observed in the spectra themselves. In the tables, beginning with Table II, there is given for each substance the observed frequency differences in one column, and the

computed differences on the assumed scheme in the next column; the last column of each table indicates the nature of the assumed combination or overtone. The fundamentals assumed behave so similarly in different compounds, that it is possible to number corresponding fundamental frequencies in different compounds with the same symbol; the symbols used are V_1 , V_2 , V_3 , V_4 . The way in which these fundamentals vary from group to group of compounds is regular and interesting. A fifth fundamental appears in the aromatic compounds.

The Raman spectrum of diethyl ether was studied, since Grignard compounds are prepared in ether solution; and for comparison with it, the Raman spectrum of ethyl alcohol was obtained. The wave-number shifts observed for ether are: 443 (1), 844 (2), 1159 (2), 1286 (2), 1466 (10), 2683 (2), 2793 (2), 2806 (5), 2873 (40), 2928 (30), 2983 (30) cm^{-1} . Nearly all these lines, except that at 2806, are broad. Other workers^{7,8V,8VII,13} list a few faint lines which we did not observe; but our list contains three lines not previously observed. Part of the difference may be due to wrong assignment of lines in the mercury arc spectra, and part may be due to the fact that our plates, while often underexposed, show the most-shifted Raman lines with greater relative intensity than reported by other workers. For alcohol, the observed shifts are: 1059 (3), 1108 (3), 1294 (3), 1461 (5), 2683 (1), 2880 (20), 2923 (20), 2976 (20). This list includes one new line, and fails to show one or two lines which are probably real, reported by other workers^{7,8V,8VII,13,16}. The only regularity of structure to point out, is that in each case the last three lines can be represented by the formula $V_4 \pm V_1$, with $V_4 = 2928$, and $V_1 = 55 \text{ cm}^{-1}$ for ether and 47 cm^{-1} for alcohol. This regularity, while similar to that found in many other compounds, may prove to be illusory, as will be pointed out below.

In Table II are given the results from methyl bromide and methyl iodide, and from the Grignard reagents made from them. The plates were all underexposed, except for methyl iodide. Dadiou and Kohlrausch^{8VII} have recorded

¹⁶ Venkateswaran and Karl, *Zeits. f. phys. Chem.* **B1**, 466 (1928).

data on the first two of these compounds, including lines at 2956 and 3050 cm^{-1} for methyl bromide. No other work on the latter two compounds appears to have been published. The interesting result is the disappearance of the frequency marked V_3 in the table, and the appearance of a higher frequency, when the C-Br or C-I linkage changes to C-Mg-Br or C-Mg-I. This seems to indicate that the V_3 frequency is associated with the carbon-halogen bond. The group of frequencies around 3000 cm^{-1} is generally assumed to be associated with the C—H bond, since such lines always occur in both Raman and infrared spectra of compounds which possess this bond. In assigning the structure to these lines in the methyl iodide spectrum, a fundamental frequency at 88 cm^{-1} was assumed.

In the case of the mono-halogen derivatives of ethane, Table III, it is found possible to make every observed line on our plates fit into a scheme

based on four fundamentals, the lower two being assumed but not observed. The plate for ethyl iodide was underexposed; this substance liberates iodine on exposure to light, and in spite of redistillation of the sample several times during the exposure, the absorption due to the iodine made the exposure time insufficient. This table is perhaps the most satisfactory of all those given.

The corresponding Grignard compounds gave no lines which could not have been attributed to the ether used as solvent. Moreover, most of these compounds are somewhat fluorescent; this difficulty prevented obtaining any other Raman spectra from Grignard reagents.

The results for dihalogen derivatives of ethane are given in the next two tables; Table IV deals with symmetrical derivatives, Table V with unsymmetrical derivatives. No other results appear to have been published on the latter group of compounds. The four-fundamental scheme works out similarly to the preceding cases, but less satisfactorily.

The results for tetrahalogen derivatives of ethane are given in Table VI. The spectra contain many lines, several of which do not fit well into the scheme of combinations assumed. The scheme seems forced and unconvincing, but it serves to point out interesting similarities with the Raman spectra of other compounds.

TABLE V. *Raman spectra of unsymmetrical ethyl dihalides.*

It is interesting to collect the values of the fundamentals used in the spectra of the various compounds described, as is done in Table VII. It will be seen that V_1 increases in frequency with increasing molecular weight (or increasing atomic weight of the halogen substituent) in all except the unsymmetrical compounds. The V_2 fundamental decreases with increase of molecular weight except in the unsymmetrical compounds, while V_3 decreases consistently in all the compounds. The V_4 fundamental is less variable, but it is thought that its variation can be explained better by an alternative method.

In addition to the foregoing data, results are here given for several compounds of cyclic structure. The plates for the first three do not show so many

In attempting to discover some sort of system in Raman spectra, one should proceed with careful attention to the probable sources of error. These may be mentioned in three groups, in the present work. First, the data are too inaccurate to warrant any very great assurance that the apparent regularities found are significant. The wave-number shifts here reported were obtained with dispersion too small to yield exact values for the differences, and it is probable further that a number of the fainter lines were overlooked. The accuracy might be improved by using results from other observers, at least for the stronger lines; but on the other hand, the results reported from mercury arc excitation apparently contain so many spurious lines, due to the difficulty of deciding which of the various mercury lines really was the exciting line, that it seems clear that much of the work done using unfiltered mercury radiation will have to be repeated, in spite of the evident care with which

¹⁵ Petrikaln and Hochberg, *Zeits. f. phys. Chem.* **B3**, 217 and 405 (1929); **B4**, 299 (1929).

¹⁷ S. Venkateswaran, *J. Phys. Chem.* **34**, 145-152 (1930).

much of this work has been done. It is, of course, pointless to try to explain lines which in fact do not exist, just as it is discouraging to try to explain a spectrum from which the fainter lines are lacking.

Second, the lack of a theoretical basis for assuming the lower fundamentals used above is against the suggested scheme, as is the almost complete absence of these lower fundamentals. At first sight it might seem safe to assume fundamental frequencies so low in frequency as to be unobservable in the Raman spectra, and so low as to lie in the region of reststrahlen, so that infrared data would be lacking. But some of them at least are high enough in frequency so that they should not be covered up by the broad exciting line. Many of the combinations that would be expected from these fundamentals are not observed; and in a few cases, the intensities do not seem to fit in well. As will be pointed out below, most of such theory as is available seems to indicate that all the stronger Raman lines are fundamentals. On the other hand, overtones and combinations occur very frequently in infrared spectra; and in many Raman spectra the number of lines is so great that it seems impossible that all of them should be fundamentals. The absence of the lower frequencies is not a fatal objection; the reststrahlen frequencies of sodium chloride, for instance, do not appear in the Raman spectrum. But it will be interesting if liquids prove to have such low characteristic frequencies.

Third, it is frequently possible to find several ways of arranging a spectrum, which appear equally probable. If three frequencies A , B , and C , are found, such that $A + B = C$, it may be that C is a combination tone, or that either A or B is a difference-tone, or that the apparent relation is simply accidental. Again, it was found, for example, that all but four of the lines in the Raman spectrum of chlorobenzene could be set equal to integral multiples of a certain assumed fundamental. No reason could be given for the high intensity of some of the multiples and the absence of many of the others. Bromobenzene showed no analogous relation. Evidently the case was just another illusory relation. One more example may be pointed out; this is the case of carbon tetrachloride, which shows well the different ways in which a spectrum may be explained. On one hand, Langer¹⁸ shows that the Raman frequencies of CCl_4 may all be explained as being due to *differences* between fundamental frequencies in the infrared spectrum, and even suggests a wave-mechanics theory to support the argument. On the other hand, Marvin¹⁹ shows that the Raman frequencies of this compound can be explained, and the infrared spectrum as well, in terms of six fundamentals and their overtones and combinations; and the spectra of SiCl_4 are explained similarly. Next, Schaefer²⁰ shows that one of Marvin's fundamentals is unnecessary, as it is the octave of another; and by assuming that two of the remaining frequencies are a doublet, he is able to bring the whole scheme into good agreement with the theoretical results of Dennison²¹ as necessarily modified to ap-

²¹ D. M. Dennison, *Astrophys. J.* **62**, 84 (1925).

ply to CCl_4 instead of to CH_4 (methane). The same is done for SiCl_4 , and the possibility of similar treatment of TiCl_4 and SnCl_4 is pointed out, as well as certain similarities with compounds containing the SO_4 group. The arguments presented, and the manner in which the scheme fits the observed spectra, are extremely convincing, and there seems to be no reason to doubt the essential correctness of Schaefer's analysis. But if this is conceded, then it seems necessary to admit that overtone frequencies do appear in Raman spectra, as both Daure⁷ and Pringsheim and Rosen¹⁰ have observed Raman frequencies in the spectrum of CCl_4 which on Schaefer's scheme must be the overtone of one of the fundamentals.

In view of such facts, the writers do not present the suggested arrangements tabulated above as anything more than an interesting set of numerical approximations which it is hoped may be of use to some one in extending the theory of the Raman effect, as Marvin's suggested plan probably helped in analyzing the spectrum of CCl_4 .

An attack on the problem from a quite different angle is made by Dadieu and Kohlrausch.⁸ It is assumed that the chemical bonds in a molecule may be treated as a first approximation as if they behaved like elastic springs; so that when two atoms of masses m_1 and m_2 vibrate with respect to each other, the restoring force F is proportional to the displacement, x ,

$$F = fx; \quad (1)$$

and the frequency of the oscillation is given by the equation

$$W_0 = 1/2\pi(f/\mu)^{1/2}, \quad (2)$$

in which μ , the "reduced mass" of the oscillating system, is given by

$$1/\mu = 1/m_1 + 1/m_2. \quad (3)$$

The theory has been extended to the case of anharmonic oscillations, and to the case of coupled vibrations, in which three bodies participate; but these parts of the theory are not immediately essential to the purpose of this paper. Dadieu and Kohlrausch have considered only longitudinal vibrations; but the case of transverse vibrations has been treated briefly in similar fashion by Andrews.²² Following the theory outlined, the constant f is taken to be approximately proportional to the energy of dissociation A of the chemical bond between the vibrating atoms, this energy being known at least roughly from thermochemical data. Hence if one frequency due to a given pair of atoms is known, the frequency due to any other pair of atoms may be computed if the A 's and the μ 's are known. In this way, starting with the aromatic C-H frequency at 3050 cm^{-1} as a reference frequency, Dadieu and Kohlrausch have computed the frequencies to be expected from a large number of types of chemical bond, the computed values being usually somewhat lower than the observed values. In this way, and by comparison of similar compounds in a list of more than a hundred compounds studied, Dadieu and Kohlrausch have

²² D. H. Andrews, *Phys. Rev.* **36**, 544 (1930).

been able to identify the characteristic frequencies of a considerable number of chemical bonds. The theory explains at once why in Raman spectra there is such a noticeable lack of lines between the C-H group, from 2850 cm^{-1} to 3100 cm^{-1} , and the lines due to the heavier atoms, most of which occur with shifts below 1700 cm^{-1} . The computations show that in cases where similar atoms are joined by single, double, and triple bonds, the average restoring forces are in the approximate ratio 1:2:3. As in infrared spectra, "internal" frequencies characteristic of vibrations within recurring groups, and "external" frequencies, associated with the vibrations of a group against the rest of the molecule, are distinguished. The theory checks with observation in so many ways that it seems impossible to doubt its essential correctness. Further evidence in this direction is afforded by the interesting experiments of Kettering, Shutts, and Andrews,²³ who constructed molecular models and, by noting resonance frequencies by stroboscopic methods when the models were vibrated, found sets of characteristic frequencies in good agreement with this theory.

So far as the theory has been applied to the compounds considered in the present article, frequencies for the carbon-halogen bonds are predicted which are in qualitative agreement with the frequencies marked V_3 in the tables; but no frequencies as low as the V_1 and V_2 assumed are predicted, and these may prove to be illusory. The V_4 frequency is clearly the C-H frequency; but if it is assumed that neighboring substituents can alter either the effective mass of the vibrating groups or the strength of the chemical bond between them, and Dadieu and Kohlrausch have presented abundant evidence that both these things occur, then it seems more probable that the occurrence of several lines in the C-H group is due to the existence of several modifications of the C-H bond in the molecules, rather than to combination with a hypothetical V_1 or V_2 frequency. The approximately equal frequency-differences observed are likely to prove not due to combinations. In all probability, more than four fundamentals will be required to explain the structure of most of the compounds discussed. This is especially likely to be true of the cyclic compounds. The fundamental V_5 is probably real, and characteristic of the benzene-ring structure. But Dadieu and Kohlrausch, Soderqvist,¹¹ and others have pointed out that there are three or four other frequencies which also seem to be characteristic of the ring structure. Whether these are all fundamentals, it is at present impossible to say. Dadieu and Kohlrausch have expressed the opinion that only fundamentals appear in Raman spectra; but an apparently valid exception to this statement has been pointed out above in the case of CCl_4 .

It is hoped that further considerations may be presented in another paper in preparation by one of the writers.

MODIFIED SCATTERING BY HYDROGEN HALIDES

BY E. O. SALANT AND A. SANDOW

WASHINGTON SQUARE COLLEGE, NEW YORK UNIVERSITY

(Received January 3, 1931)

ABSTRACT

Raman lines of the gases of HCl (previously measured by R. W. Wood), of HBr and HI and of the liquids of HCl and HBr have been measured. The Raman shifts of the lines of HCl and HBr gases agree with the infrared bands. The Raman shift of HI, 2233 cm^{-1} , does not agree with the infrared value and is considered the more accurate determination of the (0, 1) vibrational transition for HI. Intensities of scattering are in the reverse order of intensities of absorption, as might be expected from the Hill-Kemble theory of scattering by diatomic molecules of gases. The Raman lines scattered by the liquids show a different appearance from the lines scattered by the gases and their Raman shifts are smaller. The differences in the shifts are much too large to be attributed to a Lorentz-Lorenz force and are evidence of molecular interactions of a purely quantum mechanical nature, as discussed by Breit and Salant.

OF THE many measurements of modified lines scattered by liquids, usually by liquids of polyatomic molecules, few give unambiguous information about the energy levels of a molecule in both gaseous and liquid states. A notable exception is the work of McLennan and McLeod, which showed that the lower vibrational terms of O_2 , N_2 and H_2 and the lower rotational terms of H_2 are sensibly the same in the two states.¹ This paper is concerned with Raman spectra of the gases and liquids of HCl, HBr and HI.

Raman lines, both vibrational and rotational, of the gas of HCl, had been measured already by Wood and by Wood and Dieke.² The modified lines of the gases of HBr and HI have been reported briefly by us.³ Early measurements of the modified line of liquid HCl, first by us^{4a} and then by Daure,^{4b} are superseded by our later, more accurate determinations, which included also the modified line of liquid HBr.^{4c}

APPARATUS AND EXPERIMENTAL PROCEDURE

The Hilger constant deviation glass spectrograph was used, with the large camera for the liquids and both large and small camera for the gases. The dispersions on the plate in the region $\lambda 4600$ were 118 cm^{-1} per mm for the large camera, 344 cm^{-1} per mm for the small, the latter being very much the faster of the two systems, of course. The plates were calibrated by iron arc standards. Incident radiation was from mercury arcs.

With the gases, we employed the method developed by R. W. Wood,¹ a long diaphragmed tube containing gas at atmospheric pressure and a long arc alongside it, both tube and arc being surrounded by polished aluminum reflectors. For HCl and HBr we used a glass tube 2 inches by 50 inches and a 50-inch glass arc. With HI (and also HBr) we used a 20-inch quartz arc and a 20-inch glass tube, the latter having an outer shell containing a solution of quinine sulphate to absorb the short wave radiation which decomposes HI.

The cells for the liquids were the usual, small cylindrical tubes into which was focussed the incident radiation from a 6-inch quartz arc. The cell was placed inside an unsilvered Dewar flask containing enough liquid air to liquefy the gas and keep it about 5°C below the boiling point as it was distilled

Fig. 1. Spectrograms of scattering by hydrogen halides.

into the cell. Even with filters we were unable to prevent the formation of iodine sufficiently to obtain modified lines from liquid HI.

HCl was prepared by dropping H_2SO_4 on NaCl in HCl solution. HBr and HI were prepared by the action of boiled-down syrupy phosphoric acid on NaBr and NaI. The gases were dried by passing them through suitable chemical reagents (H_2SO_4 for HCl, P_2O_5 for the others) and through cooled traps. The whole system, generator-driers-cell, contained only quartz and Pyrex fused or ground joints, including no rubber tubing nor cements in the path of the gases.

In spite of the drying of the gases and of the cells, the gases all appeared misty at first, the mistiness disappearing after a few hours; this had already been noticed by Wood with HCl². Spectrograms were begun only after the substances were clear.

RESULTS

After exposures of from 19 to 72 hours with the gases and 2 to 7 hours with the liquids, modified lines could be clearly distinguished on the plates. Spectrograms are shown in Fig. 1, and microphotometer curves in Fig. 2. Lines from HCl were scattered from the mercury line $\lambda 4047$, lines from HBr from 4047 and 4358, and lines from HI from 4358, all Stokes lines.

The microphotometer curves were not at all clear, because of continuous background and because of the small deflections resulting from the short slits used in the spectrograms. Consequently, features of the modified lines were

Fig. 2. Microphotometer curves of shifted lines.

much more obvious to the eye; for example, the long-wave edges of the modified lines of all the gases appear sharper than their short-wave edges, whereas the reverse is true of the modified lines of the liquids. The comparative sharpness of the long-wave edge can be seen in the microphotometer curve of HI. The greater diffuseness of the long-wave edges of the lines of the liquids of HCl and HBr, and the greater sharpness of the gas lines as compared with the lines of the liquids can also be seen even from these curves.

For the evaluation of the Raman shifts we took $24,705.4 \text{ cm}^{-1}$ for $\lambda 4047$; $22,938 \text{ cm}^{-1}$ for $\lambda 4358$.

TABLE I. Raman shifts, gases.

	ν_L	ν_D	ν_S	Intensity
HCl	2885.5	2879	2867	Least
HBr	2558	2550	2524	
HI	2233	2216	2201	Greatest

TABLE II. Raman shifts, liquids.

	ν_L	ν_D	ν_S	Intensity
HCl	2800	2770	2756	Least
HBr	2487	2466	2455	Greatest

The measurements of the modified lines of the gases are in Table I, of the liquids in Table II. In the second column are the Raman shifts of the long-wave edge of the modified line ν_L , in the third column the shifts of the most intense point of the modified line ν_D , in the fourth column the shifts of the short-wave edge ν_S , and in the last column is the order of intensities. All values are in cm^{-1} .

The most striking difference between the modified lines of the gases and of the liquids is that the latter are displaced to smaller frequencies as compared with the corresponding gases; this will be discussed below. It is to be noted further that the points of maximum intensity of the gases of HCl and HBr are nearer the long than the short wave edge, whereas the reverse is true for the liquids of HCl and HBr.

DISCUSSION

The modified lines of the gases are, obviously, Q branches corresponding to jumps of the vibrational quantum number $\Delta v = 1$ and the frequency shifts ν_L of the long wave edges of the gas lines measure the vibrational change $\Delta G(\frac{1}{2})$, (Mulliken's notation⁵).

That this is true for HCl has already been shown by Wood,² our value $2885.5 \pm 0.5 \text{ cm}^{-1}$ being in good agreement with his, 2886.0.

Similarly, our value $2558 \pm 2 \text{ cm}^{-1}$ agrees within the limits of experimental error with the center of the ($1 \leftarrow 0$) vibration-rotation band of HBr, 2559.1, determined by Randall and Imes.⁶

Quite the contrary is the case for HI. Because of its weakness and its proximity to a strong atmospheric band of CO_2 , no really accurate measurement of the fundamental absorption band exists. In spite of these difficulties, Czerny⁷ succeeded in detecting a weak doublet which seemed to indicate the band center at about 2270 cm^{-1} . Our value $2233 \pm 2 \text{ cm}^{-1}$ differs from this certainly beyond any apparent experimental error and, since the uncertainties of the absorption experiments do not adhere to these light-scattering experiments, must stand for the present as the value of $\Delta G(\frac{1}{2})$ for HI.

The intensities of scattering of the modified lines are in the order $\text{HI} > \text{HBr} > \text{HCl}$, just the reverse of the intensities of absorption of the corresponding infrared bands. The electronic levels of these molecules nearest the exciting lines of these experiments are the levels for the ultraviolet continuous bands whose long wave heads are: HCl 45455, HBr 37879, HI 30120 cm^{-1} .^{8,9} The differences, then, between these heads and our exciting lines are in the order $\text{HI} < \text{HBr} < \text{HCl}$. Now, according to the theory of intensities of modified scattering, discussed in particular for diatomic gaseous molecules by Hill and Kemble,¹⁰ these differences would appear in the denominator of the ex-

pression for the electric moment associated with the Raman line, and should contribute, then, toward effecting just the order of intensities observed here.

With the liquids, it is not certain, as with the gases, that the shift of the long wave edge of the Raman line measures the change $\Delta G(\frac{1}{2})$ of the molecules. First there is the fact that absorption measurements of the (0, 2) bands of the liquefied hydrogen halide molecules have shown the bands to have no apparent structure but to have a single maximum of absorption;¹¹ one can hardly speak of these bands having *P*, *Q* and *R* branches, consequently. Then the distribution of intensity in the modified lines from the liquids is different from that in the gases, as noted above, and their shapes seem to correspond to the shapes of the single infra-red bands. As in these bands it is the maximum that is taken as the measure of the vibrational change, it seems reasonable to take the shift of the point of maximum intensity, ν_D , of the liquid Raman lines as a measure of $\Delta G(\frac{1}{2})$ of the liquefied molecules. (Grating measurements of the (1←0) bands in the infrared are now in progress in these laboratories to determine this point).

Defining the change in vibrational term differences due to liquefaction as $\Delta_l \Delta G = \Delta G - \Delta G_l$ where ΔG_l refers to the value of ΔG in the liquids, we have in Table 3 the various values of $\Delta_l \Delta G(\frac{1}{2})$ depending on whether the long wave edge or the point of maximum intensity of the liquid lines is taken as a measure of $\Delta G_l(\frac{1}{2})$.

TABLE III. Gas-liquid shifts of 0,1 transition.

	Values of $\Delta_l \Delta G(\frac{1}{2})$	
	From ν_L	From ν_D
HCl	86	116
HBr	71	92

The theory of shifts of frequency accompanying close packing of molecules attributes the shifts ($\Delta_l \Delta G(\frac{1}{2})$ in these experiments) to three effects (1) electrostatic interaction of a molecule with its neighbors due to its excitation, (2) the effect of the finite space extension of the eigenfunctions of neighboring molecules and (3) the Lorentz-Lorenz force with effective charge replacing classical charge.¹² It was shown in that work that the frequency displacement accompanying liquefaction of HCl was only about 2.2 cm^{-1} due to the Lorentz-Lorenz effect. Since the other factors in the expression for the Lorentz-Lorenz shift are about the same for HBr as for HCl, and since the effective charge for HBr is smaller, corresponding to its smaller intensity of absorption, the Lorentz-Lorenz shift for HBr is of the order of 2 cm^{-1} and, as for HCl quite small compared to the displacement $\Delta_l \Delta G(\frac{1}{2})$ observed here and recorded in Table III. These displacements must, then, be attributed to the first two, purely quantum mechanical effects.

Gas-liquid frequency difference of the same order of magnitude as these have been reported for other substances; for example, for NH_3 by Dickinson,

Dillon and Rasetti¹³ and by Daure,¹⁴ and for H_2S by Bhagavantam.¹⁵ It is tempting to speak of these, too, as a quantum mechanical effect, but in the absence of further information about these molecules, in particular about their effective charges, such a conclusion would be premature and open to question.

We take great pleasure in thanking Mr. R. L. Garman of the Chemistry Department of Washington Square College for the microphotometer curves, and the General Electric Vapor Lamp Co. for mercury arcs. This research was begun while one of us (E.O.S.) was a Fellow of the National Research Council.

IONIZATION OF ARGON, NEON AND HELIUM BY VARIOUS ALKALI IONS

BY RICHARD M. SUTTON AND J. CARLISLE MOUZON

CALIFORNIA INSTITUTE OF TECHNOLOGY, PASADENA

(Received January 5, 1931)

ABSTRACT

Caesium, rubidium, potassium, and sodium positive ions from Kunsman catalyst sources, and lithium ions from spodumene have been used to produce ionization in helium, neon, and argon. In most cases the ionization sets in between 100–150 volts and increases linearly to 750 volts, the highest potential used. Maximum ionization was produced in each gas by the alkali ion closest to it in atomic number.

PREVIOUS experiments have been reported¹ concerning the ionization of various gases by potassium positive ions of relatively low energies. The present paper deals with the ionization of helium, neon, and argon by a series of alkali ions representing a wide range of atomic weights from lithium to caesium. It was of interest to determine what relationship might exist be-

Fig. 1. Experimental tube and connections.

tween the various ionizing agents and the ionization which they produce in gases of different atomic weights. Some rather unexpected experimental results came to light which indicate that the field is fruitful for further investigation and explanation.

The method of measurement has been described in the previous papers. Referring to Fig. 1, it may be summarized briefly as follows. Positive ions

¹ R. M. Sutton, Phys. Rev. **33**, 364 (1929); Sutton and Mouzon, **35**, 694 (1930).

emitted from Kunsman catalyst sources by a hot coated platinum strip F are directed by the variable accelerating potential, V_a , through a small channel in the steel cathode C which completely surrounds the filament. Any ionization occurring in the gas between C and the grid G will produce an electron current I_s to the collector plate S which is connected to the high sensitivity galvanometer G_2 . The initial positive beam (except for loss by scattering and the small fraction striking the grid) falls upon the upper plate P and is recorded as a positive ion current, I_p , by the galvanometer G_1 . At each gas pressure used, the accelerating potential of the positive ions is varied in steps from zero to 750 volts. The ratio of currents, I_s^-/I_p^+ , corrected for the small secondary emission of electrons from the grid, is taken as a measure of the ionization produced in the gas between S and G . The collector S and plate P are both maintained at small positive potentials to prevent the escape of elec-

Fig. 2. N , number of neon ions formed per initial positive ion per cm path at 1 mm pressure.

Fig. 3. N for argon.

trons due to secondary emission or photoelectric effect. These potentials were in no case high enough to produce ionization of the gas by electron collision. The distance $S-G$ (2.5 cm) is made large in comparison with the distance $G-P$ (0.2 cm) in order to minimize the effect of ionization between grid and plate. To correlate the results obtained at different pressures, the ratios of I_s/I_p were divided by the length of path between S and G and by the gas pressure in mm of mercury, thus giving the number, N , of ions formed per initial positive ion per centimeter path at one millimeter pressure. The pressure range utilized was from 0.005 to 0.05 mm; in a few cases where the ionization was feeble, pressures as high as 0.1 mm were used.

In general the ionization sets in between 100 and 150 volts (except for sodium in argon) and increases practically linearly with increasing accelerating potential to 750 volts, the highest voltage used. After making correction for the stoppage of the initial positive beam by the gas, the ionization for a particular voltage is found to be linear with respect to pressure; only in the

cases of intense ionization is there evidence of more than one ionizing collision per positive ion at the higher pressures and accelerating potentials. Thus N for each positive ion in a particular gas is independent of gas pressure within the range studied and depends only upon the accelerating potential of the positive ions.

Fig. 2 and Fig. 3 show the results of a large number of runs in neon and argon respectively, in each of which several different positive ions were used as the ionizing agents. The calculated values of N are seen to be practically linear with accelerating potential after ionization once begins, in most cases by 150 volts. Sodium does not ionize argon until an accelerating potential of nearly 300 volts is reached; this behavior, together with a strong reflection of the sodium positive ions to the collector S at accelerating potentials around 150–250 volts, is strangely unaccountable. In all other cases, reflection of the

Fig. 4. N as function of atomic weight of positive ions and their energies.

Fig. 5. Comparative values of ionization at 750 volts accelerating potential for different gases as function of atomic weight of ionizing agent.

positives played a negligible part in the currents observed. This method is not sensitive enough to determine the onset of ionization closer than 25 volts, but the slopes of all the ionization curves indicate a fairly sharp origin of ionization which was scarcely to be expected; the "ionization potential" due to positive ions bears no evident relationship to ionization potentials determined by electron impact methods, nor does it seem to be critically dependent upon the mass of the bombarding ions in any regular fashion.

The most striking results of this investigation appear when the values of N in Fig. 3 are plotted against atomic weight of the ionizing agent, as shown in Fig. 4. It appears that the maximum ionization in argon is produced by potassium positive ions, which is scarcely what would be expected from any ballistic transfer of energy considerations. Similarly, as may be seen in Fig. 5, neon is most strongly ionized by sodium positives; helium is most strongly ionized by lithium. The conclusion presents itself that *ionization of a noble gas is best effected by that alkali ion closest to it in mass or number of electrons*. Evidence is not yet available to discern whether the controlling factor is one

of mass or electron configuration of the two constituents of an impact, nor can a comparison yet be made with the ionization of a gas by its own atoms or ions. The experimental difficulties in the path of this latter aspect of the problem have not been solved.

Similar results have been published recently by Dr. Otto Beeck² who secured homogeneous beams of positive ions by means of a magnetic analyzer. His method is evidently better designed for the purpose than the one here reported, and he is now in a position to complete the study of the two remaining noble gases at this Institute. The qualitative agreement between the two methods is excellent, and the quantitative agreement is as good as might be expected considering the difference in methods. The only marked departure from regularity of our results appears in the relative interchange of intensities of ionization by lithium and sodium in argon. This may be accounted for by either or both of two causes: first, an impurity of higher atomic weight in the lithium source derived from powdered spodumene (all other sources were Kunsman catalysts); second, the unaccountably large reflection of sodium ions by argon. This inversion of position was carefully checked, and as far as the accuracy of this method is concerned, the effect is real.

Not only is there maximum ionization produced by the alkali positive lying closest to the atomic weight of the gas bombarded, but the intensity of these maxima increases greatly in the heavier gases. The ionization of helium is very feeble, whereas in argon it is quite pronounced. It is rather to be expected that even greater ionization will be found in xenon and krypton. In all of the foregoing work, correction has been made for the secondary emission of electrons from the metal parts of the tube. Inasmuch as there was gas admitted into the tube, no particular precautions were taken to outgas the electrodes. Comparing the secondary emission of the metal surfaces under bombardment of the various alkali ions, the intensity of emission was found to vary in the same way as the intensity of ionization; i.e., greatest for potassium when argon had been present, etc. It would appear that the secondary emission might be due largely to a layer of gas upon the electrodes, and hence this surface effect would bear a close relationship to the volume ionization produced in the gas by different positive ions.

It is felt that more experimental evidence is necessary before an adequate explanation of ionization by two such complicated structures as an alkali ion and a gas atom can be made. This necessitates the development of additional ion sources and improved technique for the study of atom-beams in a gas.

The authors acknowledge their thanks to Dr. Otto Beeck and Dr. Fritz Zwicky for stimulating discussion of the results obtained.

A DIRECT MEASUREMENT OF MOLECULAR VELOCITIES

By I. F. ZARTMAN

UNIVERSITY OF CALIFORNIA, BERKELEY

(Received January 7, 1931)

ABSTRACT

A method is described for the direct measurement of the velocities of neutral molecules. The molecules condense on a glass plate fastened to a cylinder which rotates at a high speed, 241 r.p.s. The molecules having velocities from 168 m/sec to 673 m/sec were spread over a band 3 cm wide. A stream of bismuth molecules is studied and the vapor found to be composed of 40 percent Bi and 60 percent Bi_2 at a temperature of 851°C .

INTRODUCTION

ONE of the fundamental assumptions of the kinetic theory of gases is the continual heat motion of the molecules in the gas. Even though there was no direct experimental verification of this assumption, the theoretical development progressed rapidly, resulting in the derivation of an expression for the distribution of molecular velocities by Maxwell¹ in 1859 and, later by Boltzmann.² This law has found many applications and until 1920 was only indirectly verified.

The first attempt at a direct measurement of molecular velocities was made by Stern³ who intercepted a stream of silver atoms on a rotating plate. The displacement obtained was not sufficient to allow an analysis of the deposit beyond the location of the maximum. The results for the maximum agreed within the experimental error, about 15 percent, with that calculated from the theory. In 1927 Costa, Smyth, and Compton,⁴ using rotating radially slotted disks and a radiometer vane as a detector attempted to secure a "velocity spectrum" of neutral molecules. Their results were in general qualitative agreement with the Maxwell-Boltzmann law but rather unsatisfactory because of the insensitivity of the detector. Eldridge,⁵ using rotating disks as a velocity selector and condensing the molecules on a liquid-air cooled target, obtained a density distribution for cadmium which agreed fairly well with the theoretical distribution. Several objections might be raised, for his zero mark is not sharply defined but very broad; the zero of the theoretical curve has to be shifted about 0.05 cm to make the maximum of the theoretical curve coincide with the maximum of the deposit; his temperature measurement is unsatisfactory and his resolution is low. Lammert⁶ developed a method for

⁶ Berthold Lammert, *Zeits. f. Physik* 56, 244 (1929).

producing molecular beams containing well-defined velocity bands. By taking a series of runs in which the bands had a definite width of 50 m/sec over a range of from 90 to 360 m/sec and determining the intensity of each band, a test of the Maxwell-Boltzmann law for mercury vapor was possible. Except for a systematic difference the results agree quite well with the theoretically expected distribution.

THEORY

The aim of this experiment is to develop an apparatus with a resolving power greater than that obtained by Stern and Eldridge and thus allow a more detailed study of the "velocity spectrum" of neutral molecules. This, as shown later, can be attained by increasing the path-length and the speed of rotation.

Consider a gas issuing through a rectangular slit, g_1 (Fig. 1) in a side of the enclosure E which can be maintained at a constant temperature T . Let Knudsen's⁷ condition for molecular streaming be satisfied, i.e., let the temperature be so controlled that the mean free path of the molecules within, is greater than the width of the slit g_1 . With the aid of the slit g_2 a sharply defined rectangular beam is formed. Let a cylinder D , having a slit g_3 in its periphery and capable of being rotated, be placed in the path of this beam. If the cylinder is at rest, and slit g_3 is in the path of the molecular beam, a deposit forms on the rim at P diametrically opposite the slit. If the cylinder is rotated, the molecules entering g_3 require a finite time to traverse the diameter and consequently strike the rim at a point s to the left of P . The displacement s of a molecule moving with a speed c is given by the equation

Fig. 1.

$$s = \pi d^2 n / c = A / c \quad (1)$$

where d is the diameter of the cylinder and n is the number of revolutions per second. The equation also shows that, by making d and n large, one may secure large displacements of the molecules, i.e., high resolving power.

The molecules in the beam possess not one definite velocity, but a distribution of velocities and consequently a "velocity spectrum" is formed on the rim of the cylinder. The density of this deposit should bear some relation to the velocity distribution in the enclosure E . According to the Maxwell-Boltzmann distribution law, the number of molecules dn out of a total number N in equilibrium within the enclosure possessing speeds between c and $c+dc$, is given by the expression

$$dn = \frac{4N}{\alpha^3 \pi^{1/2}} e^{-c^2/\alpha^2} c^2 dc$$

where α is the most probable speed of the molecules within the enclosure. As

⁷ M. Knudsen, Ann. Physik 28, 999 (1909).

shown by Stern,³ while the molecules within the enclosure are in equilibrium those in the beam are not, for the number passing through the slit per second depends on the size of the opening, the shape of the enclosure, the speed of the molecules and the number of molecules in the enclosure. Let dn_1 be the number of molecules out of N_1 molecules in the beam possessing speeds between c and $c+dc$. Then

$$dn_1 = dn \cdot c \cdot K$$

where K is a constant. From this we get

$$dn_1 = (2N_1/\alpha^4)e^{-c^2/\alpha^2}c^3dc \quad (2)$$

as the expression for the velocity distribution in the beam.

To find the expression for the distribution of the molecules on the receiving plate, P , one can use the method given by Stern.⁸ Consider first that the undeflected image is of infinitesimal width and find the distribution of the molecules in the deflected portion of the plate. Consider the velocity range between c and $c+dc$ giving a deflected range between s and $s+ds$. The intensity of the beam in the deflected region may be defined as the number of molecules dn striking and condensing on a length of plate ds assuming the beam to be of uniform and constant intensity across the element of length, or

$$I = dn/ds. \quad (3)$$

From Eqs. (1), (2), and (3) we get

$$I = \frac{2N_1}{\alpha^4 A} e^{-c^2/\alpha^2} c^5. \quad (4)$$

Fig. 2.

The undeflected beam in the actual experiment is of finite width $2a$ (Fig. 2). Let ds_0 be an element of length in the undeflected region and let dn_0 be the number of molecules striking and condensing on ds_0 . Then $I_0 = dn_0/ds_0$. For an undeflected beam of width ds_0 , Eq. (4) becomes

$$I = \frac{2I_0 ds_0}{\alpha^4 A} e^{-c^2/\alpha^2} c^5. \quad (6)$$

It will be more convenient to use the intensity distribution in the deflected portion as a function of the distance s from the zero line. Then $c/\alpha = s_a/s$,

⁸ O. Stern, *Zeits. f. Physik* **41**, 563 (1927).

where s_α is the deflection of the molecules having the most probable velocity in the enclosure, and Eq. (6) becomes

$$I = \frac{2I_0 ds_0}{s_\alpha} \left(\frac{s_\alpha}{s} \right)^5 e^{-(s_\alpha/s)^2}. \quad (7)$$

Integrating (7) from $-a$ to $+a$, we get

$$I = I_0 \left\{ e^{-(s_\alpha/s+a)^2} \left[\left(\frac{s_\alpha}{s+a} \right)^2 + 1 \right] - e^{-(s_\alpha/s-a)^2} \left[\left(\frac{s_\alpha}{s-a} \right)^2 + 1 \right] \right\} \quad (8)$$

as the theoretical intensity distribution in the deflected region of the plate in terms of s_α and a .

APPARATUS

The substance whose velocity distribution is to be determined is vaporized in a steel crucible *A* (Fig. 3). The vapor then passes through the channel in

Fig. 3. Diagram of apparatus.

the neck to the slit S_1 , there escaping as a molecular beam. The crucible is fastened to the sliding base *B* by means of a rectangular strip of invar *I*. This sliding base is fitted into a dove-tailed groove in order that the entire crucible and slit assembly can be easily removed for filling purposes and then replaced without changing the alignment of the slit system. Directly above the neck of the crucible is a second slit S_2 used to define sharply the molecular beam. The crucible slit is 0.05 mm by 10 mm in size while the defining slit is 0.6 mm by 10 mm. The distance between these slits is 3.29 cm. A shutter *M* magnetically operated from the outside is used to interrupt the beam.

The crucible is heated by radiation from a 300 watt tungsten lamp filament *F* mounted with the aid of tungsten supports *T* fused to a glass tube *G*. The glass tube is fastened in a special holder *H* allowing the filament to be adjusted in any desired direction. The loss of heat by radiation is reduced by surrounding the crucible and filament assembly with nickel radiation shields. Two chromel-alumel thermocouples fastened at *D* serve as a means of determining the temperature. The thermocouples are calibrated by comparison with a standardized platinum-platinum rhodium thermocouple. A potentiometer is used to read the electromotive force of the thermocouples.

A cylinder *C*, 10 cm in diameter, machined out of a solid piece of machine steel, is placed above the slit system. This cylinder is designed to withstand the forces due to high speeds of rotation with the least possible deformation. A knife edge slit *S*₃, 0.6 mm wide, is cut into the rim of the cylinder. Directly opposite on the inner rim a device is fastened to hold a curved glass plate *P*. The cylinder is carefully balanced and mounted on the high speed spindle *J* of an internal grinder. Its speed is determined by the stroboscopic method.

The grinder consists of a 1/6 H.P. universal motor and a high speed spindle mounted on top of the motor housing. A fabric belt is used to drive the spindle. The motor armature has a speed of 10,000 r.p.m. and the spindle 30,000 r.p.m. when connected to a 110-volt circuit. The armature and spindle rotate in ball bearings and the entire assembly is so well-balanced that vibration is negligible at nearly all speeds. The bearings are properly lubricated by vacuum pump oil which has been boiled in a vacuum for several hours to drive off the more volatile products. The residue is sufficiently non-volatile so that a pressure of less than 10^{-4} mm of mercury can easily be maintained in the motor compartment by continual pumping.

The entire assembly is enclosed in a phosphor-bronze housing which is divided into three compartments, a motor, a cylinder, and a crucible compartment. A hole in the wall between the motor and cylinder compartments, slightly larger than the hub of the cylinder, allows the high speed spindle to pass through and at the same time prevents the passage of large quantities of vapor from the motor to the cylinder compartment. A water jacket surrounds the outside of that portion of the housing subjected to heating. The end of the motor compartment is flanged and can be closed by bolting a metal plate *K* to this flange. A rubber gasket *R* is placed between the flange and plate to render the joint vacuum tight. The flange surrounding the cylinder and crucible compartments is scraped to fit a plate glass cover *U*. The joint between the glass cover and the flange is made vacuum tight by giving it a thin uniform coating of a special stopcock grease to which more pure rubber and paraffin has been added than is customary.

The entire system is evacuated through an opening in each compartment. All openings and tubing are large in diameter and the tubing is kept as short as possible in order that all vapors can be quickly removed. Three mercury vapor pumps each backed by a Hyvac pump are used to evacuate the compartments. Liquid air traps are used to prevent the mercury vapor from diffusing into the system. A glass tube which can be filled with liquid air passes

vertically through the cylinder chamber into the crucible chamber. A vacuum tight joint is made by the ground-glass, metal joint at the top. Copper shields *Y* are fitted into the corners formed by the glass cover and the sides, top and bottom of the housing. Copper strips attached to these shields are fastened to the glass tube. The liquid air in the tube cooled these shields to a sufficiently low temperature to condense most of the vapors from the stopcock grease. The tube itself also acts as a large cooled surface which condenses all condensable vapors coming in contact with it. No difficulty is experienced in maintaining a pressure of less than 10^{-5} mm of mercury in the crucible and cylinder compartments.

In order that the density of the deposit can be measured by a microphotometer it is desirable to use glass plates as receivers. These plates (6 by 1.5 by 0.03 cm) are cut from microscope cover glasses. They are bent so as to fit the inner circumference of the cylinder by balancing them on a carbon block having the proper curvature, and then placing the block in an electric oven. The temperature is raised slowly until the plate bends under its own weight to the shape of the carbon form.

For the bismuth molecules to condense on the glass plate at room temperature it is necessary to place an initial, thin and uniform layer of bismuth upon it. This is accomplished by a piece of apparatus which allows the glass plate to be cooled to near the temperature of liquid air and then uniformly exposed to a stream of bismuth molecules. This apparatus consists of an electrically heated crucible and a glass liquid air container mounted in a brass housing which can be made vacuum tight and evacuated. The glass plate upon which the initial deposit is placed is held against the curved flat bottom of the liquid air container by two flat springs. The crucible containing the substance to be deposited is mounted on a shaft so that it may be rotated from one side of the plate to the other. This rotation is accomplished from the outside of the housing by fastening a bent arm to the shaft and enclosing the arm within a sylphon. A fork, attached to a motor-driven slow-speed gear, engages the sylphon thus transmitting the motion to the crucible.

EXPERIMENTAL PROCEDURE

The bismuth used in this experiment is the analyzed product of Powers-Weightman-Rosengarten Company, Philadelphia. In order to get rid of any adsorbed gases it is heated in a vacuum to a temperature of 450°C for about five hours and then allowed to cool before air is admitted.

A bent glass plate is thoroughly cleaned and dried, then placed in the "initial depositing" apparatus and given a thin uniform coating of bismuth. The plate is fastened to the cylinder. The cylinder is adjusted with the aid of a traveling microscope until the slit S_3 is observed to be directly above the defining slit S_2 . It is then fixed in this position. The system is evacuated, the crucible heated to about 800°C and the plate exposed to the molecular beam for about 20 seconds. This operation gives a visible deposit on the plate and forms the zero mark from which the displacements are measured. After ad-

mitting air to the system, the plate is removed and a microphotometer record obtained of the density of the initial deposit and location of the zero mark.

The plate is again fastened to the cylinder, the crucible filled with bismuth and the system evacuated. A slow increase in the temperature is necessary to avoid the violent expansion of gas bubbles in the molten metal which results in a "spitting" of the metal through the slit. When the temperature of the furnace reaches equilibrium and the motor speed is adjusted by varying the resistance in the line to the absence of beats, the shutter is opened and the beam allowed to pass to the plate. The maximum of the deposit first becomes visible in from three to six hours depending upon the temperature and speed of the run. The run is continued for periods ranging from eight to twenty-two hours. The plate is removed from the cylinder and again photometered. Finally, the two photometer curves are superimposed and the density due to the velocity distribution is measured.

RESULTS

The results of four runs are given. Runs 1 and 2 are represented with their theoretical curves in Fig. 4. Fig. 5 is a contact print of the photometer record from which the data for curve 1, Fig. 4, are taken. The horizontal distances are twice the actual distances on the glass plate.

TABLE I.

Run	t	n	Length of run	Bi	Bi ₂
1	851°C	120.7 r.p.s.	12 hours	0.40	0.60
2	851	241.4	22	.40	.60
3	851	60.35	7	.40	.60
4	795	120.7	8	.30	.70

In all cases the experimental results would not agree with the theoretical distribution for Bi or Bi₂ as given by Eq. (8). The work of Leu⁹ on the magnetic deflection of bismuth suggests that the beam is composed of Bi and Bi₂. On the basis of this suggestion various percentages of Bi and Bi₂ were assumed and using Eq. (8) the resultant intensity distributions plotted. These distributions were then compared with the experimental results. The theoretical distribution which best fitted the experimental results is taken as the composition of the vapor stream.

In Fig. 4 the solid lines represent the theoretical distributions for the conditions of operation given in Table I. The circles represent the experimental results obtained from Run 1, and the crosses those from Run 2. The experimental points are in close agreement (within the experimental error) with the theoretically derived curve except for a few points on the high velocity side. These points disagree by an amount greater than the experimental error. The disagreement is probably due to the lack of a sharply defined molecular beam during the entire course of the experiment. It may also be due to a "slipping"

⁹ Alfred Leu, *Zeits. f. Physik* 49, 498 (1928).

Fig. 4 also gives the velocities corresponding to various displacements for a speed of rotation of 241.4 r.p.s.

Fig. 4. Theoretical and experimental intensity distributions assuming a vapor composition of 40 percent Bi and 60 percent Bi₂. T equals 851°C. Curve 1, $n = 120.7$ r.p.s., curve 2, $n = 241.4$ r.p.s. Bottom line gives the molecular velocity corresponding to several displacements at a cylinder speed of 241.4 r.p.s.

Fig. 5. Contact print of photometer record of Run 1, $n = 120.7$ r.p.s. Abscissas twice actual deflections.

TABLE II.

Displacement interval	Velocity band
1.0-1.1 cm	61 m/sec
2.0-2.1	15
3.0-3.1	7
4.0-4.1	4

of the molecules forming the zero mark. This possibility is being investigated.

Table II gives several displacement intervals of 1 mm width and the velocity band covering that interval. The high resolution is quite evident.

As Leu⁹ observed, the dissociation of Bi_2 increased with the temperature and at about the same rate. His results disagree among themselves at the same temperature by 10 percent in some cases. If there is no "slipping" of molecules on the plate a variation in the composition of the vapor of less than 5 percent is detectable in this experiment and this method thus forms a more accurate means for the study of the dissociation of certain vapors, the results of which can be applied to calculating the heat of dissociation.

ERRORS

The temperature and speed could be kept constant to within one percent although it is doubtful if the temperature itself could be read accurately to within several percent. A possible source of error is that not all the molecules striking the plate remain there. It is possible that some escape, however this number is assumed to be negligible. It is not so certain that all molecules striking the plate remain at the point where they first make contact. There is the possibility for surface motion or "slipping." Evidence for a small amount of surface motion on fixed plates is presented by Cockcroft.¹⁰ Any motion of the molecules on the glass plate due to the high speed of rotation must be negligible since the results obtained from Runs 1, 2, and 3, taken at the same temperature but at different speeds, indicate the same percentage vapor composition.

A test showed that no error is introduced in assuming that the electrometer deflections on the photometer records are directly proportional to the densities of the deposits.

CONCLUSION

A method is described for the direct measurement of molecular velocities. Results are presented in which the molecules are spread over a distance of more than 4 cm at a cylinder speed of 241.4 r.p.s. with an error of less than 5 percent. This resolution is many times that obtained by Stern, an analysis of the distribution of the deposit being impossible from his results, and several times that obtained by Eldridge who spread a velocity band of 900 to 200 meters per second over a plate length of 1 cm while in this experiment a velocity band of 673 to 168 meters per second is spread over 3 cm.

It is a pleasure to acknowledge my gratitude to Professor Elmer E. Hall under whose direction the problem was undertaken, for his advice and inspiration; to Professor Leonard B. Loeb for the many helpful discussions and encouraging remarks, and to Mr. G. P. Kraus, mechanic, for his willing cooperation in the mechanical details.

THE AMPLIFICATION OF SMALL DIRECT CURRENTS

BY LEE A. DuBRIDGE

WASHINGTON UNIVERSITY, ST. LOUIS, MISSOURI

(Received December 29, 1930)

ABSTRACT

A new type of thermionic tube recently described by Metcalf and Thompson has made it possible for the first time to construct d.c. amplifying circuits with a current sensitivity exceeding that of any form of electrometer except the Hoffman; and with a ruggedness and dependability unattainable with any form of sensitive electrometer. The circuits are easily constructed and simple to operate. Three types of circuits have been tested out and are described. (1) A simple single-tube circuit with a Type R galvanometer has been found satisfactory for measurements of currents as small as 10^{-14} amp. (2) A two-tube bridge circuit gives greater stability and will easily measure currents of 10^{-16} amp. It has been found capable of detecting currents of 5×10^{-18} amp. (3) A two-stage circuit, using one of the new tubes and one of the UX-112A type, will amplify currents of 10^{-14} amp to such a value that they may be read on a microammeter.

INTRODUCTION

THERE is considerable interest among physicists in the possibility of using thermionic tubes for the amplification of very small direct currents, such as photo-currents, ionization currents, and currents due to electron or positive ion beams of various sorts. A number of different circuits have been described in the literature¹ by means of which ordinary radio tubes or screen grid tubes may be employed for this purpose; and while a number of observers have had considerable success in their use, for the most part the electrometer is still the instrument universally employed for measurements of this type.

The difficulties encountered in d.c. amplification are due largely to the fact that practically all thermionic tubes now available have been designed for amplification of rapidly varying currents, and possess characteristics which make them unsuitable for d.c. work. Only a few attempts have been made to design a tube particularly adapted to amplifying direct currents smaller than about 10^{-11} amp. However, very recently Metcalf and Thompson of the General Electric Laboratories have described² a new form of tube (the "FP-54 pliotron") particularly designed for this purpose and which is capable of amplifying currents as small as 10^{-17} amp. With this type of tube it is possible for the first time to construct an amplifying circuit with a sensitivity equaling or exceeding that of the best Compton electrometers, and at the same time possessing a ruggedness and dependability unattainable with these instruments. The present paper is an account of some further experi-

ments which have been made with these tubes to investigate their possibilities and limitations under actual working conditions, and to study the circuits in which they can be most efficiently used. An attempt has been made to present the results in a rather detailed and elementary way, so that physicists unfamiliar with vacuum tube technique may be aided in building workable amplifier circuits. The experiments were carried out at the General Electric Research Laboratories during the past summer, at the suggestion and under the direction of Dr. A. W. Hull, to whom the author is very greatly indebted.

It may be well to recall some of the requirements which must be met by circuits to be used for d.c. amplification.³ Suppose, for example, that it is desired to amplify a current from, say, a photoelectric cell, using a standard

Fig. 1. Simple circuit for d.c. amplification.

circuit such as is represented in Fig. 1. With the photo-cell dark let the resistance R_1 be adjusted so that the galvanometer reads zero. If the photo-cell is then illuminated, the photoelectric current will cause a drop in potential across the grid resistance R , and this will be impressed on the grid of the vacuum tube. The resulting change in plate current will cause a deflection d of the galvanometer, given by

$$d/\sigma = i_G = \Delta i_p = g_m \Delta e_g$$

where σ is the sensitivity of the galvanometer (in mm/amp), $g_m = di_p/de_g$, the mutual conductance of the tube, and Δi_p and Δe_g the changes in plate current and grid potential, respectively. (It is assumed in setting $i_G = \Delta i_p$ that the resistance R_1 is considerably larger than the galvanometer resistance,³ a condition always satisfied in practice). The voltage sensitivity S_v of the circuit, in mm/volt, then will be,

$$S_v = d/\Delta e_g = g_m \sigma. \quad (1)$$

To attain a high sensitivity to *voltage*, one would choose a tube of high mutual conductance and use it with a sensitive galvanometer. For our present purpose, however, we are more interested in the sensitivity to *current*, since the voltage applied to the grid may be made as large as we please, within limits, by simply increasing R . Since then, $\Delta e_g = Ri$, we have for the current sensitivity, S_i , (in mm/amp),

$$S_i = d/i = g_m R \sigma = S_v R. \quad (2)$$

³ For a more detailed discussion see Nottingham, Jour. Frank Inst. 209, 287 (1930).

Therefore, to attain a high *current* sensitivity it is necessary to use also a high value of R . This is the point at which circuits using ordinary radio tubes are severely limited. For it will be seen that the external resistance R is shunted by the grid resistance Z_g of the tube itself, and hence the total resistance cannot be made larger than Z_g . Now in ordinary tubes Z_g is not greater than a few hundred megohms, due to insulation leakage in the tube, to the collection of positive ions by the grid, and other causes. The first requirement, therefore, of a tube used to amplify very small currents is that the input resistance be very high, or what amounts to the same thing, that the grid currents in the tube under normal operating conditions be very small. In the new tube developed by Metcalf and Thompson all sources of grid current have been systematically eliminated or greatly reduced, so that the residual currents are of the order of 10^{-15} amp and the input resistance of the order of 10^{16} ohms. These tubes are therefore capable of giving enormously greater current sensitivity than has heretofore been possible.

In addition, since the tubes operate at a plate potential of only 6 volts, it is feasible to use large capacity storage batteries for a voltage supply, thus greatly reducing galvanometer fluctuations due to changes in battery voltages. The increased steadiness makes it possible to use a more sensitive galvanometer and thus makes up for the fact that the mutual conductance is somewhat lower than in ordinary tubes.

The FP-54 pliotrons are four-element tubes with two grids interposed between filament and plate. The inner grid serves as a space charge grid and the outer grid as a control grid. The normal operating conditions are:

Filament voltage	2.5 volts
Filament current	0.11 amps
Space charge grid	+4.0 volts
Control grid	-4.0 volts
Plate	+6.0 volts

Under these conditions the tubes have the following average characteristics:

Grid input resistance	10^{16} ohms (approx.)
Control grid current	10^{-15} amp (approx.)
Mutual conductance	25 microamp/volt
Plate current	40 microamp
Plate resistance	40,000 ohms
Voltage amplification factor	1
Grid capacity	$3 \mu\mu\text{F}$.

CIRCUITS FOR USE WITH FP-54 PLIOTRONS

It is not necessary to develop new types of circuits for use with the new tubes, for it has been found that standard circuits are quite adequate. For a given current sensitivity, of course, a much simpler type of circuit can be used than would be necessary with ordinary tubes. An excellent summary of the theory and practice of d.c. amplification, using ordinary tubes, has been given by Nottingham,³ and all of the circuits used in this investigation have been

described in detail in his paper. Slight modifications are necessary, due to the fact that the FP-54 is a four-element tube.

1. *The single-tube circuit.* A very simple type of circuit which has been found suitable for many ordinary current measurements is shown in Fig. 2. It is a standard type of single-stage d.c. amplifier, in which the plate current

Fig. 2. Single tube circuit using FP-54 Plotron. R , high resistance, 10^7 – 10^{11} ohms; R_1 , fixed resistance, 100 ohms; R_2 , 400 ohm potentiometer; R_3 , 20 ohm-rheostat; R_4 , 10,000 ohm rheostat; R_5 , fixed resistance, 40,000 ohms; V_1 , 0–200 millivoltmeter; V_2 , 0–5 voltmeter; S , Ayrton shunt.

is balanced out of the galvanometer by means of an auxiliary battery and rheostat. The numerical values of the various resistances used are given in the figure for convenience, though these are not at all critical, and will vary for different tubes.

The method of operation is as follows: With the tube operating at normal voltages the galvanometer is made to read zero by adjustment of the rheostat R_4 . The voltage sensitivity of the circuit is then determined by applying to the control grid a series of known voltages by means of the potential divider, R_2 , and observing the corresponding galvanometer deflections. If the deflection is then measured for an unknown input current i , the magnitude of i can at once be determined if R is known. There is a linear relation between galvanometer deflection and input voltage as long as the latter does not exceed about 300 millivolts, in spite of the fact that the tubes do not operate normally on the straight part of their characteristic.

The circuit may be made independent of the tube characteristics by using a null method, in which the galvanometer deflection due to the input current is brought back to zero by applying a compensating voltage e by means of R_2 . The input current is then simply equal to e/R . The accuracy then attainable is limited only by the accuracy of the voltmeter V_1 , the accuracy with which R is known, and the precision with which the galvanometer can be set to zero.

The highest voltage sensitivity which can be attained with such a circuit is limited by the fluctuations due to changes in battery voltages and other causes. By using large storage batteries (e.g. 90 amp-hr) for the voltage supply and by careful shielding it has been found possible, with a Leeds and Northrup Type R galvanometer, ($1/\sigma = 5 \times 10^{-10}$ amp/mm), to obtain a stable voltage sensitivity in excess of 50,000 mm/volt. With a resistance R of 10^{10} ohms, a current sensitivity ($= 1/S_i$) of 2×10^{-15} amp/mm is attained. Accurate measurements (to better than 1 percent) can then be made of currents of 10^{-13} amp or larger. This is just about the order of magnitude of the currents usually measured in electrometer circuits.

A somewhat higher current sensitivity may be obtained by "floating" the control grid, i.e., by making R infinite. The residual grid currents within the tube will then cause the grid to charge up slowly, and a steady drift of the galvanometer is observed. The rate of change of grid voltage will be i_g/C , where i_g is the grid current and C is the electrostatic capacity of the grid circuit. For the FP-54 tubes the grid current is in the neighborhood of 10^{-15} amp and the capacity of the grid itself is about $3\mu\mu\text{F}$. If the remainder of the grid circuit be assumed to have a capacity of $10\mu\mu\text{F}$, and if the voltage sensitivity, S_v , is 10^5 mm/volt, then the rate of drift of the galvanometer will be approximately 7.7 mm/sec. This drift is normally very constant, so that an input current as small as 10^{-16} amp can be measured by noting the *change* in the rate of drift which it causes. This is the method used in the General Electric Laboratories for measuring the grid currents in the tubes as they come from the factory.

2. *Balanced tube circuit.* It was found that, when currents of 10^{-14} amp or less are to be measured, more satisfactory operation is obtained with a two-tube circuit of the type developed by Wold, Wynn-Williams⁴ and Eglin.⁵ This method is also more satisfactory for measurement of larger currents where great steadiness and precision are desired. A diagram of the circuit actually used is shown in Fig. 3. It will be noted that it is essentially a Wheat-

Fig. 3. Two-tube bridge circuit. stone bridge, with amplifier tubes in two of the arms and resistances in the other two. When this circuit is properly balanced it can be shown³ that the galvanometer will be unaffected by fluctuations in the battery voltages. A considerably greater steadiness is thereby attained, so that a galvanometer of higher sensitivity may be used and a higher stable voltage sensitivity obtained. It was found, in fact, that satisfactory operation could be maintained

⁴ Wold, U. S. Patent 1232879 (1916). Wynn-Williams, Proc. Camb. Phil. Soc. **23**, 810 (1927); Phil. Mag. **6**, 324 (1928).

⁵ Eglin, Jour. Opt. Soc. **18**, 393 (1929).

at a sensitivity of 250,000 mm/volt, using a galvanometer sensitivity of $1/\sigma = 5 \times 10^{-11}$ amp/mm.

The method of balancing is as follows:³ With the tubes operating at normal voltages, R_1' is adjusted to bring the galvanometer to zero. By means of r_3 a small change is then made in the plate voltage and the effect on the galvanometer noted. R_1' is then changed by, say, 1000 ohms and the galvanometer brought back to zero by adjustment of the various grid potentials. The plate potential is again changed by the same amount as before, and if the resulting galvanometer deflection is smaller, R_1' has been altered in the right direction. The process is then repeated until a change in plate potential produces no effect on the galvanometer.

In a similar manner the effect of filament voltage changes is observed by varying r_2 , and a position of the contact C on r_1 is found such that small variations in r_2 produce no effect on the galvanometer. During this adjustment R_1' is left fixed and the balance restored after each change of C by manipulation of the grid potentials. The circuit is now ready for operation, and may be calibrated in the same way as the single-tube circuit.

The circuit shown in Fig. 3 was designed so that it could be used either with the steady deflection method or the rate of drift method. If only the steady deflection method is to be used the condenser C_1 may be eliminated and if only the rate of drift method is to be used, the resistances R and R' may be eliminated. In either case the operation is similar to that of the single-tube circuit, tube No. 1 being the active tube and No. 2 acting merely as a "dummy." The resistance R' in the grid circuit of the second tube makes for greater symmetry and hence increases the stability somewhat, but in many cases it may be left out and the grid connected directly to r_6 . If R is 10^{10} ohms and the voltage sensitivity 250,000 mm/volt, the current sensitivity, $1/\sigma$, will be 4×10^{-16} amp/mm. Still higher resistances may of course be used.

An exceedingly high sensitivity may be obtained with this circuit using the rate of drift method of measurement. If the grids of both tubes are floated, and if they both charge at the same rate, then there will be no effect on the galvanometer. In general, however, the grid currents of two tubes will not be the same, but the rate of charge of the two may be made the same by increasing the capacity of one grid. This was accomplished by introducing the variable $15\mu\text{F}$ condenser⁶ C_1 in the grid circuit of the second tube. The tube with the largest grid current was made No. 2 in the circuit. This condenser was then adjusted until the galvanometer showed no drift. If a current i is now started in the input circuit, this will change the rate of charge of the grid of the first tube and hence give a galvanometer drift which is proportional to i .

The smallest current which can be detected by this method is limited only by the fluctuations of the circuit. The effects of external electric and magnetic fields, especially rapidly varying fields, were carefully eliminated by enclosing the entire circuit in a metal container which was almost air tight. All

⁶ A satisfactory condenser was made by taking an ordinary radio condenser and replacing the bakelite insulation by quartz.

rheostats and connections should of course make positive contact; the storage batteries must be in good condition; to prevent insulation leaks the tubes must be kept dry. It was even found necessary to eliminate effects due to residual ionization of the air by enclosing the control grid leads in small quartz tubes painted on the outside with a suspension of graphite ("aquadag"). A wide band of aquadag was also painted around the tubes themselves to serve as a guard ring. When all these precautions were taken, it was found that the residual fluctuations were sufficiently small that an input current of approximately 5×10^{-18} amp could be detected and measured. Such a current produced a galvanometer drift in the circuit used of about 10 mm/min, and the fluctuations were also of this order. These fluctuations were of the order of magnitude to be expected from shot-effect fluctuations in the control grid currents in the two tubes, and hence the limit of sensitivity of the tubes was approximately attained.

It is of interest to note that a current of 5×10^{-18} amp is only 30 electrons per second, and the shot-effect fluctuations in such a current over a period of one second are of the order of 15 percent. If tubes could be constructed in which the grid currents were as low as 10^{-17} amp (and this may not be impossible) the sensitivity limit of the amplifier could be pushed to 5×10^{-19} amp, or 3 electrons per second. If a short period galvanometer were used, individual electron pulses could be observed.

It will be noted that the maximum voltage sensitivity attainable with this circuit is about five times that attainable with the Compton electrometer, and is 25 to 50 times greater than the usual operating sensitivity of the electrometer. There is an even greater difference between the current sensitivities of the two instruments, due to the smaller capacity of the amplifier. The author has found that, roughly speaking, a well-built amplifier is as stable at a sensitivity of 100,000 mm/volt as a good Compton electrometer at 5,000 mm/volt. In addition the amplifier has the advantages of greater mechanical ruggedness and short period. Furthermore, the sensitivity of the amplifier circuit has been found to remain constant over long periods of time, in contrast to the frequent adjustments of quadrant and needle required to maintain a constant high sensitivity of an electrometer. In short the amplifying circuit herein described has been found to be a practical and convenient current-measuring device,⁷ with an attainable sensitivity greater than that of any known instrument, with the exception of the Hoffman electrometer and the Geiger counter.

3. *The two-stage amplifier.* For many problems it is desirable to measure very small currents, such as photoelectric currents, but at the same time to use an extremely rugged meter.⁸ In order to test out the possibility of using instruments still more rugged than the Type R galvanometer, a two-stage

⁷ Such a circuit is now being used successfully by Professor G. E. M. Jauncey and Mr. W. D. Claus at Washington University for measurements of ionization currents in an x-ray spectrometer.

⁸ This is true, for example, in the photoelectric photometry of stars, where the measuring instrument must be mounted directly on the telescope.

amplifier circuit shown in Fig. 4 was constructed. By employing a UX-112A tube in the second stage it is possible to measure the output with an ordinary microammeter (0–100 μ amp). A second state of amplification could of course be employed with either of the two circuits previously described. It seemed, however, that the greatest simplicity and convenience could be attained by using in the first stage a balanced circuit in which the dummy tube is replaced by a variable resistance. In place of the galvanometer, the second stage of amplification is substituted.

It is evident that the requirements for the tube to be used in the second stage are quite different from those for the first stage. For, while the chief requirement for the first stage is a high grid resistance, this is not at all necessary in the second stage, since the resistances R_1 and R_2 are relatively small. One will therefore use in the second stage a tube of high mutual conductance.

Fig. 4. Two-stage amplifier. R_1, R_2 , Fixed resistances, 10,000 ohms: R_3 , variable resistance, 20,000 ohms: r_1, r_3, r_4 , 400 ohm potentiometers: r_2 , fixed resistance, 1000 ohms: r_5 , 60 ohm rheostat: r_6 , 6 ohm rheostat: r_7 , rheostat with fine adjustment, 1000 ohms: R , high resistance, 10^7 – 10^{11} ohms.

If a voltage e is applied to the grid of the first tube, then the change in the voltage of the grid of the second tube will be ke , where k stands for the expression

$$\mu R_p / (R_p + r_p).$$

Here μ is the voltage amplification factor of the first tube, R_p the external resistance in the plate circuit, and r_p the internal impedance of the first tube. The change in the plate current of the second tube will then be

$$\Delta i_p = g_{m2} ke$$

where g_{m2} is the mutual conductance of the second tube. This change in plate current will be read on the microammeter. Now the voltage amplification obtained by the FP-54 in the circuit shown is actually less than 1, so that if another FP-54 were used in the second stage, the overall sensitivity of the combination would be less than for a single tube. However, if a tube of large mutual conductance is used in the second stage, an increase in sensitivity is obtained. With the circuit shown in Fig. 4 the over-all sensitivity was found to be approximately 375 microamp/volt. Using an input resistance, R , of 10^{11} ohms, an output current of 1 microamp was obtained for an input current of 2.7×10^{-14} amp. This is a current amplification of 3.75×10^7 .

The method of operating the circuit is as follows: With the double-pole-double-throw switch in position 1, the microammeter reads the output of the first stage only. The first stage is then balanced until the meter reads zero. The balance is obtained in a manner similar to the balance of the two-tube circuit by adjustment of R_3 and r_4 . The microammeter switch is then thrown to position 2 and r_5 adjusted until the meter again reads zero. The circuit is then ready for operation.

The usefulness of such a circuit is quite apparent for problems in which ruggedness, portability or economy are of importance. A very inexpensive microammeter may be used since it serves only as an indicating instrument, and will be calibrated in terms of input voltage by means of the potentiometer r_1 and voltmeter V .

As a test of the practical use of this circuit the input terminals were connected to a G.E. caesium photoelectric cell, type UX-867, illuminated by a small headlight lamp. An output current of several microamperes was observed when the lamp filament was at a temperature such that it was scarcely visible to the eye in a dimly lighted room.

There are many variations and improvements on the two-stage circuit which at once suggest themselves. The circuit shown in Fig. 4 was chosen primarily for its simplicity, and it is described here because it was found to give quite satisfactory operation. Its stability and sensitivity could undoubtedly be improved by using a complete two-tube bridge circuit in each stage, using two FP-54 tubes in the first and two UX-112A tubes in the second stage.

4. *General precautions.* The chief purpose of the present paper is to bring out the fact that with the new FP-54 pliotrons the construction of a highly sensitive d.c. amplifier has been made a relatively simple task. It may be well to remark, however, that *regardless of the instrument used to measure or detect small currents*, the circuits which carry them must always be insulated and shielded with the greatest care. The problem of shielding is of even greater importance for an amplifier circuit than for an electrometer. This is due to the fact that an electrometer is practically insensitive to high frequency electric fields of constant intensity, while the amplifier actually serves as a detector for such fields. Air-tight shielding of the grid circuits is therefore essential if the amplifier is to be used in the vicinity of high voltage equipment (e.g., x-ray tubes). Shielding of *all parts* of the amplifier circuit is advised.

In all other respects (such as choice of insulation material, construction of grounding keys and high resistances, etc.) the grid circuits of an amplifier may be treated exactly as an electrometer circuit of equal sensitivity. It has been found necessary to operate the tubes at their rated voltages for from half an hour to two hours before readings are begun, in order that temperature equilibrium be obtained and that the electrostatic charges on the walls of the tubes and other places shall have reached a steady state.

A MACHINE FOR AUTOMATIC GENERATION OF AIRFOILS

BY DIMITRY E. OLSHEVSKY

SLOANE PHYSICS LABORATORY, YALE UNIVERSITY AND SIKORSKY AVIATION CORPORATION

(Received January 5, 1931)

ABSTRACT

The present paper is a short account of work done with the purpose of adapting the speed, accuracy, reproducibility, and system which a drawing machine is capable of delivering to drawing large sets of systematically varied airfoils for wind tunnel research. An airfoil is defined in the paper merely as a closed curve without discontinuities in curvature and with a sharp trailing edge. Use is being made of the fact that such curves are produced by kinematical mechanisms as trajectories or coupling curves for pencil points on or near the polar curve. A machine based on the four member linkage is described and a table showing a set of systematically varied airfoils obtained with the machine is reproduced.

PRESENT methods of mechanical and analytical generation of airfoils assume a function of a complex variable to be responsible for the particular airfoil. The airfoil appears as the closed streamline in the conformal representation of a flow around a circle or some other contour, the flow around which is already known. Thus the airfoils of Zoukowsky, Drzewiecki, Miller and others have been calculated analytically and scattered attempts were made to build machines capable of delivering the particular transformation of a circle or ellipse. This mechanical-analytical method of approach has the advantages of permitting calculation of flow around the airfoil and forces acting upon it on the basis of frictionless incompressible fluid theory.

There exists however the possibility of a different viewpoint on the problem: airfoils can be defined merely as closed curves without discontinuities in curvature having a "sharp" trailing edge, the latter being, according to Prandtl's theory of boundary layer, the essential requirement for maintenance of circulation in the viscous, actual fluid. Decision as to their efficiency is left with the experimental methods. A machine capable of drawing such curves can be regarded as a mathematical operator applied to a certain closed curve described by the primary point (point *A* on Fig. 1, say) of the machine; this mathematical (or rather physical) operator is defined by the parameters of the machine. The transformation function drops out of the picture, at least when not expressly required, and the determination of aerodynamical qualities of the airfoil is left with the experiment.

Justification of this method of approach is its simplicity, speed and accuracy as well as efficiency of the drawing machines regarding reproducibility and systematization.

Kinematical considerations concerning shape of coupling curves of mechanisms¹ lead to the conclusion that machines having two branches of their

¹ L. Burmester, *Lehrbuch der Kinematik*. Felix, Leipzig, p. 297 (1888).

characterized by the pencil point coordinates x and y with origin at B and X and Y axes along AB and BY respectively. The procedure of drawing consisted in slowly rotating the arm OA slightly over one full turn. Airfoils were plotted for position of the pencil not far from the polar curve on sheets of paper fixed to the drawing table.

Fig. 2. The experimental model of the airfoil drawing machine.

Each airfoil is thus characterized by six parameters showing the dimensions of a , b , c , d , x and y . Any airfoil can be easily reproduced by merely setting the machine to the desired values of the parameters.

RESULTS

A set of airfoils is shown on Fig. 3. It has the following values of the parameters: $a=3$, $b=14$, $c=9$, $d=18$, x and y variable. The curves were filled in with india ink and arranged in a two dimensional scheme according to the

Fig. 3. A family of airfoils drawn by the machine. The photograph is considerably reduced. variable parameters x and y . Each of the twins appearing in the center region of the set should be regarded as an airfoil with finite trailing edge angle. The analytical nature of curves drawn by the machine permits but zero angle trailing edge for single curves.

Several more promising airfoils are reproduced on Figs. 4 and 5.

Fig. 4. Three full-scale drawings of airfoils plotted by the machine ($x = -1\frac{3}{4}$; $y = 7, 6, 5$, the largest airfoil corresponding to the smallest y).

Fig. 5. Airfoil $x = 2\frac{1}{2}$, $y = 7$.

As a rule the accuracy of plotting was well within $\frac{1}{4}$ percent of the chord. A machine of the type described permits drawing of a set of 150 airfoils in the course of a few days. With balance plotting automatically the polar diagram and with automatic model making machinery (as designed by the writer) the total time and expenditure connected with the investigation of properties of a large set of airfoils can be reduced to a very reasonable figure.

RECIPROCAL RELATIONS IN IRREVERSIBLE PROCESSES. I.

BY LARS ONSAGER

DEPARTMENT OF CHEMISTRY, BROWN UNIVERSITY

(Received December 8, 1930)

ABSTRACT

Examples of coupled irreversible processes like the thermoelectric phenomena, the transference phenomena in electrolytes and heat conduction in an anisotropic medium are considered. For certain cases of such interaction reciprocal relations have been deduced by earlier writers, e.g., Thomson's theory of thermoelectric phenomena and Helmholtz' theory for the e.m.f. of electrolytic cells with liquid junction. These earlier derivations may be classed as quasi-thermodynamic; in fact, Thomson himself pointed out that his argument was incomplete, and that his relation ought to be established on an experimental basis. A general class of such relations will be derived by a new theoretical treatment from the principle of microscopic reversibility. (§§1-2.) The analogy with a chemical monomolecular triangle reaction is discussed; in this case a simple kinetic consideration assuming microscopic reversibility yields a reciprocal relation that is not necessary for fulfilling the requirements of thermodynamics (§3). Reciprocal relations for heat conduction in an anisotropic medium are derived from the assumption of microscopic reversibility, applied to fluctuations. (§4.) The reciprocal relations can be expressed in terms of a potential, the dissipation-function. Lord Rayleigh's "principle of the least dissipation of energy" is generalized to include the case of anisotropic heat conduction. A further generalization is announced. (§5.) The conditions for stationary flow are formulated; the connection with earlier quasi-thermodynamic theories is discussed. (§6.) The principle of dynamical reversibility does not apply when (external) magnetic fields or Coriolis forces are present, and the reciprocal relations break down. (§7.)

I. INTRODUCTION

WHEN two or more irreversible transport processes (heat conduction, electrical conduction and diffusion) take place simultaneously in a thermodynamic system the processes may interfere with each other. Thus an electric current in a circuit that consists of different metallic conductors will in general cause evolution or absorption of heat at the junctions (Peltier effect). Conversely, if the junctions are maintained at different temperatures an electromotive force will usually appear in the circuit, the thermoelectric force: the flow of heat has a tendency to carry the electricity along.

In such cases one may naturally suspect reciprocal relations by analogy to the reciprocal relations which connect forces and displacements in the equilibrium theory of mechanics and in thermodynamics. Relations of this type have been proposed and discussed by many writers. The earliest of them all is due to W. Thomson;¹ it deals with thermoelectric phenomena. We shall cite Thomson's reciprocal relation in a simple form as a symmetry condition for the relations which connect the forces with the velocities. The electric current we shall call J_1 , the heat flow J_2 . The current is driven by the elec-

¹ W. Thomson (Lord Kelvin), Proc. Roy. Soc. Edinburgh 1854, p. 123; Collected Papers I, pp. 237-41.

tromotive force, which we shall call X_1 . In corresponding units the "force" which drives the flow of heat will be:

$$X_2 = -\frac{1}{T} \text{ grad } T,$$

where T denotes the absolute temperature (Carnot). If the heat flow and the current were completely independent we should have relations of the type:

$$X_1 = R_1 J_1$$

$$X_2 = R_2 J_2$$

where R_1 is the electrical resistance and R_2 a "heat resistance." However, since the two processes interfere with each other we must use the more complicated phenomenological relations

$$\begin{aligned} X_1 &= R_{11}J_1 + R_{12}J_2 \\ X_2 &= R_{21}J_1 + R_{22}J_2. \end{aligned} \tag{1.1}$$

Here Thomson's contention is:

$$R_{12} = R_{21}. \tag{1.2}$$

Thomson arrived at this relation from thermodynamic reasoning, but he had to make one additional assumption, namely: "*The electromotive forces produced by inequalities of temperature in a circuit of different metals, and the thermal effects of electric current circulating in it, are subject to the laws which would follow from the general principles of the thermodynamic theory of heat if there were no conduction of heat from one part of the circuit to another.*" Thomson thought this assumption very plausible. Even so, he cautiously considered his reciprocal relation (1.2) a conjecture, to be confirmed or refuted by experiment, since it could not be derived entirely from fundamental principles known at that time. At present Thomson's relation is generally accepted, because it has been confirmed within the limits of error of the best measurements. As regards the theory, the same relation has frequently been found as a by-product of investigations in the electron theory of metals. However, Thomson's relation has not been derived entirely from recognized fundamental principles, nor is it known exactly which general laws of molecular mechanics might be responsible for the success of Thomson's peculiar hypothesis.

In the following, a general class of reciprocal relations in irreversible processes will be derived from the *assumption of microscopic reversibility*. No further assumptions will be necessary, except certain theorems borrowed from the general theory of fluctuations. Among the relations to be derived, many have been proposed before, but some will be new. An important group among these relations can be summarized in a variation-principle, which is nothing but an extension of Lord Rayleigh's "*principle of the least dissipation of energy*"; we shall retain the name for the extended principle. According to this theorem the *rate of increase of the entropy* plays the rôle of a potential.

Thomson's hypothesis covers only part of the cases which we are going to consider, yielding the same results as the more general "principle of the least dissipation of energy." This connection will be discussed in §6; here, however, we shall comment on the natural interpretation of Thomson's hypothesis, because his formulation is somewhat ambiguous: He assumes that the temperature differences present are bound to cause a certain degradation of energy by conduction of heat; if another irreversible process (electrical conduction) takes place simultaneously, this process must cause an additional degradation of energy, making the total rate of increase of the entropy greater than it would be by heat conduction alone.

The derivation of such results from the principle of microscopic reversibility will hardly be a surprise to workers who are acquainted with the theory of irreversible processes. In many familiar cases this principle guarantees an independent balancing of different classes of molecular processes maintaining a statistical equilibrium. The writer actually conceived the idea for the new derivation of reciprocal relations by comparing the relations due to Thomson,¹ Helmholtz² and others with the conditions for reversibility in certain chemical reactions, as presented in §3.

The principle of microscopic reversibility is less general than the fundamental laws of thermodynamics; the consequent limitations to our reciprocal relations will be briefly described in §7. It is easy to show that Thomson's relation is no thermodynamic necessity. According to (1.2) the rate of production of entropy per unit volume of the conductor equals

$$\frac{dS}{dt} = \frac{1}{T}(X_1 J_1 + X_2 J_2) = \frac{1}{T}(R_{11} J_1^2 + (R_{12} + R_{21}) J_1 J_2 + R_{22} J_2^2).$$

Thermodynamics requires only:

$$dS/dT > 0$$

identically, except when J_1 and J_2 vanish simultaneously, or, by simple algebra:

$$R_{12} + R_{21} < 2(R_{11}R_{22})^{1/2}. \quad (1.3)$$

This condition (in a somewhat different form) was given by Boltzmann.³

In the present communication only one special case, namely heat conduction in an anisotropic medium (crystal), will be adequately treated (§4). This limitation allows a simplified derivation, which nevertheless brings out clearly the essential ideas of the new theoretical treatment. The derivation of other reciprocal relations, including Thomson's, will be reserved for later publication; here we shall merely enumerate the most important cases.

2. EXAMPLES OF MUTUAL INTERACTION OF IRREVERSIBLE PROCESSES

The formulation (1.1) of the laws of irreversible processes in terms of resistances R_{11} , etc., is well adapted to a comparison with the thermodynamic requirements; but as a rule it is a little easier to see the physical meaning of such

¹ H. v. Helmholtz, Wied. Ann. **3**, 201 (1876); Wiss. Abh. **1**, 840.

² L. Boltzmann, Wien. Ber. **96**, 1258 (1887).

laws when they are expressed in terms of conductances L_{11} , L_{12} . . . etc.:

$$\begin{aligned} J_1 &= L_{11}X_1 + L_{12}X_2 \\ J_2 &= L_{21}X_1 + L_{22}X_2 \end{aligned} \quad (2.1)$$

where:

$$L_{11} = R_{22}/(R_{11}R_{22} - R_{12}R_{21})$$

etc. The reciprocal relation (1.2) takes the form:

$$L_{12} = L_{21}. \quad (2.2)$$

So far we have only mentioned the interaction of heat conduction and electrical conduction. In mixtures of gases and in solutions a third transport process is possible, namely diffusion. Experience shows that any two possible transport processes are likely to interfere with each other to some extent.

It is well known that an electric current in a conductor of the second kind causes transport of matter. Conversely, a concentration gradient between two identical reversible electrodes causes an electromotive force. The relations between "forces" and velocities may again be expressed in the form (2.1). J_1 may again be the electric current, and X_1 the e.m.f.; for J_2 we take the flow of solute relative to the solvent, for X_2 the gradient $-\text{grad } \mu = X_2$ of the thermodynamic potential μ of the solute. The coefficients L_{11} . . . L_{22} are connected, in a manner which we need not discuss in detail, with the electrical resistance, the diffusion coefficient, the "transference number" and the e.m.f. caused by a given concentration gradient. Usually the fourth is not mentioned, since Helmholtz³ has derived the reciprocal relation.

$$L_{12} = L_{21}. \quad (2.2)$$

His derivation is quite analogous to Thomson's treatment of the thermoelectric phenomena, and it suffers from the same weakness. However, the experiments confirm the result, Nernst⁴ has given a kinetic derivation from assumptions that are somewhat specialized, and the theorem is generally accepted.

For the interaction between heat conduction and diffusion a reciprocal theorem has been derived by Eastman;⁵ the case is quite analogous to the preceding. The diffusion caused by a temperature gradient is known as the Soret effect; the inverse effect has been demonstrated in a qualitative manner for a mixture of gases.⁶ Eastman has also discussed thermoelectric forces in electrolytes. In that case three different transport processes are involved simultaneously. The phenomenological relations can be expressed in the form

$$\begin{aligned} J_1 &= L_{11}X_1 + L_{12}X_2 + L_{13}X_3 \\ J_2 &= L_{21}X_1 + L_{22}X_2 + L_{23}X_3 \\ J_3 &= L_{31}X_1 + L_{32}X_2 + L_{33}X_3 \end{aligned} \quad (2.3)$$

and we may suspect $3 \cdot 2/2 = 3$ reciprocal relations

$$L_{12} = L_{21}; L_{13} = L_{31}; L_{23} = L_{32}. \quad (2.4)$$

⁴ W. Nernst, *Zeits. f. physik. Chem.* **2**, 613 (1888).

⁵ E. D. Eastman, *J. Am. Chem. Soc.* **48**, 1482 (1926); **50**, 283, 292 (1928).

⁶ Dufour, *Arch. d. sc. phys. et nat. Genf* **45**, 9 (1872); *Pogg. Ann.* **148**, 490 (1873).

The case of simultaneous diffusion of several substances in the same solution completes the list of possibilities for coupling between transport processes in isotropic bodies.

Transport processes in anisotropic bodies afford a few interesting examples of mutual interaction, for instance the conduction of heat in crystals of low symmetry. In the most general case of a triclinic crystal the phenomenological relations can be written in the form (2.3). We chose a cartesian frame of coordinates x_1, x_2, x_3 ; then J_1, J_2, J_3 are the components of the heat flow along these axes, and the "forces" are $X_1 = -(1/T)\partial T/\partial x_1$ etc. In a suitable frame of reference x_1^*, x_2^*, x_3^* parallel to the main axes of the ellipsoid:

$$L_{11}x_1^2 + (L_{12} + L_{21})x_1x_2 + \dots + L_{33}x_3^2 = \lambda_1x_1^{*2} + \lambda_2x_2^{*2} + \lambda_3x_3^{*2} = \text{const.} \quad (2.5)$$

the equations of heat conduction take the form

$$\begin{aligned} J_1^* &= \lambda_1 X_1^* + \omega_3 X_2^* - \omega_2 X_3^* \\ J_2^* &= -\omega_3 X_1^* + \lambda_2 X_2^* + \omega_1 X_3^* \\ J_3^* &= \omega_2 X_1^* - \omega_1 X_2^* + \lambda_3 X_3^*. \end{aligned} \quad (2.6)$$

If the reciprocal relations (2.4) are valid, then:

$$\omega_1 = \omega_2 = \omega_3 = 0 \quad (2.7)$$

and the conducting properties of the crystal are entirely determined by the ellipsoid (2.5); whenever the gradient of the temperature is parallel to one of the axes x^* the heat flows in exactly the same direction. If $\omega_1, \omega_2, \omega_3$ do not vanish there may still be three such directions of direct heat flow, in which case these directions will no longer be perpendicular to each other, or there may be only one such direction. For instance, for crystals belonging to the tetragonal or hexagonal systems the inherent symmetry fixes the axes $x_1^* = x_1$; $x_2^* = x_2$; $x_3^* = x_3$ and demands certain relations between the coefficients, so that (2.3) and (2.6) take the form

$$\begin{aligned} J_1 &= \lambda_1 X_1 + \omega_3 X_2 \\ J_2 &= -\omega_3 X_1 + \lambda_2 X_2 \\ J_3 &= \lambda_3 X_3. \end{aligned} \quad (2.8)$$

If clockwise and counterclockwise rotations around the axis x_3 are equivalent ω_3 vanishes for reasons of symmetry, but certain classes of the crystallographic systems in question do not possess such a symmetry. When ω_3 does not vanish the flow of heat in the x_1, x_2 plane will always form an angle:

$$\arctan(-\omega_3/\lambda_1)$$

with the temperature gradient. If we should take a circular plate of such a crystal, cut parallel to the base (x_1, x_2 plane), and heat it in the middle, maintaining cylindrical symmetry, the heat would flow in spirals. Attempts by Soret and W. Voigt to detect this spiral motion met with negative results, in spite of a very sensitive method.⁷

⁷ Ch. Soret, Arch. de Geneve 29, no. 4 (1893); 32, no. 12 (1894). W. Voigt, Gött. Nachr. 87, (1903).

The case of electrical conduction in highly anisotropic crystals is quite analogous to the heat conduction, and the thermoelectric phenomena in crystals afford a variety of possibilities for reciprocal relations. We need only mention these two examples; a detailed discussion would not bring out any new features of the general problem.

3. ANALOGY WITH CHEMICAL REACTIONS

We shall compare (2.3) with the equations for a chemical monomolecular triangle reaction. Suppose that a certain substance may exist in a homogeneous phase in three different forms A , B , C . Suppose further that any one of these may spontaneously transform itself directly into either of the others according to the scheme

We shall assume that the reactions obey a simple mass-action law. That is, the fraction of A molecules which will change into B in a given short time Δt is

$$k_{BA}\Delta t$$

where k_{BA} is a constant. Then the rates of change of the amounts n_A , n_B , n_C are given by the equations

$$\begin{aligned} \frac{dn_A}{dt} &= -(k_{BA} + k_{CA})n_A + k_{AB}n_B + k_{AC}n_C \\ \frac{dn_B}{dt} &= k_{BA}n_A - (k_{AB} + k_{CB})n_B + k_{BC}n_C \\ \frac{dn_C}{dt} &= k_{CA}n_A + k_{CB}n_B - (k_{AC} + k_{BC})n_C. \end{aligned} \quad (3.2)$$

If one or several of the coefficients k_{BA} etc. vanish the case becomes trivial; we shall therefore assume that they are all ≥ 0 . This condition is by itself sufficient to insure finite equilibrium concentrations \bar{n}_A , \bar{n}_B , \bar{n}_C , which are given by the relations

$$\frac{d\bar{n}_A}{dt} = 0 = -(k_{BA} + k_{CA})\bar{n}_A + k_{AB}\bar{n}_B + k_{AC}\bar{n}_C \quad (3.3)$$

together with

$$\bar{n}_A + \bar{n}_B + \bar{n}_C = n_A + n_B + n_C = n \quad (3.4)$$

expressing the conservation of the total amount. If the equilibrium ratios $\bar{n}_A:\bar{n}_B:\bar{n}_C$ are known this implies two independent relations between the 6 coefficients k_{AB} , k_{AC} , \dots , k_{CB} , leaving 4 of them free.

Here, however, the chemists are accustomed to impose a very interesting additional restriction, namely: when the equilibrium is reached each indi-

viual reaction must balance itself. They require that the transition $A \rightarrow B$ must take place just as frequently as the reverse transition $B \rightarrow A$ etc. Now if the ratios between \bar{n}_A , \bar{n}_B , and \bar{n}_C are known the condition of detailed balancing imposes three relations between the k 's instead of the two expressed by (3.3), namely

$$\begin{aligned} k_{BA}\bar{n}_A &= k_{AB}\bar{n}_B \\ k_{CB}\bar{n}_B &= k_{BC}\bar{n}_C \\ k_{AC}\bar{n}_C &= k_{CA}\bar{n}_A. \end{aligned} \quad (3.5)$$

These reciprocal relations are analogous to (2.4). From (3.5) we can obtain just one relation between k_{AB} etc. alone, namely

$$k_{AC}k_{CB}k_{BA} = k_{AB}k_{BC}k_{CA}.$$

This relation is not necessary for fulfilling the thermodynamic requirements; those are satisfied as soon as an equilibrium exists, and the existence of an equilibrium is secured by any set of positive values of $k_{AB} \cdots k_{CB}$. In terms of equations: (3.5) is not contained in (3.3).

Suppose that (3.5) were not fulfilled, how could the equilibrium be maintained? Besides a certain number of transitions balancing each other directly according to the scheme

we should have additional transitions taking place around the cycle

Now the idea of an equilibrium maintained by a mechanism like (3.6) whether entirely or only in part, is not in harmony with our notion that molecular mechanics has much in common with the mechanics of ordinary conservative dynamical systems. Barring certain exceptional cases⁸ which can readily be recognized and sorted out, the dynamical laws of familiar conservative systems are always reversible, that means: if the velocities of all the particles present are reversed simultaneously the particles will retrace their former paths, reversing the entire succession of configurations. We like to think that the dynamical laws which govern the world of atoms are also reversible. The information that we have about the atoms affords considerable support for this belief of ours, and we have no serious counter-indications, if any. If the dynamical laws of an isolated molecular system are reversible the kinetic theory requires that in the long run every type of motion must occur just as often as its reverse, because the congruence of the two types of motion makes them *a priori* equivalent. This implies that if we wait a long time so as to make sure of thermodynamic equilibrium, in the end every type of motion

⁸ Coriolis forces, external magnetic fields (and permanent magnets). See §7.

is just as likely to occur as its reverse. One consequence of this *principle of dynamical reversibility* is the condition that when a molecule changes a certain number of times per second from the configuration A to the configuration B the *direct* reverse transition $B \rightarrow A$ must take place equally often, as expressed by (3.5).

In order to see the full analogy between the reciprocal relations (3.5) and 2.4) we must find an expression for the change in free energy involved by the chemical reactions (3.1). Assuming in accordance with the ideal mass-action formula (3.2) that the molecules A , B , and C form an ideal solution we may express the dependance of the "free energy at constant pressure" Z of n_A , n_B and n_C in the form

$$Z = Z_{\min} + RT(n_A \log (n_A/\bar{n}_A) + n_B \log (n_B/\bar{n}_B) + n_C \log (n_C/\bar{n}_C)) \quad (3.7)$$

Thus

$$\delta Z_{(P,T,n)} = RT(\log (n_A/\bar{n}_A)\delta n_A + \log (n_B/\bar{n}_B)\delta n_B + \log (n_C/\bar{n}_C)\delta n_C)$$

We shall introduce the notation

$$x_A = n_A - \bar{n}_A \quad \text{etc.} \quad (3.8)$$

and write

$$\delta Z = -X_A \delta x_A - X_B \delta x_B - X_C \delta x_C.$$

In order to obtain proportionality between the "forces" X and the displacements x we must limit ourselves to the consideration of cases where the system is nearly in equilibrium, i.e.

$$x_A \ll \bar{n}_A \quad \text{etc.}$$

Then we have

$$\begin{aligned} X_A &= -RT \log (n_A/\bar{n}_A) \sim -\frac{RT}{\bar{n}_A} x_A \\ X_B &\sim -\frac{RT}{\bar{n}_B} x_B \\ X_C &\sim -\frac{RT}{\bar{n}_C} x_C. \end{aligned} \quad (3.9)$$

Observing (3.3) and 3.8) the Eqs. (3.2) may be written in form

$$\dot{x}_A = \frac{dx_A}{dt} = -(k_{BA} + k_{CA})x_A + k_{AB}x_B + k_{AC}x_C$$

or, finally, with the aid of (3.9)

$$\begin{aligned} \dot{x}_A &= (k_{BA} + k_{CA})\frac{\bar{n}_A}{RT}X_A - \frac{k_{AB}\bar{n}_B}{RT}X_B - \frac{k_{AC}\bar{n}_C}{RT}X_C \\ \dot{x}_B &= -\frac{k_{BA}\bar{n}_A}{RT}X_A + (k_{AB} + k_{CB})\frac{\bar{n}_B}{RT}X_B - \frac{k_{BC}\bar{n}_C}{RT}X_C \\ \dot{x}_C &= -\frac{k_{CA}\bar{n}_A}{RT}X_A - \frac{k_{CB}\bar{n}_B}{RT}X_B + (k_{AC} + k_{BC})\frac{\bar{n}_C}{RT}X_C. \end{aligned} \quad (3.10)$$

Comparing (3.10) with (2.3) the complete analogy between (3.5) and (2.4) is apparent.⁹

This comparison suggests that reciprocal relations of the type (2.4) can be derived from the principle of microscopic reversibility. It is true that in the above derivation of (3.5) we started out from a special picture; but we saw at least that this picture was not by itself sufficient to yield the reciprocal relations (3.5). The feature that simplified the consideration so much was the assumed mechanism of elementary transitions, which permitted us to apply the condition of reversibility, or "detailed balancing," to each type of transitions separately. We can already recognize the essential elements in the derivation of (1.2) (which is only another form of (2.4)) from the electron theory of metals. In those deductions it was assumed that the rates of transport processes were limited by collisions between particles whose velocities were distributed according to Maxwell's law. Now the collision is in effect a kind of transition leading from a state characterized by one pair of velocities (v_1', v_2') to another state (v_1'', v_2'') . The requirement of microscopic reversibility enters through the condition that the transitions:

$$(v_1', v_2') \rightarrow (v_1'', v_2'') \text{ and } (-v_1'', -v_2'') \rightarrow (-v_1', -v_2')$$

must occur equally often when the system has reached thermodynamic equilibrium.

For a general derivation of reciprocal relations like (2.4) we should like to make no reference whatsoever to any particular type of mechanism. We understand already that any mechanism representing an irreversible process as the net resultant of many independent elementary transitions is liable to yield the expected relations; but we have to deal with many cases where no such mechanism can reasonably be assumed. For that reason we want to consider only the integral changes that are involved by the irreversible process. At the same time we want to apply our basic assumption of microscopic reversibility. There is just one possible way: We must consider the *fluctuations* in a system which has been left isolated for a length of time that is normally sufficient to secure thermodynamic equilibrium.

4. HEAT CONDUCTION AND FLUCTUATIONS OF THE DISTRIBUTION OF ENERGY IN A CRYSTAL

We shall show in a simple concrete example how the principle of microscopic reversibility demands reciprocal relations in transport processes. The

⁹ Strictly speaking, one may object that there is a difference between the two cases inasmuch as x_A , x_B , and x_C are subject to the restriction:

$$\begin{aligned} x_A + x_B + x_C &= 0 \\ \dot{x}_A + \dot{x}_B + \dot{x}_C &= 0 \end{aligned}$$

(because of (3.3) and (3.8)); so that (3.10) actually contains only two independent variables. However, this only means that (3.10) is analogous to a set of equations of the type (2.3) written out for two variables J_1 , J_2 instead of three, i.e., (2.1), with only one reciprocal relation (2.2). This statement may be verified by eliminating one of the variables x , say x_C , in the equations (3.7) etc. The whole complication is quite trivial, and we shall spare ourselves the trouble of going through the details of the calculation here.

consideration of fluctuations will enable us to treat the stationary thermodynamic equilibrium as the average result of transitions in different directions without any explicit assumption regarding elementary transitions. We must of course connect the fluctuations with the macroscopic laws of thermodynamics and irreversible processes by reasonable general assumptions. The principles involved are not new; they are classical theorems of statistical mechanics. To begin with, let us contrast the thermodynamic to the statistical point of view.

In thermodynamics we assume that when a system has been left isolated for a sufficient length of time it will reach a state of equilibrium, where all the visible properties of the system remain constant. The approach to equilibrium is irreversible.

The kinetic theory allows only a statistical interpretation of the second law of thermodynamics; the reversible fundamental laws of dynamics are not compatible with absolutely irreversible processes. For instance, we take the point of view that the uniform distribution of a gas within an enclosure is a stable equilibrium state simply because any other distribution is much less probable. We recognize the possibility that a gas may by some freak occurrence compress itself without external aid into one-half of the available volume, although we do not expect ever to observe such an event; the probability is exceedingly small, namely: 2^{-N} , where N is the total number of molecules present. While such large deviations from the normal are exceedingly rare smaller deviations will occur much more frequently, and the common deviations from the average number of molecules in either half of the vessel will be of the order of magnitude $(N)^{1/2}$.

In connection with the theory of heat conduction we shall naturally study the fluctuating deviations from the thermal equilibrium. For instance, we may follow the variations in the position of the center of gravity of the energy.¹⁰ According to thermodynamics this point will remain at rest after thermal equilibrium has been reached. According to statistical mechanics we may expect a succession of slightly asymmetrical distributions of energy. Then the motion of the center of gravity of the distribution is a legitimate object of study.

The ordinary macroscopic laws of heat conduction relate the flow of heat to the temperature gradient at any given time, so that the distribution of energy at any one time determines all subsequent distributions. From the point of view of the kinetic theory this pre-determination cannot be interpreted as absolute; for instance, we do not expect to find an ultimate motionless and completely uniform distribution as required by the macroscopic laws. Still these laws will have a quite definite meaning in the kinetic theory as well. Suppose that we reproduce the same distribution of energy many times independently. Then the subsequent distributions will not be exactly the same in all cases, nor will the rates of change agree exactly with the macroscopic laws in each individual case; but the average rates for a large number

¹⁰ Coordinates $\xi_1 = \alpha_1/E$; $\xi_2 = \alpha_2/E$, α_1 and α_2 being defined by (4.3). We must of course make an arbitrary convention about the total content of energy E .

of cases will follow definite laws, and these laws will agree exactly with the macroscopic laws for the conduction of heat.

We also expect that an asymmetric distribution of energy will be exactly the same whether it has arisen accidentally from fluctuations or has been produced purposely by means of suitable external heating and cooling. Once a given distribution of energy is present its history is immaterial, but, as we have pointed out above, the distribution that is present at any given time determines an average expectancy for the rates of the subsequent changes. In all instances this average expectancy for the rate of transport of heat is related to the momentary distribution by the ordinary macroscopic laws for the conduction of heat.

We shall consider the simplest case that is not trivial, namely: a crystal with a 3-, 4- or 6- counting axis of symmetry (x_3)

$$x_1 + ix_2 \rightarrow (x_1 + ix_2)e^{2\pi im/n} \quad (n = 3, 4 \text{ or } 6) \quad (4.1)$$

$$(m = 1, 2, \dots)$$

and no other elements of symmetry except possibly a plane of symmetry perpendicular to x_3 ($x_3 \rightarrow -x_3$) and a center of symmetry ($x_1, x_2, x_3 \rightarrow -x_1, -x_2, -x_3$). The equations for the conduction of heat take the form (2.8), or

$$\begin{aligned} -TJ_1 &= \lambda_1 \partial T / \partial x_1 + \omega_3 \partial T / \partial x_2 \\ -TJ_2 &= -\omega_3 \partial T / \partial x_1 + \lambda_1 \partial T / \partial x_2 \\ -TJ_3 &= \lambda_3 \partial T / \partial x_3. \end{aligned} \quad (4.2)$$

Since clockwise and counterclockwise rotations are not equivalent, and $\omega_3 \gtrless 0$ and the spiral motion of heat which we mentioned in §2 are allowed by the symmetry of the crystal. However, if we may rely on the principle of microscopic reversibility, then a state of motion in any direction is equivalent to a state of motion in the opposite direction, and for that reason ω_3 must vanish. Argument and statements are admittedly incomplete. We could not reason in such a simple manner if the case were not so symmetrical, nor would the results be quite as simple. However, let us undertake a more detailed analysis.

We shall study the fluctuations of the distribution of energy in an isolated crystal. In order to take full advantage of the rotational symmetry expressed by (4.1) and (4.2) we give the external shape of the crystal rotational symmetry about the x_3 axis. The origin of our frame of reference may be at the center of gravity of the crystal; the orientation of the axes is already determined by the symmetry. We shall consider displacements of heat in the directions x_1 and x_2 . We measure the asymmetry of a given distribution of heat by the moments

$$\begin{aligned} \alpha_1 &= \int \epsilon \cdot x_1 dV \\ \alpha_2 &= \int \epsilon \cdot x_2 dV \end{aligned} \quad (4.3)$$

where $\epsilon = \epsilon(x_1, x_2, x_3)$ is the local density of energy,¹¹ and the integration is extended over the total volume V of the crystal. The displacements α_1 and α_2 will differ a little from zero most of the time because of fluctuations; their averages will vanish

$$\bar{\alpha}_1 = \bar{\alpha}_2 = 0.$$

For reasons of symmetry the average squares of α_1 and α_2 must be equal, and displacements in the directions x_1 and x_2 will be independent

$$\overline{\alpha_1^2} = \overline{\alpha_2^2}; \quad \overline{\alpha_1 \alpha_2} = 0. \quad (4.4)$$

The same displacement (α_1, α_2) of energy may be produced by different distributions of energy, and, accordingly, of temperature. However, to each value of α_1 , there will correspond a certain average temperature gradient

$$\overline{\partial T / \partial x_1}^{\alpha_1} = -T \bar{X}_1(\alpha_1)$$

in the x_1 direction, the averaging to be extended over all cases where α_1 takes the same value, and in each case over all volume elements of the crystal. This average gradient will be proportional to α_1 :

$$\overline{\partial T / \partial x_1}^{\alpha_1} = -T \bar{X}_1(\alpha_1) = TC\alpha_1.$$

In a similar manner

$$\overline{\partial T / \partial x_2}^{\alpha_2} = -T \bar{X}_2(\alpha_2) = TC\alpha_2$$

and if we consider a displacement (α_1, α_2) in an arbitrary direction:

$$\begin{aligned} -T \bar{X}_1(\alpha_1, \alpha_2) &= TC\alpha_1 \\ -T \bar{X}_2(\alpha_1, \alpha_2) &= TC\alpha_2 \end{aligned} \quad (4.5)$$

The factor C can be calculated on the basis of the general theory of fluctuations.¹² In this particular case we shall be content to know that α_1 causes no temperature gradient in the x_2 direction, and *vice versa*, in spite of the fact that rotations in opposite directions in the x_1, x_2 plane are not equivalent. The reason is that in questions regarding the distribution the anisotropy of the crystal is immaterial anyway, and only the external boundary of the crystal is important, because all the volume elements of a homogeneous crystal are equivalent irrespective of location or mutual connections. The anisotropy becomes important as soon as one considers the *rate of exchange* of energy.

The temperature gradient determines the average rate of transport of heat according to (4.2)

$$\begin{aligned} \bar{J}_1(\alpha_1, \alpha_2) &= \lambda_1 \bar{X}_1(\alpha_1, \alpha_2) + \omega_2 \bar{X}_2(\alpha_1, \alpha_2) = -\lambda_1 C \alpha_1 - \omega_2 C \alpha_2 \\ \bar{J}_2(\alpha_1, \alpha_2) &= -\omega_2 \bar{X}_1(\alpha_1, \alpha_2) + \lambda_1 \bar{X}_2(\alpha_1, \alpha_2) = \omega_2 C \alpha_1 - \lambda_1 C \alpha_2. \end{aligned} \quad (4.6)$$

¹¹ Strictly speaking, one may identify heat with energy only when the crystal has no thermal expansion in any direction. In general heat must be defined as energy less work of deformation and expansion. This complicates the discussion slightly without changing the results; the symmetry conditions (4.4) and (4.5) remain valid.

¹² Einstein, Ann. d. Physik 33, 1275 (1910).

Finally, if V is the volume, then $V\bar{J}_1$ is the total rate of transport of heat in the x_1 direction:

$$d\alpha_1/dt = V\bar{J}_1$$

and we obtain

$$\begin{aligned}\overline{d\alpha_1/dt} &= -\lambda_1 V C \alpha_1 - \omega_3 V C \alpha_2 \\ \overline{d\alpha_2/dt} &= \omega_3 V C \alpha_1 - \lambda_1 V C \alpha_2.\end{aligned}\quad (4.7)$$

Suppose now that we watch our crystal for a great length of time. Whenever the displacement of energy in the x_1 direction happens to be $\alpha_1 = \alpha_1'$ we note down the displacement α_2 in the x_2 direction Δt seconds later. The average of a great number of such observations we shall denote by

$$\bar{\alpha}_2(\Delta t, \alpha_1').$$

For reasons of symmetry

$$\bar{\alpha}_2(0, \alpha_1') = 0$$

because this average does not depend on the rate of transport, but only on the relative probabilities of different distributions of energy (simultaneous values of α_1 and α_2). The average change of α_2 in a time Δt subsequent to distributions for which $\alpha_1 = \alpha_1'$ is therefore

$$\bar{\alpha}_2(\Delta t, \alpha_1') - \bar{\alpha}_2(0, \alpha_1') = \bar{\alpha}_2(\Delta t, \alpha_1').$$

If Δt is sufficiently small we can calculate this change from (4.7):

$$\bar{\alpha}_2(\Delta t, \alpha_1') = \bar{\alpha}_2(\Delta t, \alpha_1') - \bar{\alpha}_2(0, \alpha_1') = \overline{d\alpha_2/dt}^{\alpha_1'} \cdot \Delta t = \omega_3 V C \alpha_1' \Delta t \quad (4.8)$$

Now we can calculate the average product

$$\overline{\alpha_1(t)\alpha_2(t+\Delta t)} = \lim_{t'' \rightarrow \infty} \frac{1}{t'' - t'} \int_{t=t'}^{t=t''} \alpha_1(t)\alpha_2(t+\Delta t) dt$$

Obviously:

$$\overline{\alpha_1(t)\alpha_2(t+\Delta t)} = \overline{\alpha_1' \bar{\alpha}_2(\Delta t, \alpha_1')} = \omega_3 V C \bar{\alpha}_1^2 \Delta t. \quad (4.9a)$$

In a similar manner, or directly from (4.9a) by taking into account the rotational symmetry (4.1) of the crystal we obtain:

$$\overline{\alpha_2(t)\alpha_1(t+\Delta t)} = -\omega_3 V C \bar{\alpha}_1^2 \Delta t = -\omega_3 V C \bar{\alpha}_2^2 \Delta t. \quad (4.9b)$$

Here

$$\bar{\alpha}_1^2 = \bar{\alpha}_2^2$$

The principle of microscopic reversibility demands that a displacement $\alpha_1 = \alpha_1'$ of energy in the x_1 direction, followed τ seconds later by a displacement $\alpha_2 = \alpha_2''$ in the x_2 direction, must occur just as often as $\alpha_2 = \alpha_2''$, followed τ seconds later by $\alpha_1 = \alpha_1'$. Consequently

$$\overline{\alpha_1(t)\alpha_2(t+\tau)} = \overline{\alpha_2(t)\alpha_1(t+\tau)} \quad (4.10)$$

where τ may have any value, for example $\tau = \Delta t$. Comparing with (4.9a, b) we have

$$\omega_3 = 0 \quad (4.11)$$

in accordance with Voigt's experimental result,⁷ the simplest example of a reciprocal relation in irreversible processes.

Here we have taken a little more out of the principle of microscopic reversibility than we did in section 3 with the assertion that transitions between two (classes of) configurations A and B should take place equally often in the directions $A \rightarrow B$ and $B \rightarrow A$ in a given time τ . Above we have discussed transitions between different distributions of energy. We must expect that the energy will depend not only on the configuration of elementary particles, but also on their velocities; we do not know exactly how. However, assuming microscopic reversibility, the energy must depend on the velocities in such a manner that every type of motion has the same energy as its reverse; otherwise a "reverse" energy would exist, different from the ordinary energy but with similar properties of conservation, and we should not know the energy as a unique function of the state of the system. If the energy can be localized so that we can speak about distributions of energy in space, the distribution of energy must be the same for corresponding phases of direct and reverse motion, or similar discrepancies would arise. Since, by hypothesis, direct and reverse motion of every conceivable type occur pairwise equally often, if A and B be two distributions of energy, the transitions $A \rightarrow B$ and $B \rightarrow A$ (in time intervals of a given length τ) must occur equally often.

We shall comment on another question regarding the premises of the derivation, although the substance of a satisfactory answer is known from a famous discussion between Loschmidt and Boltzmann.¹³ We have assumed microscopic reversibility, and at the same time we have assumed that the average decay of fluctuations will obey the ordinary laws of heat conduction. Already an apparent contradiction occurs when we consider the simpler case of heat conduction in one dimension. Let α be a displacement of heat, then:

$$\dot{\alpha} = d\alpha/dt = -K\alpha. \quad (4.12)$$

Microscopic reversibility requires

$$\bar{\alpha}(\tau, \alpha') = \bar{\alpha}(-\tau, \alpha'). \quad (4.13)$$

Clearly

$$\dot{\alpha}(\tau, \alpha') = -\dot{\alpha}(-\tau, \alpha')$$

and:

$$\dot{\alpha}(0, \alpha') = -\dot{\alpha}(0, \alpha') = 0.$$

According to the ordinary laws for conduction of heat $\bar{\alpha}$ decreases for positive τ (if $\alpha' > 0$). According to (4.13), then, $\bar{\alpha}$ increases for negative τ (average growth of fluctuations), and $\dot{\alpha} = 0$ for $\tau = 0$. It may appear somewhat startling

¹³ See P. and T. Ehrenfest. *Enz. d. math. Wiss.* IV. 32.

that we apply (4.12) to fluctuations only for $\tau > 0$, and not for $\tau \leq 0$. Yet in this there is no logical contradiction—we have stated bluntly and honestly that α has a discontinuity for $\tau = 0$ —but such a statement disappoints our expectation of continuity in nature. However, the objection is removed when we recognize that (4.12) is only an approximate description of the process of conduction, neglecting the time needed for acceleration of the heat flow. This time τ_0 is probably rather small, e.g. in gases it ought to be of the same order of magnitude as the average time spent by a molecule between two collisions. For practical purposes the time-lag can be neglected in all cases of heat conduction that are likely to be studied, and this approximation is always involved in the formulation of laws like (4.12), (4.7) and (4.2). Even the differential form (e.g. (4.8)) of these equations is justified; because we can usually choose a time Δt such that:

$$1 \gg K\Delta t \gg K\tau_0.$$

Then following $t = \tau_0$, which is practically the same as $t = 0$, we have a time interval $\Delta t \gg \tau_0$ in which (by (4.12)) α and therefore $d\alpha/dt$ are sensibly constant. We may also recall that the time needed for equalization of temperature in a body is proportional to the square of its linear dimensions l , i.e.:

$$K \sim 1/l^2.$$

In gases $K\tau_0$ should be of the order l^2/Λ^2 , where Λ is the mean free path. The ordinary laws for conduction of heat are therefore asymptotic laws for $l \gg \Lambda$.

The preceding considerations leading to (4.11) are easily extended to the more general case of heat conduction in a crystal of arbitrary symmetry. The phenomenological equations have the form

$$\begin{aligned} J_1 &= L_{11}X_1 + L_{12}X_2 + L_{13}X_3 \\ J_2 &= L_{21}X_1 + L_{22}X_2 + L_{23}X_3 \\ J_3 &= L_{31}X_1 + L_{32}X_2 + L_{33}X_3 \end{aligned} \quad (2.3)$$

where

$$TX_1 = -\partial T/\partial x_1; \quad TX_2 = -\partial T/\partial x_2; \quad TX_3 = -\partial T/\partial x_3. \quad (4.14)$$

We shall derive the reciprocal relations:

$$L_{12} = L_{21}; \quad L_{23} = L_{32}; \quad L_{31} = L_{13}. \quad (2.4)$$

We chose the external shape of our crystal spherical. Since the anisotropy of the crystal has nothing to do with the distribution of heat the arguments leading to (4.4) and (4.5) apply equally well in this case, and we obtain

$$\begin{aligned} \overline{\alpha_1^2} &= \overline{\alpha_2^2} = \overline{\alpha_3^2}; \quad \overline{\alpha_1\alpha_2} = \overline{\alpha_2\alpha_3} = \overline{\alpha_3\alpha_1} = 0 \\ -\overline{X_1}(\alpha_1, \alpha_2, \alpha_3) &= C\alpha_1 \\ -\overline{X_2}(\alpha_1, \alpha_2, \alpha_3) &= C\alpha_2 \\ -\overline{X_3}(\alpha_1, \alpha_2, \alpha_3) &= C\alpha_3. \end{aligned} \quad (4.15)$$

Instead of (4.6) and (4.7) we find

$$\begin{aligned}\overline{J_1}(\alpha_1, \alpha_2, \alpha_3) &= -L_{11}C\alpha_1 - L_{12}C\alpha_2 - L_{13}C\alpha_3, \text{ etc.} \\ \overline{d\alpha_1/dt} &= -L_{11}VC\alpha_1 - L_{12}VC\alpha_2 - L_{13}VC\alpha_3, \text{ etc.}\end{aligned}$$

The analogy of (4.8) becomes

$$\overline{\alpha_2(\Delta t, \alpha_1')} = \overline{d\alpha_2/dt} \alpha_1' \Delta t = -L_{21}VC\alpha_1' \Delta t$$

and we have in the place of (4.9)

$$\overline{\alpha_1(t)\alpha_2(t+\Delta t)} = \overline{\alpha_1' \overline{\alpha_2}(\Delta t, \alpha_1')} = -L_{21}VC\alpha_1'^2 \Delta t \quad (4.16a)$$

Likewise

$$\overline{\alpha_2(t)\alpha_1(t+\Delta t)} = -L_{12}VC\alpha_2'^2 \Delta t \quad (4.16b)$$

Microscopic reversibility (4.10) requires

$$\overline{\alpha_1(t)\alpha_2(t+\Delta t)} = \overline{\alpha_2(t)\alpha_1(t+\Delta t)}.$$

Comparison with (4.16a, b) and (4.15) yields the generalization of (4.11)

$$L_{12} = L_{21}.$$

The other two equations in (2.4) are obviously derived in the same way.

5. THE PRINCIPLE OF THE LEAST DISSIPATION OF ENERGY

Like the reciprocal relations of mechanics and thermodynamics the relations (2.4) can be expressed in terms of a potential, and permit the formulation of a variation principle. As a preliminary we re-write (2.3) and (4.14) expressing the "forces" X by the "velocities" J :

$$\begin{aligned}-\frac{1}{T} \frac{\partial T}{\partial x_1} &= X_1 = R_{11}J_1 + R_{12}J_2 + R_{13}J_3 \\ -\frac{1}{T} \frac{\partial T}{\partial x_2} &= X_2 = R_{21}J_1 + R_{22}J_2 + R_{23}J_3 \\ -\frac{1}{T} \frac{\partial T}{\partial x_3} &= X_3 = R_{31}J_1 + R_{32}J_2 + R_{33}J_3\end{aligned} \quad (5.1)$$

where $R_{11} \dots R_{33}$ are connected with $L_{11} \dots L_{33}$ in (2.3) by the well known relations

$$\sum_{m=1}^3 L_{im} R_{mk} = \sum_{m=1}^3 R_{im} L_{mk} = \delta_{ik} = \begin{cases} 1 & (i = k) \\ 0 & (i \neq k) \end{cases}$$

and the reciprocal relations (2.4) are equivalent to:

$$R_{12} = R_{21}; R_{13} = R_{31}; R_{23} = R_{32}. \quad (5.2)$$

Here, if we write:

$$2\phi(J, J) \equiv \frac{1}{T} \sum_{i,k} R_{ik} J_i J_k \quad (5.3)$$

the relations (5.1) may be written:

$$\frac{1}{T}X_k = \frac{\partial}{\partial x_k}\left(\frac{1}{T}\right) = \frac{\partial \phi(J, J)}{\partial J_k}. \quad (5.4)$$

We also observe that:

$$2T\phi(J, J) \equiv \sum_{k=1}^3 J_k T \partial \phi / \partial J_k = J_1 X_1 + J_2 X_2 + J_3 X_3 \quad (5.5)$$

The function $\phi(J, J)$ we shall call the *dissipation-function*. It is a direct generalization of a function which was introduced by Lord Rayleigh¹⁴ and applied to mutual interaction of frictional forces; it plays the part of a *potential* for such forces. Actually Lord Rayleigh used the function $F(J, J) = T\phi(J, J)$ and called F the dissipation-function; for our purposes we shall find the function ϕ more generally useful. As we shall see immediately, $2\phi(J, J)$ equals the rate of production of entropy due to heat flow across a volume element (of unit size), so that $2T\phi = 2F$ equals the rate of "dissipation" of free energy.

The rate of local accumulation of heat equals

$$Tds/dt = -\operatorname{div} J = -\partial J_1/\partial x_1 - \partial J_2/\partial x_2 - \partial J_3/\partial x_3 \quad (5.6)$$

writing s for the local entropy density, and the total rate of increase of the entropy S equals

$$dS/dt = \int (ds/dt)dV = \int \left(-\frac{1}{T} \operatorname{div} J \right) dV.$$

By Green's theorem:

$$\begin{aligned} & \int \int \int (-\operatorname{div} J) \frac{1}{T} dV + \int \int \frac{J_n}{T} d\Omega = \int \int \int \left(J, \operatorname{grad} \frac{1}{T} \right) dV \\ & = \int \int \int \left(J_1 \frac{\partial}{\partial x_1} \left(\frac{1}{T} \right) + J_2 \frac{\partial}{\partial x_2} \left(\frac{1}{T} \right) + J_3 \frac{\partial}{\partial x_3} \left(\frac{1}{T} \right) \right) dV \end{aligned}$$

where the double integral on the left is extended over the boundary Ω of the body in question, and J_n is the normal component of the heat flow at the boundary. If we write

$$\dot{S}^*(J_n) \equiv \int \int (J_n/T) d\Omega \quad (5.7)$$

for the entropy given off to the surroundings, and

$$\dot{S}(J) \equiv \int \int \int \left(-\frac{1}{T} \operatorname{div} J \right) dV \quad (5.8)$$

¹⁴ Lord Rayleigh, Proc. Math. Soc. London 4, 357, [363], (1873). Theory of Sound, (London, MacMillan Co., 1st ed. 1877), Vol. I, p. 78; (2d ed. 1894), Vol. I, p. 102.

for the entropy change of the system proper, we have:

$$\begin{aligned}\dot{S}(J) + \dot{S}^*(J_n) &\equiv \int \left(J, \text{grad} \frac{1}{T} \right) dV \equiv \int \sum_k J_k \frac{\partial}{\partial x_k} \left(\frac{1}{T} \right) dV \\ &\equiv \int \frac{1}{T} \sum_k J_k X_k dV\end{aligned}\quad (5.9)$$

(observing (4.14)). Now, by (5.4) and (5.5)

$$\int \sum_k J_k \frac{\partial}{\partial x_k} \left(\frac{1}{T} \right) dV = \int \sum_k J_k \frac{\partial \phi(J, J)}{\partial J_k} dV = \int 2\phi(J, J) dV.$$

Inserting this in (5.9) we find

$$2\phi(J, J) \equiv 2 \int \phi(J, J) dV = \dot{S}(J) + \dot{S}^*(J_n). \quad (5.10)$$

Now we shall show that the relations (5.4) are equivalent to the *variation principle*

$$\dot{S}(J) + \dot{S}^*(J_n) - \Phi(J, J) = \text{maximum} \quad (5.11)$$

with the conventions that the temperature distribution $T(x_1, x_2, x_3)$ is prescribed, the flow $J(x_1, x_2, x_3)$ is varied, and the functions \dot{S} , \dot{S}^* and Φ are defined by (5.7), (5.8) and (5.10), respectively (reading \equiv), but not $(=)$: "identical in J ". Observing (5.9) we have

$$\begin{aligned}\delta[\dot{S}(J) + \dot{S}^*(J_n) - \Phi(J, J)] \\ &= \delta \int \left[\sum_k J_k \frac{\partial}{\partial x_k} \left(\frac{1}{T} \right) - \phi(J, J) \right] dV \\ &= \int \sum_k \left[\frac{\partial}{\partial x_k} \left(\frac{1}{T} \right) - \frac{\partial}{\partial J_k} \phi(J, J) \right] \delta J_k dV\end{aligned}$$

so that (5.4) is clearly equivalent to

$$\delta[\dot{S}(J) + \dot{S}^*(J_n) - \Phi(J, J)] = 0.$$

Here, since \dot{S} and \dot{S}^* are linear functionals of J , and Φ is a homogeneous quadratic functional, the expression in the brackets can have only one extremum. This extremum is a maximum because $\Phi(J, J)$ must be positive-definite (otherwise (5.10) would not agree with the second law of thermodynamics).

If the boundary is isolated the restriction

$$J_n = 0 \quad (5.12)$$

enters, and, since then $\dot{S}^*(J_n)$ vanishes

$$\dot{S}(J) - \Phi(J, J) = \text{maximum}. \quad (5.13)$$

Thus the vector field J of the heat flow is described by the condition that the rate of increase of the entropy, less the dissipation-function, be a maximum.

In applications the difference between the formulations (5.11) and (5.13) is trivial. From a fundamental point of view (5.13) has some merit of greater simplicity because it applies to an isolated system, and is thus more directly connected with the theory of fluctuations. Above we have demonstrated (5.13) for anisotropic heat conduction. A more general theorem applying to all transport processes (conduction of electricity and heat, and diffusion) can be derived in a similar manner, only it is then necessary to make full use of the general theory of fluctuations, involving Boltzmann's classical relation between entropy S and probability W

$$S = k \log W + \text{const.}$$

This general development will be deferred to a following communication.

6. STATIONARY FLOW AND QUASI-THERMODYNAMICS

A brief discussion of the conditions for stationary flow of heat through an anisotropic body will bring out an interesting simple consequence of (5.11) and throw light on the connection with previous quasi-thermodynamic derivations of reciprocal relations in irreversible processes.

The condition for stationary flow of heat is

$$\text{div } J = \partial J_1 / \partial x_1 + \partial J_2 / \partial x_2 + \partial J_3 / \partial x_3 = 0 \quad (6.1)$$

for the interior of the body under consideration. No heat is accumulated in the interior, so that $\dot{S}(J) = 0$. Thus (5.11) becomes:

$$\dot{S}^*(J_n) - \Phi(J, J) = \text{maximum} \quad (6.2)$$

Eqs. (6.1) and (6.2) determine the field of flow J as well as the temperatures in the interior when the temperatures at the boundary are prescribed. (An eventual dependence of $\phi(J, J)$ on the temperature should be ignored in carrying out the variation: $\delta\phi(J, J) = \Sigma(\partial\phi/\partial J_k)\delta J_k$). In this case, where $\dot{S}(J) = 0$, (5.10) becomes

$$\dot{S}^*(J_n) = 2\Phi(J, J) \quad (6.3)$$

and we have

$$2(\dot{S}^*(J_n) - \Phi(J, J)) = \dot{S}^*(J_n).$$

We may therefore state (6.2) in the alternative form

$$\dot{S}^*(J_n) = \text{maximum} \quad (6.4)$$

with the restrictions (6.1) and (6.3).

Now let us consider the effect of obstacles to the heat flow, like cracks in the crystal, introducing restrictions of the type:

$$J_n' = 0$$

for the changed heat flow J' at certain interior surfaces. Since the field J of the original heat flow made $\dot{S}^*(J_n)$ a maximum under restrictions that are also imposed on J' , we must have

$$\dot{S}^*(J_n) \geq \dot{S}^*(J_n') \quad (6.5)$$

Restrictions can only decrease the rate of production of entropy, or cause no change.

Assumptions of the type (6.5) are involved in all quasi-thermodynamic derivations proposed by earlier writers for reciprocal relations in irreversible processes. As good an example as any is Thomson's case (1.1), where J_1 is the electrical current and J_2 the heat flow (in the same direction). We maintain a constant temperature gradient $-TX_2$, while X_1 may be varied. The restriction: $J_1=0$ may be imposed by breaking the electric circuit. The rate of production of entropy equals

$$\dot{S}(J) + \dot{S}^*(J_n) = (V/T)(X_1J_1 + X_2J_2)$$

(cf. (5.9)). With the aid of (1.1) we transform this relation into:

$$T(\dot{S}(J) + \dot{S}^*(J_n)) = (V/R_{22})[X_2^2 + (R_{12} - R_{21})X_2J_1 + (R_{11}R_{22} - R_{12}R_{21})J_1^2].$$

Here, if we assume that the restriction

$$J_1 = 0$$

makes $\dot{S} + \dot{S}^*$ a minimum for given X_2 (cf. (6.5)), we find

$$R_{12} - R_{21} = 0. \quad (1.2)$$

In conclusion, let us describe the case which has given name to the "principle of the least dissipation of energy." The flow of heat J_n across all sections of the boundary Ω is prescribed, and the condition

$$\int J_n d\Omega = 0$$

is fulfilled. Then $\dot{S}^*(J_n)$ in (6.2) is prescribed, and the condition for stationary flow reduces to

$$\Phi(J, J) = \text{minimum} \quad (6.6)$$

subject to the restrictions:

$$J_n \text{ prescribed} \quad (6.7)$$

$$\operatorname{div} J = 0. \quad (6.1)$$

These conditions determine J , and the temperatures are determined everywhere if known at one point.

7. NON-REVERSIBLE SYSTEMS

A dynamical system is reversible as long as the (mechanical) forces depend only on the coordinates or, if they depend on the velocities as well, are even functions of these. We know *conservative* systems which do not fulfill this condition. (i) An electric charge moving in a magnetic field is deflected by a force proportional to the product of charge and velocity. (ii) Relative to a rotating frame of reference a free particle moves as if it were subject to a transverse force proportional to the product of mass and velocity (Coriolis force) besides the centrifugal force.

When magnetic forces and Coriolis forces destroy the reversibility of macroscopic motion we must expect that the microscopic motion will fare no better. The reciprocal relations (2.4) and their equivalent, the principle of the least dissipation of energy (5.11) are derived from the assumption of microscopic reversibility. We may expect that these relations will break down in cases where magnetic or Coriolis forces are acting, and they do. The influence of Coriolis forces on heat conduction is presumably small and not easily studied; but magnetic fields are known to modify the relation between heat flow and temperature gradient in metals. In an isotropic body, the simplest case, the temperature gradient has the same direction as the heat flow as long as no magnetic field is present. However, if a transverse magnetic field is applied the temperature gradient will have a component in the third direction perpendicular to flow and field. The direction of the temperature gradient is rotated with respect to the heat flow, about an axis parallel to the magnetic field. This phenomenon is known as the Righi-Leduc effect. If a circular metal plate is placed perpendicular to the magnetic field, heated in the middle and cooled at the edge, the heat will flow outward in spirals. The equations of the heat flow take the form (2.8), or rather

$$\begin{aligned} J_1 &= \lambda X_1 + \omega X_2 \\ J_2 &= -\omega X_1 + \lambda X_2 \\ J_3 &= \lambda X_3 \end{aligned} \quad (7.1)$$

where ω is proportional to the intensity of the magnetic field (for weak fields); the field is thought parallel to the x_3 direction. The principle of the least dissipation of energy is no longer valid; radial cracks in the plate will *increase* the rate of radial transport of heat for a given temperature gradient.

More familiar than the Righi-Leduc effect is perhaps the Hall effect. When a constant current is flowing through a metallic conductor a transverse magnetic field causes an e.m.f. perpendicular to both. Eqs. (7.1) describe the isotropic case if J_1, J_2, J_3 , denote the components of the current and X_1, X_2, X_3 the components of the electric field.

In the presence of a magnetic field the principle of microscopic reversibility may be applied in a modified form: The entire motion may be reversed by reversing the magnetic field together with the velocities of all the particles composing a dynamical system. Eqs. (7.1) are in accord with this requirement.

An analogous effect of Coriolis forces is known in hydrodynamics. The principle of the least dissipation of energy applies to the motion of very viscous fluids (Stokes' limiting case) as long as the motion is not referred to a rotating frame of reference.

THE DIELECTRIC CONSTANT AND ELECTRIC MOMENT OF SOME AMINES

BY P. N. GHOSH AND T. P. CHATTERJEE

APPLIED PHYSICS LABORATORY, CALCUTTA UNIVERSITY

(Received January 6, 1931)

ABSTRACT

By using a heterodyne null-beat arrangement, the electric moments have been calculated and the following results obtained: methyl amine, $A = 1.37 \times 10^{-3}$, $\mu = 0.99 \times 10^{-18}$; dimethyl amine, $A = 1.22 \times 10^{-3}$, $\mu = 0.90 \times 10^{-18}$; trimethyl amine, $A = 1.19 \times 10^{-3}$, $\mu = 0.82 \times 10^{-18}$; ethylamine, $A = 2.37 \times 10^{-3}$, $\mu = 0.99 \times 10^{-18}$; diethyl amine, $A = 2.59 \times 10^{-3}$, $\mu = 0.90 \times 10^{-18}$; and triethyl amine, $A = 2.90 \times 10^{-3}$, $\mu = 0.82 \times 10^{-18}$.

INTRODUCTION

IT HAS been found by several investigators that the dipole moment for a series of homologues is sensibly constant and is the property of a polar group present in them. For the primary alcohols¹ such a relationship has been obtained. The halogen-derivatives² of methane and ethane also support this view. Hojen-dahl³ has tested the above hypothesis in many other cases. On the basis of certain assumptions, he has calculated the dipole-moment from the data of Pohrt⁴ who had used a bridge method to determine the dielectric constants of vapors at a standard temperature and at varying pressures. It was, however, found from his calculations, that the amines do require a more careful study and thus form the object of the present investigation.

EXPERIMENTAL

The apparatus used was the heterodyne null-beat arrangement described by Mahanti in a recent paper.² The same procedure was followed for the measurements presented in this paper.

The electric moments have been calculated from the relation

$$\mu^2 = 1.208 \times 10^{-36} B, \quad (1)$$

which has been deduced from the Debye equation.

DISCUSSION

It is evident from Table II that the dipole-moments of the methyl and ethyl amines are equal in magnitude while those of dimethyl and diethyl amines are among themselves equal. The dipole-moments of the trimethyl

and the triethyl amines present a similar result. Thus in the case of the *n*-amines, the polar group (NH_2) is mainly responsible for the development of the dipole-moment in the molecule. Similarly the (NH) group in the diamines and the (N) radicle in the triamines give rise to dipole moments in the respective molecules.

TABLE II.

Compound	<i>A</i>	<i>B</i>	$\mu \times 10^{18}$	Calculated values of Hojendahl
Methyl amine	0.00137	0.826	0.99	1.31
Dimethyl amine	0.00122	0.675	0.90	1.05
Trimethyl amine	0.00110	0.560	0.82	—
Ethyl amine	0.00237	0.826	0.99	1.31
Diethyl amine	0.00259	0.675	0.90	0.94
Triethyl amine	0.00290	0.560	0.82	0.76

Table II also indicates that the dielectric constant increases with the boiling points of the compounds as is usually expected. The only exception is found in the case of methyl amine.

It is also interesting to note that Venkateswaran and Bhagavantham⁵ have found a Raman line arising from a frequency of 3300 cm^{-1} (approx.) present in both methyl and ethyl amines, and have attributed this to the N-H linkage. This line, is however, absent in the spectrum of triethylamine.

VARIATIONS WITH TEMPERATURE AND FREQUENCY OF
DIELECTRIC LOSS IN A VISCOUS, MINERAL,
INSULATING OIL

BY HUBERT H. RACE

GENERAL ELECTRIC COMPANY, SCHENECTADY, NEW YORK

(Received December 29, 1930)

ABSTRACT

Debye's theory of polar molecules has been extended to give simple expressions for conditions of maximum loss per cycle in terms of equivalent circuit bridge or substitution measurements. The *dielectric loss* in a good grade of viscous mineral insulating oil has been separated into two components; one resulting from conduction, and the other showing characteristics with frequency and temperature qualitatively explained on the basis of the presence of polar molecules in the oil. A quantitative check shows the order of magnitude of this second loss to be the same as that which would be predicted by Debye's theory. The experimental curve shows a wider frequency response than the theoretical curve, indicating that the simple theory is not sufficient to account for the observed data. This may result from the presence of polar molecules of many different sizes giving an average response rather than molecules of one size only, as assumed in the theory. The size of the polar molecules necessary to give the observed effects was calculated from Debye's theory and found to be of the right order of magnitude. Data taken over a wide range of frequency and temperature indicate the danger in drawing conclusions as to the characteristics of a material from data taken for limited ranges of experimental conditions. The curves show that either increasing or decreasing *power factor* can be obtained as a function of either frequency or temperature for certain narrow limits of experimental conditions. The dielectric loss in good commercial mineral insulating oils at power frequencies and operating temperatures results from conduction only, the contribution of polar molecules to the loss being negligible. Before a definite statement is made regarding the mechanism of the observed loss, studies should be made to determine whether a satisfactory theory can be developed which is based only on the motion of charged particles in a viscous medium.

INTRODUCTION

THE object of this investigation is the experimental and theoretical study of the changes of the electrical characteristics of a viscous insulating oil, such as is used in "solid type" cables, with changes in temperature and in frequency of the applied alternating potential. The data reported in this paper have been collected at intervals during the past eighteen months. Previous tests have shown that, under certain conditions, the d.c. conductivity and the equivalent parallel a.c. conductivity calculated from 1000 cycle bridge measurements, are identical.* Therefore, the ranges of frequency and temperature were extended to determine under what conditions this agreement fails. The work of Kitchin and Müller¹ indicated the possibility of explaining

* These tests are reported in a paper on "Some Electrical Characteristics of Cable Oils," which has been submitted for publication in the A.I.E.E. Journal.

¹ D. W. Kitchin and Hans Müller, Phys. Rev. 32, 979 (1928).

variations in dielectric loss with frequency and temperature in terms of Debye's theory of polar molecules. The desire to check this theory offered another incentive in making the experiments reported in this paper.

The resulting data show characteristics qualitatively similar to those predicted by Debye's theory of polar molecules. A quantitative check was therefore made and found to be of the right order of magnitude.

APPARATUS AND PROCEDURE

1. *Testing cells.*—For most of the measurements reported in this paper, the cell shown in Fig. 1 was used. The two concentric cylinders are made of a steel alloy containing 18 percent chromium and 8 percent nickel. This alloy is not attacked by hot oil and has a very small catalytic effect on the oil. The inner cylinder (1) is hollow with hemispherical ends welded on, using an atomic hydrogen flame, thereby making an oil-tight joint and completely seal-

Fig. 1. Oil resistivity cell.

Fig. 2. Vacuum cell for electrical measurements of insulating oils.

ing the interior. The bottom of the outer cylinder (2) has a central conical hole into which the fused quartz post (3) of the inner cylinder fits. The inner electrode is centered at the top by the fused quartz collar (4) which is made with a sliding fit so that the inner electrode can be easily removed for cleaning. The temperature is indicated by a thermometer placed in the tube in the top of the inner electrode. The fused quartz insulation was shown to have negligible surface leakage, volume conductivity and dielectric loss.

Before a measurement, the oil to be tested was placed in the cell and carefully evacuated. Then the fused quartz collar was placed in position effectively sealing the oil against the absorption of moisture from the atmosphere. The temperature was controlled by placing the cell in a thermostatically controlled heater.

However, to make certain that absorbed moisture or absorbed gases were not responsible for the observed dielectric loss, the vacuum cell shown in Fig.

2 was prepared. The electrodes were concentric nickel cylinders, 10 cm high and spaced about 2 mm apart. The outer cylinder (1) was supported by two wires sealed into the bottom of the Pyrex cell, one of which acted as the ground lead (2). The inner cylinder (3) was supported only by a stiff wire (4) which was sealed into the top of the cell and served as the other lead. The Pyrex tube (5) supporting the inner cylinder was sealed to the top of the cell wall (6) to form an annular expansion chamber for the oil and also to provide a very long glass path between the two electrodes. A small tube (7) with a closed end was sealed into the bottom of the cell so that the temperature of the oil in the cell could be determined with a small thermocouple.

For filling, two glass tubes extended from the top of the annular chamber. One was sealed to a good vacuum system. The other led through a stop-cock to a reservoir of oil at atmospheric pressure. The oil was heated to about 125°C and allowed to bubble very slowly through the stop-cock thereby liberating all gases. When the cell was filled to a level near the top of the expansion chamber and all bubbling had ceased, both tubes were sealed off leaving completely degasified oil in the cell ready for the electrical measurements.

Tests on this cell before and after filling showed the following:

(a) The dielectric loss in the oil showed the same characteristics as those observed with the quartz insulated cell. (b) The errors of measurement caused by leakage over the surface at low frequencies and by dielectric loss in the Pyrex at high frequencies were greater than for the quartz insulated cell. (c) The actual measurements with the vacuum cell were less accurate because the cell constant was much smaller than for the quartz insulated cell. (d) The errors could have been eliminated by using guard ring electrodes but for commercial oils these complications seemed unnecessary.

For these reasons all subsequent measurements were made with the open, quartz insulated cell and only measurements made with this cell are reported.

2. *D. C. Measurements.*—The source of potential was a 350 volt "B" battery and a sensitive galvanometer with an Ayrton shunt was used to measure the current. The galvanometer calibration was checked before and after each run.

3. *Low-Frequency Measurements.*—A variable frequency vacuum tube oscillator² having a range from 200 to 10,000 cycles per second was used to supply a modified General Radio "power factor bridge." The variable capacitance standard was a General Radio precision instrument. This same standard was used for both low and high frequency measurements.

4. *High-Frequency Measurements.*—These tests were made with equipment permanently installed in a well shielded room built especially for radio frequency measurements. The standard substitution method (Bureau of Standards Circular No. 74) was used throughout. The generating circuit was a vacuum tube oscillator having a frequency range from 4×10^4 to 3×10^6 cycles per second. The power rating was sufficient to prevent any change in either the frequency or the voltage when changes were made in the loosely

² Gen. Elec. Rev. P. 521, October, 1929.

coupled measuring circuit. The oscillator gave an approximate sine wave, having less than 5 percent harmonic components.

The measuring circuit is shown in Fig. 3. The generating circuit (1) has been discussed above. Coupling coils (2) having from 1 to 10 turns were used depending upon the frequency desired. The measuring circuit was loosely coupled to the generating circuit by the coil (3). The special high frequency switch (4) was used for connecting either the test cell (5) or the standard capacitance (6) into the measuring circuit. The switch was composed of six mercury cups mounted on fused quartz tubes. Amalgamated copper wires were used for making contact between the desired pairs of cups. The current-indicating device in this circuit was a special vacuum thermocouple whose heater resistance had a constant value of 0.72 ohm over the entire frequency range. This type of couple is designed so as to have a long leakage path between the heater leads. The thermocouple was connected through the radio frequency choke (8) to the sensitive galvanometer (9). The sensitivity of the

Fig. 3. High frequency measuring circuit.

combination was such that 2×10^{-4} amp. input to the heater of the thermocouple gave approximately 1 mm deflection on the galvanometer scale. The link resistors (10) were made of short straight lengths of non-magnetic, resistance wire sealed in evacuated glass tubes. These were approximately the same length and range from 0.115 to 26.2 ohms. For greater resistances a shielded General Radio decade resistance box, having 0.1 ohm steps, was used.

The procedure for a high frequency measurement differed slightly from that prescribed by A.S.T.M.D. 150-27T, and was as follows:

(a) The supply oscillator was set at the desired frequency and a coupling coil was selected which would resonate with the test cell connected and a short circuiting link at (10). This circuit was then tuned exactly to resonance by varying the supply frequency and the galvanometer deflection recorded. With no further change in the supply oscillator, the standard capacitor was substituted for the test cell and adjusted to give resonance of the measuring circuit. The setting of the standard was then the capacitance of the test cell. If the galvanometer deflection was not the same as it was with the test cell in the circuit, the effective resistance of the circuit must be different. That is, the dielectric loss of the standard capacitance differed from that of the test cell. Since the standard was an air capacitance with good insulation, its dielectric loss was very small and was considered negligible. Link resistors were added in series with the standard capacitance until the deflection was the

same as that recorded for the test cell, thus giving the equivalent series resistance of the test cell. For each point this procedure was repeated several times to make certain of the value obtained and then the exact frequency was determined with a wave meter.

CALCULATIONS FROM A. C. MEASUREMENTS

The alternating current measurements have been interpreted in terms of the equivalent parallel circuit shown in Fig. 4. C is the equivalent capacitance

Fig. 4. Equivalent circuit for an imperfect dielectric.

and is considered to have zero loss and zero inductance. G is the equivalent a.c. parallel conductance and is considered to have zero capacitance and zero inductance. This simple equivalent circuit has been used for the following reasons:

(a) The mechanism of dielectric loss in oils is not sufficiently well understood to enable one to represent it exactly in terms of ideal resistances and capacitances. Therefore *a circuit which is assumed to be equivalent rather than one which is theoretically exact, must be used.*

(b) The actual measurements were made with a series connection of a resistance having negligible capacitance and a capacitance having negligible loss. Therefore the interpretation of the results *must be made* in terms of this simple series measuring circuit.

(c). However the parallel circuit is chosen in preference to the series circuit because G represents a coefficient of dielectric loss independent of C . That is, G is proportional to the component of current in the external circuit which is in phase with the applied potential. Therefore it is a measure of the dielectric loss regardless of the mechanism by which that loss may have been produced.

(d). With the coefficient G , the dielectric losses of different materials can be compared without reference to their dielectric constants. It is therefore preferable to the commonly used coefficient of power factor which represents a ratio of dielectric loss to dielectric coefficient and therefore involves two independent characteristics of the material.

(e). Under certain special conditions the equivalent parallel conductance obtained by a.c. measurements is identical with the d.c. conductance so that this method of representing the a.c. measurements is very convenient, in correlating a.c. and d.c. tests.

To obtain the relations between equivalent series and parallel circuits let:

R = the known equivalent series resistance of the test cell

C_s = the known equivalent series capacitance of the test cell

G = the desired equivalent parallel conductance of the test cell

C = the desired equivalent parallel capacitance of the test cell

$w = 6.28$ (frequency in cycles per second of the applied potential).

The equivalence between the series and parallel circuits is expressed by the complex relation

$$G + iwC = (R - i/wC_s)^{-1} \quad (3)$$

from which are obtained the two real equations:

$$G = \frac{R}{R^2 + (1/wC_s)^2} \quad (4)$$

and

$$wC = \frac{(1/wC_s)}{R^2 + (1/wC_s)^2} \quad (5)$$

For good dielectrics the loss component of current is small compared to the capacitance component so that it may be assumed that,

$$R^2 \ll (1/wC_s)^2 \quad (6)$$

With this assumption Eqs. (4) and (5) become:

$$G = R w^2 C_s^2 \quad (4a)$$

and

$$C = C_s \quad (5a)$$

The apparent power factor of a dielectric is generally used as a measure of its quality and may be calculated from either the equivalent series or equivalent parallel circuit. The definition of power factor is:

$$\text{power factor} = \frac{\text{real power}}{\text{apparent power}} \quad (7)$$

For the series circuit

$$P.F. = \frac{I^2 R}{I^2 (R^2 + (1/wC_s)^2)^{1/2}} \quad (8)$$

and if $R^2 \ll (1/wC_s)^2$ this reduces to,

$$P.F. = R w C_s \quad (8a)$$

For the parallel circuit,

$$P.F. = \frac{E^2 G}{E^2 (G^2 + (wC)^2)^{1/2}} \quad (9)$$

or again if $G^2 \ll (wC)^2$ Eq. (9) reduces to

$$P.F. = G/wC \quad (9a)$$

Since both low and high frequency measurements were made in terms of an equivalent series circuit, Eqs. (4) and (8) were used to obtain the equivalent parallel conductance and the equivalent power factor of the test samples.

DISCUSSION OF EXPERIMENTAL RESULTS

The results of previous tests led to a study of a single oil through a wide range of frequency and temperature. Properties of the oil on which these measurements were made are given in Table I.

TABLE I. *Physical data for the oil studied.*

(1) Flash point	280°C
(2) Fire point	320°C
(3) Acid value	0.035 milligram of KOH per gram
(4) Dielectric strength at 30°C	37 kilovolts for 0.1 inch gap
Dielectric strength at 100°C	29 kilovolts for 0.1 inch gap
(5) Specific gravity at 30°C	0.9085
Specific gravity at 100°C	0.8654
(6) Viscosity at 30°C	11.76 poises
Viscosity at 100°C	0.27 poises

The equivalent parallel conductance was taken as a measure of the dielectric loss and the results of the entire series of tests are shown in Fig. 5. Inasmuch as no equipment was readily available for measurements at frequencies between 3,000 and 125,000 cycles per second, there is a gap in the data between these frequencies. The curves indicate no sudden change in the characteristics of the oil so that it did not appear necessary to set up special equipment for this frequency range.

The most interesting deductions to be drawn from these data are as follows:

(a). As the temperature is increased all of the curves approach the line representing the d.c. conductance. For example at 150°C the conductance is the same for all frequencies below 125,000 cycles per second since curves (1) through (5) all pass through the point (a).

(b). For each frequency there is a temperature below which the total dielectric loss is greater than can be explained by the mechanism of conduction.

These observations may be stated in a slightly different way; namely,

(c). For a given temperature there is a critical frequency such that for all lower frequencies the a.c. loss is independent of the frequency and for all higher frequencies the loss increases with the frequency. Within the first frequency range the mechanism of d.c. conduction and of a.c. loss appear to be the same, and both are probably due to the migration of charged ions or larger particles in the oil.

(d). The higher the temperature, the higher the critical frequency below which the a.c. and d.c. losses are the same.

These data seem to indicate that the total dielectric loss can be separated into two components,—one independent of frequency and due to the same mechanism as d.c. conduction, and the other independent of conduction and varying with both frequency and temperature. In the remainder of this discussion, therefore, the total dielectric loss will be considered to be the algebraic sum of these two components.

$$\text{Total dielectric loss } (P) = \text{d.c. loss } (P_d) + \text{a.c. loss } (P_a) \quad (10)$$

The name d.c. loss is used as the simplest designation for the component that is independent of frequency and the name a.c. loss is used to mean the component which varies with frequency. They are so separated because it seems that they result from two entirely different effects of the applied potential and are independent of each other as far as their variation with frequency and temperature is concerned.

Fig. 5. Total dielectric loss in a heavy cable oil as a function of frequency and temperature. Loss per $\text{cm}^3 = (E^2/V)G$ watts/ cm^3 . E is the potential in volts, G the equivalent parallel conductance in mhos, and V the effective volume of oil in test cell (73.7 cm^3).

These two components are represented by their equivalent conductances as shown in Eq. (10a).

$$P = E^2 G = E^2 (G_d + G_a) \quad (10a)$$

so that G_a may be obtained as the algebraic difference of G and G_d .

Accordingly the next step in studying these data was to plot curves for $(G - G_d)/f$. As shown in Fig. 6 they give the a.c. loss per cycle as a function of frequency for seven different temperatures. These curves are very interesting since they show that, after the loss due to d.c. conduction has been subtracted, the remainder, when plotted as loss per cycle goes through a maximum as a function of either temperature or frequency. The curves at different temperatures are similar. The higher the temperature (or the lower the viscosity), the higher is the frequency necessary to produce maximum loss.

Fig. 6. a.c. loss in a heavy cable oil as a function of frequency for different temperatures. Loss per cycle per $\text{cm}^3 = (E^2/fV)(G - G_d)$ joules/cycle/ cm^3 . E is the potential in volts, G is the equivalent parallel conductance in mhos, G_d is the d.c. conductance in mhos, f is the frequency in cycles per second and V is the effective volume of oil in test cell (73.7 cm^3).

Another and perhaps more usual way of measuring the dielectric loss per cycle per unit volume is to plot the power factor as shown in Fig. 7. From the equivalent parallel circuit the total dielectric loss is given by,

$$P = E^2G \text{ watts} \quad (11)$$

and loss per cycle per unit volume is

$$E^2G/fV \text{ watts per cycle per cm}^3. \quad (12)$$

For low loss dielectrics (power factor less than 10%) we have from Eq. (9a)

$$P.F. = G/2\pi fC$$

from which $G/f = 2\pi C (P.F.)$, which when substituted in Eq. (12) gives,

$$\text{loss per cycle per cm}^3 = (2\pi CE^2/V)(P.F.). \quad (13)$$

This shows that power factor is a coefficient proportional to the dielectric loss per cycle per unit volume, if the capacitance can be assumed constant.

Except for scale, the only difference between corresponding curves in Figs. 6 and 7 is that in the latter the ordinates are proportional to the total loss per cycle while in the former they are measures of the "a.c. loss" only.

From these curves we have an explanation of the V curves of power factor as a function of frequency. Consider first curve (7) corresponding to 150°C . Fig. 5 shows the total loss in watts to be independent of frequency below 125,000 cycles per second at this temperature. Therefore in computing power factor, the loss per cycle becomes greater as the cycles per second are de-

Fig. 7. Total dielectric loss in a heavy cable oil as a function of frequency for different temperatures. Loss per cycle per $\text{cm}^3 = (2\pi CE^2/V)(\text{P.F.})$ joules/cycle/ cm^3 . E is the potential in volts, C is the capacitance in farads, and V is the effective volume of oil in test cell (73.7 cm^3).

creased. In other words, as the frequency is decreased, the loss component of current remains constant but the capacitance component decreases with the frequency so that the power factor increases approaching unity as a limit.

Now consider curve (1) corresponding to 0°C . Fig. 5 shows that the d.c. loss is negligible compared to the measured loss and Fig. 6 shows that this a.c. loss per cycle goes through a maximum as a function of the frequency. For intermediate temperatures, the curve may be a combination of these two distinct types. Thus curves (4), (5) and (6) show the descending portions of the d.c. characteristic at low frequencies and the ascending portions of the a.c. characteristic at high frequencies.

To represent more clearly the data shown in Fig. 7 as functions of both temperature and frequency, the curves were cut out of stiff card board and

placed in a frame at equal intervals to represent a three dimensional graph as shown in Fig. 8.

Fig. 8. Variation with frequency and temperature of dielectric loss in heavy cable oil. Composite curve chart.

Fig. 9. Variation with frequency and temperature of dielectric loss in heavy cable oil. Composite curve chart.

In Fig. 9 the direction of increasing temperature has been reversed to show the curves that are hidden in Fig. 8. These data show the danger in drawing conclusions as to the character of a material from measurements taken only for narrow ranges of experimental conditions. It is possible to obtain for certain limited areas of this three-dimensional graph either increasing or decreasing power factor as a function of either frequency or temperature. Similar studies over wide ranges of frequency and temperature may explain apparent discrepancies between the results of different experimenters working in different limited ranges of measurement.

Data somewhat similar to these are shown by Emanuelli³ for an oil containing 35 percent rosin. An analysis of these data shows that he did not carry his test to high enough frequencies to obtain maxima in the curves for (G/f) vs. (f) similar to those shown in Fig. 6.

DEBYE'S THEORY OF POLAR MOLECULES

We shall not reproduce the theory as developed by Debye⁴ although the attendant assumptions will be indicated in the discussion. As a result of the solution of a differential equation of motion of a polar particle in a viscous medium, Debye arrives at the following relation for the dielectric coefficient* of the medium,

$$\epsilon = \frac{\left(\frac{\epsilon_0}{\epsilon_0 + 2}\right) + i\omega\tau\left(\frac{\epsilon_\infty}{\epsilon_\infty + 2}\right)}{\left(\frac{1}{\epsilon_0 + 2}\right) + i\omega\tau\left(\frac{1}{\epsilon_\infty + 2}\right)} \quad (14)$$

where-

ϵ_0 = dielectric coefficient at zero frequency

ϵ_∞ = dielectric coefficient at infinite frequency

or ϵ_∞ = (refractive index)²

τ = relaxation time

ω = 6.283 (cycles per second).

By expanding Eq. (14), this relation can also be written in the form,

$$\epsilon = \epsilon' - i\epsilon'' \quad (14a)$$

where

$$\epsilon' = \frac{\epsilon_0(\epsilon_\infty + 2)^2 + \omega^2\tau^2\epsilon_\infty(\epsilon_0 + 2)^2}{(\epsilon_\infty + 2)^2 + \omega^2\tau^2(\epsilon_0 + 2)^2} \quad (15)$$

and

³ L. Emanuelli, High Voltage Cables, P. 38, (John Wiley & Sons, 1930).

⁴ P. Debye, "Polar Molecules," The Chemical Catalog Co., 1929.

* This is usually called "dielectric constant," but as pointed out by Addenbrook in Nature 126, 808 (1930), the quantity varies considerably with different experimental parameters and therefore might better be called "dielectric coefficient."

$$\epsilon'' = \frac{\omega\tau(\epsilon_0 - \epsilon_\infty)(\epsilon_\infty + 2)(\epsilon_0 + 2)}{(\epsilon_\infty + 2)^2 + \omega^2\tau^2(\epsilon_0 + 2)^2} \quad (16)$$

At this point we shall depart from the method of Debye, who, because of similarity with optical phenomena interprets the dielectric coefficient in terms of the relation,

$$\epsilon = r^2(1 - ik)^2 \quad (17)$$

where r and k are the indices of refraction and absorption. Our experience indicates that the data can be analyzed without the use of the optical index of absorption.

In Eq. (14a), ϵ' is the true dielectric coefficient in the ordinary usage of the term, since it is a measure of the current in the external circuit which leads an applied sinusoidal potential by 90° . ϵ'' being at right angles to ϵ' is really a measure of the current which is in phase with the applied potential and therefore proportional to the dielectric loss. The relation between ϵ'' and G in Eq. (3) may be shown as follows:

In the equivalent parallel circuit

$$Y = (\text{admittance}) = (\text{impedance})^{-1} = G - i\omega\epsilon'C_v \quad (18)$$

where

$$\epsilon' = C/C_v \quad (19)$$

according to the definition that the dielectric coefficient is the ratio of the capacitance with a given material as a dielectric, to the capacitance of the same system with vacuum as a dielectric.

Using Debye's generalized dielectric coefficient from Eq. (14a) to account for both the in-phase and out-of-phase components of the current we have,

$$Y = 0 - i\omega C_v(\epsilon' - i\epsilon'') \quad (20)$$

which when expanded gives,

$$Y = \omega\epsilon''C_v - i\omega\epsilon'C_v. \quad (21)$$

By comparing Eq. (18) and (21), we have a relation between our equivalent parallel conductance G and Debye's imaginary component ϵ'' of the generalized dielectric coefficient, namely

$$G = \omega\epsilon''C_v. \quad (22)$$

For a given test cell, C_v is a constant so that ϵ'' is proportional to G/f . Therefore the curves in Fig. 6 are directly proportional to Debye's ϵ'' , for conditions under which the d.c. conductance is negligible.

The next logical step is therefore to set the first derivative with respect to ω of Eq. (16) equal to zero, and obtain a relation for the frequency at which

the loss is a maximum. The result of this operation is that ϵ'' should be a maximum when,

$$w\tau = (\epsilon_{\infty} + 2)/(\epsilon_0 + 1). \quad (23)$$

Now, if this value be substituted back in Eq. (16) we have,

$$\epsilon_m' = \frac{1}{2}(\epsilon_0 + \epsilon_{\infty}) \quad (24)$$

and

$$\epsilon_m'' = \frac{1}{2}(\epsilon_0 - \epsilon_{\infty}) \quad (25)$$

ϵ_0 and ϵ_{∞} are independent of frequency and change with temperature, only as the density changes. Therefore Eq. (23) indicates that *the frequency at which the maximum loss occurs will vary inversely with the relaxation time of the polar molecules.*

Debye develops the following relation for the relaxation time

$$\tau = 4\pi\eta a^3/kT \quad (26)$$

where

η = the coefficient of viscosity in poises

a = the effective radius of the polar molecule in cm

k = Boltzmann's constant $= 1.37 \times 10^{-16}$

T = absolute temperature.

Eq. (25) indicates that except for changes with temperature due to changes in density, *the maximum value of the loss per cycle should be independent of temperature or frequency.*

The assumptions made by Debye in developing this theory may be stated briefly as follows:

(a). The solution of polar molecules in a non-polar solvent is sufficiently dilute so that the interaction between neighboring polar molecules is negligible.

(b). The laws of an ideal gas may be applied and use made of Boltzmann's constant and Avogadro's number.

(c). Viscosity coefficients, as ordinarily measured, and Stoke's law for falling spheres in a viscous medium may be applied to forces between polar and non-polar molecules.

Of these assumptions the third is probably the one which is most open to criticism in applying this theory to a viscous mineral oil.

There is more evidence that insulating oils contain charged particles than that they contain polar molecules. Therefore it may be possible that mathematical relations, which would also explain experimental observations, could be developed for the motion of charged particles in a viscous medium.

In a recent discussion of Debye's theory, Whitehead⁵ sets up a relation for

⁵ S. Whitehead. Phil. Mag. 9, 865 (1930).

power factor in terms of the physical coefficients of the material instead of in terms of the limiting values of ϵ as suggested by Debye. Whitehead then differentiates this expression with respect to ω to determine the conditions for maximum power factor.

The development we have given above seems much preferable to that suggested by Whitehead for the following reasons:

(a). The limiting values of the dielectric coefficient ϵ_0 and ϵ_∞ can be measured more easily and more accurately than the electric moment and the molecular viscosity, which are required to evaluate Whitehead's relations.

(b). The study of power factor relations is inherently more complicated than the study of the loss coefficient alone, because the former involves a ratio between two quantities which vary as different functions of temperature and frequency.

(c). Not only is it easier to measure separately the capacitance and the loss coefficients, but such a study will lead to a clearer understanding of both, than is possible from a determination of power factor, which measures only their ratio.

QUANTITATIVE CHECK OF DEBYE'S THEORY

To apply the above theory to our experimental data, the following quantities were determined for 25°C:

$$\epsilon_0 = 2.30$$

$$\epsilon_\infty = (\text{refractive index})^2 = (1.5077)^2 = 2.27$$

$$C_v = 65.1 \times 10^{-12} \text{ farads}$$

and f_m = frequency at which the maximum loss per cycle occurs = 316,000 cycles per second.

Using these particular values and Eqs. (16) and (22), a curve of (G/f) against frequency can be calculated and plotted as shown in Fig. 10. The difference between the calculated and observed maximum ordinate can be easily explained as an experimental error. According to Eq. (25) the maximum ordinate is proportional to the difference between ϵ_0 and ϵ_∞ . This difference is only 1.3 percent of the measured values, so that a 1 percent error in either coefficient would cause of 75 percent error in their difference. The index of refraction should be accurate to 0.1 percent but ϵ_0 might easily be in error by 0.5 percent, since the measurement was made before the need for such extreme accuracy was recognized. Thus the *maximum ordinate may be considered to check the theory within the limits of experimental accuracy.*

Eq. (16) shows that $(\epsilon_0 - \epsilon_\infty)$ enters as a multiplying factor for all frequencies, so that even though ϵ_0 were corrected to give an agreement between the maxima of the two curves, their shapes would be entirely different. This indicates that, *while the order of magnitude is correct, the theory in this simple form is not sufficient to predict quantitatively the observed results.* An obvious and possible explanation of the difference in the shapes of the experimental and

theoretical curves is that the theory postulates particles of only one size. If there are any polar particles in the oil they are probably of many different sizes, so that a much broader frequency response is obtained than would be given by the presence of particles of only one size.

Fig. 10. a.c. loss per cycle for a heavy cable oil at 25°C. Curve 1 from observed data, curve 2 calculated from Debye's theory of polar molecules.

Fig. 11. Viscosity characteristic of a viscous cable oil.

Another indication of the validity of the theory may be obtained by determining the effective radius of the polar particles from Eq. (26). This can be done by reading from the curves in Fig. 6, the frequency at which each isothermal curve is maximum. Then τ can be determined for each tempera-

ture from Eq. (23), so that it is possible to solve for (a) in Eq. (26). The results of such a calculation are shown in Table II.

TABLE II. *Calculation of size of polar molecule.*

$T^{\circ}\text{C}$	ϵ_{∞}	ϵ_0	$\omega\tau$	f cyc/sec $\times 10^3$	τ $\times 10^{-7}$	η Poise	a cm $\times 10^{-8}$
0	2.31	2.34	.993	16.	98.7	230	5.04
25	2.27	2.30	.993	316.	5.0	17	4.58
50	2.23	2.26	.993	2000.	0.79	2.9	4.59

As the temperature of the oil is increased the viscosity decreases rapidly according to Fig. 11. Therefore the relaxation time decreases very rapidly with increased temperature resulting in a corresponding large increase in the frequency necessary to cause maximum loss as shown in Fig. 6.

Here again we have a qualitative check of the theory in that three determinations for the calculated size of particles agree fairly well and the value obtained is of the right order of magnitude.

The author is pleased to express his indebtedness to Mr. S. I. Reynolds of the General Electric Company for his careful work in making the high frequency measurements reported in this paper.

LETTERS TO THE EDITOR

Prompt publication of brief reports of important discoveries in physics may be secured by addressing them to this department. Closing dates for this department are, for the first issue of the month, the twenty-eighth of the preceding month; for the second issue, the thirteenth of the month. The Board of Editors does not hold itself responsible for the opinions expressed by the correspondents.

Wave-length Measurement of Gamma-Rays from Radium and its Products

In my paper on the γ -ray spectrum of radium and its products (Phys. Rev. [2] 36, 460 (1930)) it was pointed out that the peaks appearing on the intensity curve and interpreted as γ -ray lines were sharp, and were apparently resolved by the spectrometer when the glancing angles of reflection from calcite differed as little as 20 seconds of arc, although the geometry of the arrangement did not account for such high resolving power.

Professor Niels Bohr in private correspondence with Professor Kovarik has emphasized the importance of this question concerning resolution in my experiments, and a further study of the matter has shown that the discrepancy between the resolving power as estimated from the experimental curves and that computed from the dimensions of the apparatus is greater than can be accounted for by any reasonable hypothesis regarding accidental inclination of the slit faces. He also points

out that besides this there is a further difficulty in connection with the apparently great relative intensity of the very short wave-length lines or bands. Theories of scattering predict much lower intensity for scattered radiation of such high frequency. The reality of the reported results thus assumes considerable theoretical importance and needs more experimental justification.

It is impossible to give, at present, any other interpretation of the experimental results than that first offered. It is my intention, therefore, to reinvestigate the problem with improved apparatus. Meanwhile the question regarding the existence or non-existence of new lines of strong intensity in the γ -ray spectrum of radium and its products must be left open.

Arrangements of Atoms in Crystals

In the January 1st number of the Physical Review (37, 105 (1931)) is an abstract of a paper by Zachariasen in which the author reports the results of crystal structure investigations of KBrO_3 , KCl_3 , NaClO_3 and Na_2SO_3 . He finds, in agreement with the earlier work on NaClO_3 and NaBrO_3 (Kolkmeijer, Bijvoet and Karssen, Verslag akad. Wetenschappen Amsterdam 23, 644 (1920); Dickinson and Goodhue, J. Am. Chem. Soc. 43, 2045 (1921)) that the XO_3 groups in these crystals can be described as "tetrahedral groups with one tetrahedral corner removed," and notes that this is a similar arrangement to that around As or Sb in As_2O_3 crystals (Bozorth, J. Am. Chem. Soc. 45, 1621 (1923)). The statement is then made that in each case "the cation has

got only 2 electrons in the outer shell," the non-coplanar arrangement being explained "as due to deformation in the outer shell of the cation, where the charge distribution is very diffuse."

It seems more likely to the writer that these are merely cases of shared electron pairs, as postulated by G. N. Lewis ("Valence and the Structure of Atoms and Molecules," Chem. Cat. Co., New York, 1923). The total number of valence electrons in each of these ions is 26, and if Lewis is correct, that there is a tendency toward the completion of valence shells containing eight electrons (four pairs tetrahedrally oriented) around the kernel of every electronegative atom, the distribution in space of the atoms must be similar to that observed,

the electrons being shared as indicated by the formula

In the case of the oxides of arsenic and antimony, there are five electrons per As or Sb and six per O. To complete a four-pair tetrahedral valence shell around each atom requires that each As or Sb shares 3 electron pairs, at tetrahedron corners, with 3 oxygen atoms and each oxygen shares 2 pairs, at tetrahedron corners, with two As or Sb atoms,—precisely the arrangement determined from x-ray data.

It is plain that one can not only predict from this theory the number of electron pairs (per molecule or crystal unit) shared between electronegative atoms, but one can also predict that if an electronegative atom is adjacent to 2, 3, or 4 others, the arrangement will be that of 2, 3, or 4 corners of a (not necessarily regular) tetrahedron around its center.

Such predictions can be tested very readily by the results of x-ray analysis and in general they are found to be in agreement with experiment. Thus in iodine the negative atoms are in pairs; in crystals of Se and Te, each atom is adjacent to two others in a spiral chain; in P, As, Sb and Bi the atoms are in puckered layers, each adjacent to three others at three corners of a tetrahedron, while in the diamond, Si, Ge and gray Sn each atom is tetrahedrally surrounded by four others. Among compounds, several have been mentioned already; many others might be given.

As Lewis readily admits, there are exceptions to this tendency. Examples he gives are the molecules SF_6 and PCl_5 in which the central P and S atoms probably have 5 and 6 valence pairs, respectively. Other examples are afforded by such compounds as $CsICl_2$ and CsI_3 , in which the three halogen atoms form a colinear group. The number of valence electrons (counting 7 per halogen and 1 per Cs) in each X_3 ion is 22. The most reasonable distribution of these would seem to be one in which the central atom has 5 pairs and each of the others four.

Energies and Wave-Functions of the State $(1s)(2s)^1S$ in Helium-like Atoms

Eckart, in the Physical Review, September 1, 1930 (pp. 878 *et seq.*) pointed out that his modification of the Ritz method there pre-

In $CaCO_3$ and $NaNO_3$ both crystallographic and x-ray data indicate a 3-fold axis of symmetry through each C and N center and two-fold axes of symmetry through each C-O and N-O centerline. If the oxygen tetrahedra are oriented in agreement with this symmetry, each C or N kernel is surrounded by six pairs, joining it by double bonds to the neighboring oxygens.

The four pair valence shell is apparently stable if the valence shell is not made too large (as by the pull of surrounding electron atoms) in which case more pairs can be accommodated. The smaller the kernel charge—in general, the more electropositive the atom,—the more pairs can be accommodated in the valence shell but the less tightly each is held. Although in quartz (SiO_2), HgI_2 , ZnS , AgI and many other compounds relatively electropositive atoms are surrounded by four electronegative atoms at tetrahedron corners, suggesting electron sharing with tetrahedral valence shells around *all* the atomic kernels, in many others the electropositive atoms are surrounded by six or eight negative atoms. In some cases, (e.g. $NaCl$) the valence shells of the latter cannot be oriented so as to place the valence pairs on the centerlines between adjacent atoms; evidently in such polar crystals other considerations, such as the relative sizes of the atoms (or ions) are of the greatest importance in determining the type of arrangement. (Cf. Pauling, J. Am. Chem. Soc. **51**, 1010 (1929); Huggins, J. Phys. Chem., in print.)

It should perhaps be pointed out that the point of view taken here is quite in agreement with recent developments in wave mechanics theory. (Cf. Bartlett, Phys. Rev. **36**, 1096 (1930) and papers by Bartlett and by Slater at the Cleveland Meeting of the American Physical Society.) The pairing of valence electrons, the sharing of such pairs between two atoms, and preferred orientations of electron orbits, once bones of contention between physicists and chemists, can now be agreed to by both.

MAURICE L. HUGGINS

January 27, 1931.

sented fails when applied to a state other than the lowest of a given series, e.g. $(1s)(2s)^1S$ of helium-like atoms, and suggested that a pro-

cedure might be worked out for applying the method to this case. This has been done by the author, using a comparison function designed to be orthogonal to the wave-function of the ground state.

The following comparison function is orthogonal to the exact wave-function ψ_1 of the ground state: $K(\phi_2 - \gamma_1\psi_1)$, where ϕ_2

culated ionization potential. The parameters ϵ and η correspond to Eckart's α and β for the state $(1s)^2$.

This comparison function gave the results summarized in the following table (α_0 and β_0 are the adjusted values of the parameters, $R_\infty h$ =unit of energy, W =energy, V_i =ionization potential):

	Z	α_0	β_0	W (calc.)	W (obs.)	V_i (calc.)	V_i (obs.)
He I	2	2.00	1.17	4.289	4.292	0.289	0.292
Li II	3	2.98	2.19	10.073	10.082	1.073	1.082
Be III	4	3.97	3.18	18.361	—	2.361	—
B IV	5	4.97	4.19	29.146	—	4.146	—

$= [u(\alpha_1)v(\beta_2) + u(\alpha_2)v(\beta_1)]/[2(1+b^2)]^{1/2}$, $b^2 = (2x)^3(x-1)^2/(x+\frac{1}{2})^8$, $x = \alpha/\beta$ (Eckart, Phys. Rev. **36**, 886), ψ_1 =exact wave-function of ground state, $\gamma_1 = \int \phi_2 \psi_1 d\tau$, $K = [1 - \gamma_1^2]^{1/2}$. Actually the use of a very accurate wave-function for ψ_1 (such as that of Hylleraas), was found to introduce too great complexities into the maximization. The function $\phi_1 = [u(\epsilon_1)u(\eta_2) + u(\eta_1)u(\epsilon_2)]/[2(1+c^2)]^{1/2}$, where $c^2 = 64(\epsilon\eta)^3/(\epsilon+\eta)^8$, was used for ψ_1 , (due to Eckart, Phys. Rev. **36**, 883). The validity of this approximation can be judged from the fact that a 10% change in γ_1^2 was found to produce only a 1% change in the cal-

One notices that α_0 is approximately equal to Z , ($Z - \alpha_0 \sim 0.02$); that $Z - \beta_0$ is essentially constant and ~ 0.82 ; and that $W(\text{calc.}) = (5/4)Z^2 + aZ + b$, where $a = -0.464$, $b = 0.216$.

Hylleraas (Zeits. f. Physik **65**, Hefte 11 and 12, Nov. 14, 1930) has recently performed a calculation of this term for the special case of He I; his method, which results in a much more complicated wave-function, yields the value 0.290.

A Theory of Collision Processes Involving No Radiation of Energy

The writers have developed a generalization of the Born collision method for dealing with collision processes. In the usual Born method the zero-order wave function for the colliding particle is a plane wave, undistorted by the presence of the stationary particle; which is so poor an approximation that the series for the cross section for many processes diverges; and in every case the first term is a bad approximation for small relative velocities. The writers use as a zero-order wave function one already distorted by an approximate mutual interaction field. The interaction energies effecting the transition have been expanded in a series which converges well for energies less than about 100 electron-volts. The cross sections for the various processes can be then computed and are valid for all except very large relative kinetic energies.

These cross sections, as a function of the size of the particles, of the nature of the transition

caused by the impact, of the mutual kinetic energy, and of the energy transferred from kinetic to energy of excitation, check quantitatively with such widely different experimental data as: Bleakney's¹ curves for ionization of Hg; Zemansky's² curves for transfer of excitation; Hanle's³ curves for excitation of various atoms; and Latyscheff and Leipunsky's⁴ curves for collisions of the second kind.

BOOK REVIEWS

Ergebnisse der Exakten Naturwissenschaften. Vol. VIII. E. BRÜCHE, *Freie Elektronen als Sonden des Baues der Molekeln.* Springer, Berlin, 1929.

This article deals primarily with experiments on passage of very slow electrons through gases. Stimulated by the observations of Ramsauer, a number of papers in this field have appeared within the last ten years. The present article gives a valuable critical survey of this work including a few new results. In his early paragraphs the author takes great pains to explain the significance of the "effective cross-section" in different types of apparatus. This is essential and well done. Later on almost equally elaborate discussions are given concerning points of minor significance. However, one may well overlook this lack of balance and rejoice to have a clear and systematic presentation of the experimental results including a classification of the "*WQ*" (*Wirkungsquerschnitt*) curves into four distinct types. The interpretation of these results can hardly be satisfactory without a consideration of energy losses of electrons in collisions, a field that is outside the scope of this article.

H. D. SMYTH

The Wave Mechanics of Free Electrons. G. P. THOMSON. Pp. 161, figs. 53. McGraw-Hill, 1930.

This book contains the subject matter of lectures delivered by the author as George Fisher Baker Non-Resident Lecturer in Cornell University. As the title implies, the book deals with that part of the subject which concerns electrons not forming part of an atom. It is primarily concerned with an account of experimental work, but also contains a treatment of the theory which is immediately applicable.

After an introductory lecture, the first two chapters treat the General Theory of Waves and de Broglie's Wave Mechanics, respectively. The following 8 chapters include a brief account of the Theory of Wave Diffraction by Crystals; a discussion of various diffraction experiments confirming de Broglie's relation for the wave-length of the electron; the effect on electron diffraction of an inner potential and the resulting refractive index; a discussion of the author's own work on the determination of the atom form factor from intensity measurements, and a theoretical interpretation of certain aspects of these experiments; an outline of Sir J. J. Thomson's physical theory of electron waves; theoretical considerations of the possibility of electron polarization with a list of the various experimental attempts to detect a possible polarization effect; and finally the application of electron diffraction to the study of surface films.

The following errors are noted. Under the discussion of the reviewer's results on pages 101, 102, it is stated that the inner potential Φ was calculated "by subtracting the actual voltage of the electrons from the voltage V given by $V = 150/\lambda^2$, where λ is the wave-length in Angstrom units which would give a spot in the observed position, ignoring refraction. This process is equivalent to ignoring the bending of the waves on emerging from the crystal." This is incorrect since the wave-length λ as used in the equation referred to is not that which would give a spot in the observed position, ignoring refraction, but is the theoretical wave-length, determined from the geometry of the crystal for unit refractive index, with which an experimental beam is associated. The colatitude angles for the theoretical and experimental beams are not the same so that the bending of the waves on emerging from the crystal has not been ignored.

On page 102 M. Davis is incorrectly referred to as Miss.

To my knowledge this is the first collection into book form of the experimental investigations in this new field, and will be a valuable reference to the status of the work at the time the book was written (Jan. 31, 1930), although several important contributions have since been made. It is particularly fitting to have an account by a pioneer worker who has made many notable contributions in this field.

H. E. FARNSWORTH

Textbook of Practical Physical Chemistry. K. FAJANS AND J. WÜST. Pp. 233+xiv, figs. 74. E. P. Dutton, New York, 1930. Price \$4.95.

The experiments outlined in this book cover a much wider range of subjects than is customary in manuals of physical chemistry. In addition to the material commonly presented, there are chapters on Adsorption from Solutions, Coagulation of a Sol by Electrolytes, Transformation of Radio-Elements, Quantitative Spectrophotometry, Electrochemical Preparations, and the Lead Accumulator. The outlines of the more common experiments follow the classical methods quite closely.

Each chapter is preceded by an unusually complete and worthwhile discussion of the related theory. Numerous references are given to the better known textbooks of theoretical physical chemistry. The description of the experimental procedure is apparently planned to render the student practically independent of the help of a laboratory instructor. The apparatus and experiments are described with meticulous detail, and in several cases this description is followed by a discussion of the probable difficulties and ways of avoiding or overcoming them.

The reviewer feels that it is regrettable that the authors decided to present the experiments on solutions, including the chapter on electromotive force, in terms of the older theory. The authors state in the preface "that to introduce the new system into this book would involve too great a departure from the treatment at present given in most of the general textbooks." This statement certainly does not apply to two of the better-known general texts to which many references are made in this book.

The text bears little evidence that it is a translation from the German; the style is throughout clear and readable. Without resorting to small type, the publishers have been successful in economizing space by their arrangement of the print, so that a large amount of material is presented on 230 pages.

ROBERT LIVINGSTON

Band Spectra and Molecular Structure. R. DE L. KRONIG. Pp. x+163, figs. 16. The Macmillan Company, New York, 1930. Price \$3.50.

Books on band spectra are appearing, and more are promised. The volume under review is brief and devoted almost exclusively to the theoretical side of the subject. That, however, is as it should be. If each author will confine himself to those aspects of the field with which he is thoroughly conversant, we will get a set of books which, collectively, will be both authoritative and useful. This volume makes a good start in that direction. In spite of its brevity, it covers a multitude of topics, including an entire chapter on "Macroscopic Properties of Molecular Gases" (scattering, dispersion, Kerr and Faraday effects, dielectric constants, etc.). The range of material is indicated by a few sub-titles, chosen almost at random: Stark and Zeeman Effects, Energy Levels of Polyatomic Molecules, Rotational Distortion of Spin Multiplets, Perturbations and Predissociation, Band Spectra and Nuclear Structure. Moreover, the author kindly marks off those sections for which a knowledge of wave mechanics is essential, and even summarizes their contents, so that the "experimental physicist" may omit such sections without losing the continuity of the argument. I am sure this will be appreciated by the great majority of readers. A few more diagrams, however, might well have been used.

It is not surprising, in a theoretical book, to find an occasional mis-statement of experimental fact. The reviewer was, however, really startled to read, on page 97, that Birge and King had discovered the isotopes of oxygen (as well as that of carbon), and that these discoveries had been made by means of the appearance of the alternate lines which are missing or weakened in the spectra of homonuclear molecules. Such errors are perhaps not serious, for the reader, but Giauque and Johnston may well object, from the personal standpoint. Their beautiful articles on the discovery and confirmation of the oxygen isotopes are not even listed in the very extensive and valuable bibliography which concludes the volume.

The author states that he has used the new nomenclature recently recommended by band spectroscopists (R. S. Mulliken, *Phys. Rev.* **36**, 611, 1930), and this is the case, with a few more or less unimportant exceptions. In just one instance, however, the reviewer considers the matter not unimportant. Dr. Kronig uses unprimed and primed symbols for upper and lower levels,

respectively, whereas the National Research Council committee, after considerable correspondence, recommended in 1926 single and double primed symbols, and this recommendation has been almost universally followed since that time.

These criticisms are not to be taken as an adverse judgment on the volume, as a whole. Many persons will welcome a brief, clear and comprehensive account of the recent important theoretical developments in the field of band spectra, and the present volume gives just such information.

RAYMOND T. BIRGE

PROCEEDINGS
OF THE
AMERICAN PHYSICAL SOCIETY

MINUTES OF THE CLEVELAND MEETING, DECEMBER 30-31, 1930

The Thirty-second Annual Meeting (the 168th regular meeting) of the American Physical Society was held in Cleveland, Ohio at the Case School of Applied Science and Western Reserve University on Tuesday and Wednesday, December 30 and 31, 1930, in affiliation with Section B—Physics—of the American Association for the Advancement of Science. The presiding officers were Professor Henry G. Gale, President of the Society, Dr. W. F. G. Swann, Vice-president, and Professor F. W. Loomis. The average attendance was about 300.

The annual joint session with Section B was held on Wednesday morning. The presiding officer was Professor F. K. Richtmyer, Vice-president of Section B. The program consisted of the address of the Retiring Vice-president of Section B, Professor Charles E. Mendenhall, on the subject, "Recent Developments in Photoelectricity." This address was followed by a Symposium on Acoustics consisting of three invited papers, as follows: "Recent Development in Architectural Acoustics" by Dr. Paul E. Sabine of the Riverbank Laboratories; "Some Physical Characteristics of Speech and Music" by Dr. Harvey Fletcher of the Bell Telephone Laboratories, Inc.; and "Concerning Some of the Problems Encountered in Recording and Reproducing Photographic Sound Records on Moving Picture Film," by Dr. Clarence W. Hewlett of the General Electric Company. The attendance at this session was 350.

On Tuesday evening the Society joined with the Society of Sigma Xi for dinner at the Cleveland Club after which they attended a lecture by Dr. C. E. K. Mees, of the Eastman Kodak Company, given in the auditorium of the John Hay High School.

Annual Business Meeting. The regular annual business meeting of the American Physical Society was held on Tuesday afternoon, December 30, 1930, at 2:00 o'clock in the lecture room of the Case School Physics Laboratory. A canvass of the ballots for officers resulted in elections for the year 1931 as follows:

President:	W. F. G. Swann
Vice-president:	Paul D. Foote
Secretary:	W. L. Severinghaus
Treasurer:	George B. Pegram
Members of the Council, four year term:	W. D. Coolidge
	F. W. Loomis
Members of the Board of the Physical Review,	A. J. Dempster
three year term:	D. M. Dennison
	J. C. Slater

The Secretary reported that during the year there had been 189 elections to membership. The deaths of 11 members have been reported during the year; 36 have resigned and 28 have been dropped. The membership of the Society as of December 29, 1930 is as follows: Members: 1963; Fellows: 516; Honorary Members: 5; Total Membership: 2484.

The Treasurer presented a summary of the financial condition of the Treasury of the Society. The complete audited report has been printed and distributed to all members.

The Managing Editor presented an informal report stating that the journals of the Society were being well received by the membership as well as by physicists in foreign countries. The financial condition was reported to be one that needed careful attention since the continually increasing quantity of publication brought about an increasing financial deficit which had to be met by the generosity of individuals or organizations. The complete audited financial report of the Managing Editor has been printed and distributed to all members.

Revision of By-Laws. On motion it was voted to approve the recommendation from the Council that Article VI of the By-Laws be changed to read:

"Each fellow or member of the Society who has paid his dues in full shall receive the Physical Review published by the Society and Science Abstracts Section A—Physics."

(Omit paragraph 2 as superfluous.)

Place sentence regarding Science Abstracts—Section B—with footnote concerning Reviews of Modern Physics.

Important Resolutions. On motion the Society voted approval of the following resolutions passed by the Council;

1. That the Council approve the establishment of a Journal of Applied Physics, with the first issue appearing July 1, 1931, and that the editor of the Physical Review be appointed editor of this journal.
2. That the Council authorize the substitution of a subscription for the Reviews of Modern Physics (or a subscription for the proposed Journal of Applied Physics, if and when established) in lieu of a membership subscription for the Physical Review in the case of any member or fellow who so desires.
3. That the Council approve, in principle, the formation of sections in the Society by subjects and also the encouragement of affiliation of local physics clubs.
4. That the Council propose the formation of an Institute of Physics for the purpose of coordinating various societies whose interests are primarily in the field of physics and for the purpose of supporting their publications.

Resolution number 4 was approved with the addition:

"That the Council consider specifically the possibility of such organization under Section B of the American Association for the Advancement of Science."

Meeting of the Council. At its meeting held on Monday, December 29, 1930, three persons were elected to fellowship, seven persons were transferred from membership to fellowship, and thirty-eight were elected to membership. *Elected to Fellowship:* J. Frenkel, Otto Oldenberg and W. H. Zachariasen. *Transferred from Membership to Fellowship:* Thomas H. Johnson, Julian E. Mack, George F. McEwen, Chester Snow, Thomas Spooner, Harvey E. White and John G. Winans. *Elected to Membership:* John Bardeen, B. Franklin Blair, L. W. Chubb, C. W. Curtis, R. K. Dahlstrom, R. L. Echols, Russell Fanning, Sherman L. Gerhard, Edith Gideon, Lynn G. Howell, David R. Inglis, H. D. Koenig, J. B. Horner Kuper, W. Wallace Lozier, Charles H. Lutz, Alfred F. Meyer, Parry H. Moon, Lewis M. Mott-Smith, Willard J. Poppy, Charlotte Purdy, Russell W. Raitt, G. H. Rockwood Jr., Paul N. Russell, Frances O. Severinghaus, G. D. Shallenberger, Paul E. Shearin, Klaus J. Sixtus, Louis Statham, Paul Talmey, Josiah Taylor, George S. Thomas, Kenneth, B. Thomson, Louisa E. Townshend, John F. Wagner, Clarence W. Wallace, Charles A. Whitmer, Ralph E. Winger, and Bruno O. Winkler.

The regular scientific program of the Society consisted of 82 papers, numbers 24, 56, 62, 78 and 80 were read by title. The abstracts of these papers are given in the following pages. An **Author Index** will be found at the end.

W. L. SEVERINGHAUS, *Secretary*

ABSTRACTS

1. Mass absorption coefficient of the *K* shell according to the Dirac relativistic equation. LOUIS C. ROESS, *Cornell University*. (*Introduced by E. H. Kennard.*)—Taking as model an atom containing two non-interacting electrons and a fixed nucleus with charge Ze , the mass absorption coefficient is calculated using the proper functions of the Dirac relativistic equation. Z is determined so as to make the lowest energy level agree with the experimental value determined from the *K* absorption edge. The numerical calculation presented difficulty because of lack of tables of complex gamma functions. The relativistic coefficient is found to be from 0% to 40% smaller than the non-relativistic coefficient calculated by Nishina and Rabi, the greatest difference occurring for the heavy elements and short wave-lengths; it agrees slightly worse with experiment than the non-relativistic coefficient. The difference between theory and experiment is least for the heavy atoms, as would be expected, since for the heavy atoms (large Z) the neglected electronic interaction-field is small in comparison with the nuclear field. The variation of the relativistic coefficient with wave-length is complicated, but in the range $\frac{1}{2}\lambda_k$ to λ_k (λ_k = wave-length of *K* absorption edge) it is more nearly linear with λ^3 than the non-relativistic coefficient. The importance of using the relativistic equation for heavy atoms and short x-ray wave-lengths is emphasized by these results, which also show that the model chosen is too approximate, even for the heavy elements.

2. Nature of magnetic doublet in para-azoxyanisol at 122° and 128°C as determined by x-ray diffraction. G. W. STEWART, *University of Iowa*.—A difference of opinion exists as to whether the magnetic moment of para-azoxyanisol in its liquid crystalline form, 117°C to 134°C, is an induced one or is independent of the field. A magnetic field is applied perpendicular to the axis of rotation of the spectrometer and to the x-ray beam passing through the sample. The effect of the field in the diffraction halo is studied quantitatively. Boltzmann's distribution law is assumed. The data are in agreement with the computations assuming the magnetic moment to be not polarized but permanent and to possess a value of 2.65×10^4 Bohr magnetons, in agreement with the results of Kast. This suggests, but does not make certain,

that a group of that number of molecules gives rise to the magnetic moment. The diffraction of x-rays at temperatures above 134° shows the disappearance of the magnetic moment, but a retention of groups otherwise similar to those just suggested. The groups causing optical anisotropy are larger and not regular enough throughout to produce coherent x-ray diffraction. These large groups are easily affected by the stirring of the liquid. The time required for orientation is easily shown by the application of an alternating magnetic field. The experiment shows the value of the direct x-ray investigation.

3. The utilization of intensity data from Laue photographs. MAURICE L. HUGGINS, *Stanford University*.—The measurement of Laue photograph intensities and the calculation of structure factors from them are discussed. Methods of correcting for differences (in intensity of the incident radiation, in absorption and in photographic effect) dependent on the wavelength, for differences (in size of the spot, in absorption and in the background of scattered radiation) dependent on the reflection angle, and for absorption (including primary and secondary extinction) dependent on the nature of the crystal, are considered and the results of preliminary measurements and calculations presented.

4. The characteristic x-ray absorption of molecules in the vapor state. J. D. HANAWALT, *National Research Fellow, University of Michigan*.—The purpose of the work here described is to provide a better understanding of the secondary absorption discontinuities which appear on the short wave-length side of the K and of the L x-ray absorption edges of many substances. The interpretation of the secondary discontinuities has been especially difficult because the absorption has not been obtained for atoms in the isolated state. In the present work the characteristic x-ray absorption spectra of numerous polyatomic and monatomic molecules in the vapor state have been photographed with a dispersion of about 5 XU/mm, and the results compared with the absorption spectra exhibited by the same substances in the solid state. The monatomic substances investigated are superheated Hg vapor, superheated Zn vapor and krypton. The polyatomic substances are the vapors of As_4 , $AsCl_3$, As_2O_3 , Br_2 , $NaBr$, $HgCl_2$, Se_8 , SeO_2 . It is found that none of the monatomic molecules show any absorption discontinuities at distances from the main edge greater than the ionization potential of the atom. The polyatomic molecules, however, show secondary absorptions in the vapor state differing only in minor details from the absorption of the same substance in the solid state. This makes it appear that the secondary discontinuities are only observed for atoms which are bound to other atoms. If the discontinuities are to be attributed to simultaneous jumps of two or more electrons within the atom, one has yet to understand why they do not occur in isolated atoms.

5. X-ray absorption coefficients of the light elements and their relations to the various absorption formulae. S. J. M. ALLEN, *University of Cincinnati*.—The x-ray absorption coefficients of the elements have been measured with greater precision and care at $\lambda = 1.539\text{\AA}$ and 1.934\AA with especial reference to the low atomic weight elements, O, C, B, Be, Li, H. It was found necessary for these to have a complete chemical analysis carried out and corrections made by the additive law to ensure resultant values of μ/ρ , for which some degree of certainty could be stated. An impurity of iron of less than 0.1 percent at $\lambda 1.539$ can have a marked effect. The values of μ/ρ , so far obtained, are compared to those predicted by the various formulae. A new formula developed by the author which was found to hold exceedingly well down to neon indicated irregularities below that point, C, N, and O certainly falling below the formula and Be and Li probably above. The same was generally true with the Z^4/A (Owens) law. The value of μ/ρ for Li at $\lambda 1.539$ extended by the λ^3 law to $\lambda 0.71$ ($K\alpha$ of Mo) gives values much less than those previously reported (Hewlett, Mazumdar) at this wave-length.

6. The upper atomic number limit of the satellites of the x-ray line $L\beta_2$. ROBERT D. RICHTMYER, *Cornell University*. (Introduced by F. K. Richtmyer.)—Five satellites of the line $L\beta_2$ have previously been reported for the elements in the atomic number range 40 to 51. An attempt was made to extend this range to higher atomic numbers, and to determine whether there is a limit in the atomic number scale beyond which the satellites do not exist. A Siegbahn vacuum spectrometer was used, the only departure from the usual photographic method of

x-ray spectrometry being the comparatively high voltage on the x-ray tube. The satellite $L\beta_2(a)$ was observed and measured for elements 50, 51, 52, 53, 56, 58, and 60; and two others, $L\beta_2'$ and $L\beta_2''$, only as far as element 53. For elements above Xe (54), the diagram lines (Siegbahn) $L\beta_1$, $L\beta_3$, and $L\beta_{10}$ shift their positions in the spectrum relative to $L\beta_2$ in such a way that they occupy the region just where one would expect to find the satellites $L\beta_2'$ and $L\beta_2''$, making observations difficult. The plates seem to show, however, that these satellites fade out and disappear with atomic number 53. The satellites $L\beta_2(b)$ and $L\beta_2(c)$ are not found above number 50. Throughout these extensions of their ranges the satellites, where found, obey the law that $(\Delta\nu/R)^{1/2}$ is a linear function of atomic number.

7. Upper atomic number limit of the satellites of the x-ray line $L\alpha_1$. E. RAMBERG, *Cornell University*. (Introduced by F. K. Richtmyer.)—The satellites of $K\alpha_1$, namely $K\alpha_3$ and $K\alpha_4$, decrease in intensity rapidly with increasing atomic number above Cu(29) and have not been reported above As(33). Their disappearance seems to coincide, roughly, with the completion of Period IV of Bohr's periodic table. Similarly the satellites of $L\alpha$, although strong at Cd(48), fade out very rapidly as the end of (Bohr's) Period V is approached. The present paper is concerned with an attempt to map, by very long exposures, these $L\alpha$ satellites in the atomic number range Sn(50) to Ce(58). There is no certain evidence of their existence above Xe(54). From Sn(50) to I(53) they fade out into a very faint, diffuse band which shows very little evidence of structure, and in which therefore the identification of the lines and their wavelength measurements are difficult. The bearing of these data on the problem of the origin of satellites is discussed.

8. Are the wave-lengths of x-ray satellites affected by chemical combination? F. K. RICHTMYER, *Cornell University*.—The "two-electron jump" theory of the origin of satellites, proposed by the author, postulates that one of the jumps should be between outer electron shells and should therefore be somewhat affected by chemical combination. That is, the difference in wave-length $\Delta\lambda$ between a satellite and its parent line should depend on the chemical state of the emitting atom. The present paper describes an attempt to detect such a shift in wave-length for the $K\alpha$ satellites of Si(14), S(16), Ca(20), Ti(22) and the $L\beta_2$ satellites of Ag(47). Except in the case of Si(14) the data are inconclusive because of the possible reduction or oxidation of the element in the target and the resulting well-known change in wave-length of the parent lines. Measurements on Si(14) were less ambiguous. Comparing the $K\alpha_{3,4}$ satellites of metallic silicon with those from Na_2SiO_3 , the $\Delta\lambda$ for the silicate is 3.9 percent greater in the case of $K\alpha_3$, and 2.8 percent greater in the case of $K\alpha_4$ than for metallic silicon. These data are in substantial agreement with those of Bäcklin (Zeits. f. Physik 38, 215, 1926). It will apparently be necessary to study fluorescence spectra to avoid spurious effects of chemical reduction in the target.

9. Interpretation of x-ray satellite lines. R. M. LANGER, *Massachusetts Institute of Technology*.—Quantum mechanical calculations show that double electron jumps involving two electrons in different shells would give lines too faint to account for observed x-ray satellites. A theory can be given for single electron jumps in doubly ionized atoms which would give lines of much greater intensity and which would be compatible with the experimental results of Richtmyer and Taylor, and DuMond and Hoyt. According to this theory the $K\alpha$ satellites α' , α_1 , α_3 , α_5 , α_6 of the elements from Na on, are due to the transitions

$$\begin{aligned} (1s)(2s)(2p)^6\ ^1S - (1s)^2(2s)(2p)^5\ ^1P \dots (\alpha') \\ (1s)(2s)(2p)^6\ ^3S - (1s)^2(2s)(2p)^5\ ^3P \dots (\alpha_1) \\ (1s)(2s)^2(2p)^5\ ^3P - (1s)^2(2s)^2(2p)^4\ ^3P \dots (\alpha_3) \\ (1s)(2s)^2(2p)^5\ ^1P - (1s)^2(2s)^2(2p)^4\ ^1S \dots (\alpha_5) \\ (1s)(2s)^2(2p)^5\ ^1P - (1s)^2(2s)^2(2p)^4\ ^1D \dots (\alpha_6) \end{aligned}$$

There are five transitions to be expected and five are observed. Moreover the relative intensities come out in agreement with experiment. Accurate calculations of the separations between lines cannot at present be made because exact wave functions are not known. The

best available wave functions give separations about 50 percent off. The present theory can be extended to explain the structure of absorption edges and the shift of absorption edge with valence.

10. A check on the lattice constants and axial ratios of stibnite. JOHN G. ALBRIGHT, *Case School of Applied Science*.—Dana (Textbook of Mineralogy) classifies stibnite as orthorhombic with axial ratios 0.9926:1:1.0179. Gottfried (*Zeitschrift für Kristallographie* 65, 427-434, 1927) gives the axial ratios as 0.992:1:0.338 and the lattice constants as $a=11.39\text{\AA}$, $b=11.48\text{\AA}$, $c=3.89\text{\AA}$, making the value for the unit cell along the c axis about one third of that indicated by Dana's values. In view of Dana's reputation for accuracy it was thought desirable to check the determinations of Gottfried. X-ray diffraction and reflection photographs give values for the lattice constants of $a=11.29\text{\AA}$, $b=11.45\text{\AA}$, $c=3.87\text{\AA}$, making the axial ratios 0.986:1:0.339, which agree very well with the values given by Gottfried.

11. X-ray analysis of cold rolling and recrystallization in steel. C. NUSBAUM, *Case School of Applied Science*.—A careful and extensive study, by means of Laue photographs, has been made of the effect of cold rolling on low carbon steel and the subsequent heat treatment necessary for its complete removal. The changes due to increasing degrees of cold rolling may be considered as taking place in three stages (1) introduction of internal stresses as indicated by radial asterism, (2) the fragmentation of the individual crystals, and (3) the increasing degree of preferred orientation of the crystal fragments. The necessary temperature in the subsequent heat treatment for the complete removal of the effect of cold rolling is a function of the degree of the cold work. However, recrystallization is necessary for the complete removal of preferred orientation.

12. The "spread" as a measure of deviation in physical measurements. ELLIOT Q. ADAMS, *Lamp Development Laboratory, Nela Park*.—In order to compare results of incandescent lamp tests expressed in terms of the spread (maximum difference) observed in sets of various numbers of lamps, it was necessary to calculate factors to convert these results to a comparable basis. The average deviation of a single observation was chosen as the basis of comparison. Assuming a Gaussian distribution of errors, the factors have been calculated by mathematically approximate methods, and may be expressed by the semi-empirical formula: Spread/(av. deviation) = $f(n) = (5.304 - 2.11/(0.47 + \lg n))(\lg n)^{1/2}$ with an error not exceeding 0.01 in the factor. This error is negligible in comparison with the unavoidable error in determining by any method the average deviation in a set of fewer than 10^8 observations, i.e., in practically all physical measurements. While it may be shown mathematically that the average deviation so computed is less precise than that computed from the sum of the residuals, or *a fortiori* of their squares, the difference seldom exceeds the probable error of the more refined measures. The labor of computation is so much less than that of the more precise methods that an expression of the internal consistency of *all* results of physical measurements may reasonably be required.

13. The wave-mechanical theory of radiation. E. H. KENNARD, *Cornell University*.—A complete theory can easily be developed in terms of traveling plane waves instead of standing oscillations; such a form should be especially useful in dealing with phenomena which like the Compton effect involve motion. Replacing the usual Fourier integral by a series we write for the classical vector-potential of the radiation field, $A = \Sigma(i)(a_i I_i' \cos \theta_i + a_i'' I_i'' \sin \theta_i) \Delta\nu \Delta\omega$ where $\theta_i = 2\pi\nu_i(t - gx_i)$, $c=1/g$ being the speed of light, x_i distance along the ray, I_i' and I_i'' two perpendicular unit vectors and $\Delta\omega$ an element of solid angle. As coordinates and momenta we take $Q = \beta_1 a' \cos 2\pi\nu t$, $P = \beta_1 a' \sin 2\pi\nu t$, and $Q = \beta_1 a'' \sin 2\pi\nu t$, $P = -\beta_1 a'' \cos 2\pi\nu t$, $\beta_1^2 = c\Delta\nu\Delta\omega/2\nu$; the energy is then $W = \Sigma(\sigma)\pi\nu_\sigma(Q_\sigma^2 + P_\sigma^2)$, and $A = \Sigma A_\sigma = \Sigma \beta_\sigma I_\sigma(Q_\sigma \cos \theta_\sigma + P_\sigma \sin \theta_\sigma)$ where $\theta_\sigma = 2\pi g\nu_\sigma x_\sigma$, $\beta_\sigma = 2\nu\beta_1/c$. We now replace P_σ by $\hbar/2\pi i \partial/\partial Q_\sigma$ and form the Schrödinger time equation, adding in the Hamiltonian for a non-relativistic free electron simply $1/2m(\nabla - e/c\Sigma A_\sigma)^2$. The motion of a packet is easily followed; formulas almost classical in form are obtained for its centroid, with the operators $-\Sigma \partial A_\sigma/\partial x_\sigma$ and $\Sigma \nabla \times \Sigma A_\sigma$ acting as electric and magnetic field-strengths. The acceleration vanishes when the field is in its normal

or any other pure quantum state, showing that the "zero-point" infinite energy does not imply the existence of a physical electromagnetic field.

14. On the mechanism of light absorption in solid bodies. J. FRENKEL, *Visiting professor from Leningrad, University of Minnesota*. (Introduced by H. A. Erikson.)—Starting from the analogy between a crystal and a molecule, it is shown that the electronic excitation, forming the first step in the process of light absorption, is not confined to a particular atom, but is diluted between all of them in the form of "excitation waves," similar to sound waves which are used to describe the heat motion in the same crystal. Owing to the interaction between the atoms the excitation state is split up into substates whose number is equal to the number of atoms n (excitation multiplet). By superposing several excitation waves "excitation packets" can be constructed representing the travelling of the excitation state from one atom to another. To each excitation (sub.) state there corresponds a definite crystal structure (lattice constant, vibration frequencies) slightly different from that of the normal one, and giving rise to slightly different vibrational states. This influence of the excitation on the vibrational states provides an indirect coupling between them, which allows the excitation energy to be shared between a few hundred heat-oscillators with practically no direct coupling (nor anharmonicity) in a radiationless transition which forms the second state of the process of light absorption.

15. Interchange of translation, vibration, and rotation energy. CLARENCE ZENER, *Harvard University*.—A modification of the Born collision method is used to calculate the effective cross-sections of inelastic collisions of the first and second kind between atoms and molecules. The unperturbed Hamiltonian is taken to be the exact Hamiltonian averaged over the internal coordinates of the molecule. The internal motions of the molecule is treated as the perturbation that results in a transfer of energy. The sharpness of the collisions is approximately obtained from the mean ionization potentials of the two colliding systems. The small probability of transfer of vibrational and translational energy arises from the duration of the collision being greater than the time of oscillation. In general, the effective cross-section for a collision of the second kind is comparable to the kinetic theory cross-section only when a frequency of the molecule is comparable to a frequency associated with the combined system of molecule and atom.

16. Orbital valency. JAMES H. BARTLETT, JR. *University of Illinois*.—The problem of interaction of two identical atoms, each with one p valence electron, has been investigated. The total system has originally a twelve-fold degeneracy, and a first order perturbation calculation is made, using a method analogous to that of Kemble and Zener for the excited states of the hydrogen molecule. This enables one to give an estimate of the relative positions of the resulting molecular states as a function of the internuclear distance. A simple atomic wave function similar to those employed by Zener (with no radial nodes) has been used in the present work to facilitate the calculations. Complete potential energy curves have now been obtained, and agree in general with the results reported in a letter to the *Physical Review* 36, 1096 (1930).

17. Directed valence in polyatomic molecules. J. C. SLATER, *Massachusetts Institute of Technology*.—By means of wave mechanics one can draw conclusions regarding valence in polyatomic molecules, finding in particular that the different shared electron bonds from a single atom tend to be at definite angles to each other. The two bonds in atoms like oxygen, and the three in nitrogen, tend to be mutually perpendicular, while in carbon a tetrahedral structure is indicated. These conclusions in the first two cases rest on the nature of the wave function for a p electron: the three types of p electron may be considered to have densities large along three mutually perpendicular directions. With carbon, one must combine these three with an s electron to produce tetrahedral valences. The conclusions can be supported by a wide range of experimental facts, from the structure of simple inorganic molecules, metals, and organic compounds.

18. Polarizabilities and intra-atomic energies of hydrogen and helium. JOHN G. KIRKWOOD, *Massachusetts Institute of Technology*. (Introduced by J. C. Slater.)—A method of calcu-

lating polarizabilities and intra-atomic energies has been developed. An approximate separation of variables in the original wave equation is effected. From the approximate wave function which is obtained, a more exact one is constructed with the use of the variation principle. The polarizability and energy of two atoms at large distances have been calculated for hydrogen and helium.

19. On the Michelson-Morley-Miller experiment. N. GALLI-SHOHAT, *Mount Holyoke College*.—At the meeting of the American Physical Society held in Washington in April, 1930, it was suggested by the writer that Professor Miller's effect can be explained by means of the effect observed by Esclangon. This further enables us to explain why Professor Michelson in the last repetition of his experiment did not observe any effect. In fact, the displacement of the fringes due to the effect of Esclangon (rotation of the whole interference pattern) depends only upon the orientation relative to the motion of the solar system of that part of the path of light in the interferometer, which goes from the last reflection directly into the eye of the observer. In the arrangement of apparatus used by Professor Michelson, this path was made stationary, being directed *along the axis of rotation*. Thus, the revolution of the interferometer around this axis *could not change* the orientation of this path in space; hence, *no effect can be expected*. While in his first arrangement, which was used also by Professor Miller, this path lies *in the plane* of the interferometer, hence, a change due to revolution and a displacement of the fringes.

20. Change in mass-weight ratio. PETER I. WOLD AND EARLE M. BIGSBEE, *Union College*.—The late Charles F. Brush carried on experiments which led him to conclude that the weight of a metal may change when strained, giving a change in the ratio of mass to weight. His experimental technique seemed to preclude the obvious sources of errors which might be urged as explanation of his results. The matter is of sufficient importance to our theories of gravitation to justify checking and at his request weighings were made on certain alloys prepared by him. The procedure was practically the same as described in his paper in *Proceedings of the American Philosophical Society* (Vol. 63, 1925, p. 36). Weighings taken on various specimens showed losses in weight when the specimen was compressed and a nearly complete recovery when the stress was removed. The changes were substantially in excess of balance errors. The losses were less than found by Brush and he considered this as due to annealing during the time between the preparation of the sample and its weighing. The shorter this time the larger were the observed effects. In the last sample studied, where elapsed time was shortest, the losses amounted to one part in 130,000. The work may be considered as confirming that of Brush. The suggestion that the effects are due to changes in the amount of adsorbed gases does not appear to be a sufficient explanation.

21. Properties of single crystal magnesium. P. W. BRIDGMAN, *Harvard University*.—Pure magnesium, which I owe to the Aluminum Company of America, was prepared in single crystal form by slowly lowering out of a vacuum furnace iron molds filled with the melted metal. The crystal structure of magnesium is known to correspond to the close packed hexagonal arrangement of spheres. It is therefore to be expected that the properties will not vary greatly with direction. This turns out to be true for the compressibility, for which was found:

$$\text{Parallel to the axis, at } 30^\circ - \Delta l/l_0 = 9.842 \times 10^{-7} p - 6.51 \times 10^{-12} p^2$$

$$\text{at } 75^\circ - \Delta l/l_0 = 10.154 \times 10^{-7} p - 7.78 \times 10^{-12} p^2.$$

$$\text{Perpendicular to the axis, at } 30^\circ - \Delta l/l_0 = 9.845 \times 10^{-7} p - 9.19 \times 10^{-12} p^2$$

$$\text{at } 75^\circ - \Delta l/l_0 = 9.659 \times 10^{-7} p - 6.95 \times 10^{-12} p^2.$$

Pressure is expressed in kg/cm², and the pressure range is 12000.

The electrical resistance, however, does not satisfy expectations. At 22.5 the specific resistance is 3.89×10^{-6} parallel to the axis, and 4.60×10^{-6} perpendicular to it. Not only does the resistance vary materially with direction, but in almost all other non-cubic metals the resistance is greater parallel to the axis. The average pressure coefficient to 12000 was found to be 4.35×10^{-6} parallel to the axis, and 4.62×10^{-6} perpendicular to it. The temperature coefficient of resistance at atmospheric pressure between 0° and 100° was 0.00523 and 0.00428 respectively.

22. **Transverse heat effect in single crystal bismuth plates.** H. P. STABLER, *Harvard University*.—The dependence of the transverse heat on the orientation of the crystallographic axis has been studied in single crystal bismuth. The metal was of three different varieties (of which one was specially prepared electrolytic bismuth) all having high temperature coefficients of resistance and giving identical results. The crystals were grown by a modification of Kapitza's method in the form of uniform rectangular plates, about 15×2.2 mm cross-section, and perfect over a length of from 4 to 16 cm. Measurements made on twenty-eight plates covering the entire range of orientation show clearly that the Thomson symmetry relation for the transverse heat, $[T(\theta) = (P_{\parallel} - P_{\perp}) \sin \theta \cos \theta]$, is not satisfied. The ratio $(T(\theta)/\sin \theta \cos \theta)$ plotted against $\sin \theta \cos \theta$, instead of being constant, varies in a roughly sinusoidal manner, with the extremes at 15° and 75° differing by $24\% \pm 5$. These values are 14.2 and 18.0×10^{-3} watt respectively, and at 45° , 15.9 . Bridgman, and Fagan and Collins have shown that the longitudinal Peltier effect also, in bismuth, deviates from the analogous Thomson relation. Ehrenfest's recent treatment of these phenomena in crystals arrives at the Thomson relations, and thus his treatment, though general, is not sufficiently comprehensive to account for these experimental results.

23. **Liquid flow through porous unsaturated mediums.** L. A. RICHARDS, *Cornell University*.—When a liquid is absorbed by a porous medium and the medium is unsaturated the pressure within the liquid is less than atmospheric pressure and is determined by the curvature of the air-water interface. Under such circumstances flow of the liquid through the medium is caused by gravity and pressure gradients within the liquid. Analogous to electrical currents in metals, this flow may be expressed in terms of the product of a potential gradient and a conductivity factor. For the capillary case, however, the conductivity is a function of the potential which in turn is a function of the liquid content of the medium. By means of specially constructed porous cells the conductivity of water through clays, soils and sands has been measured at various potentials. These data furnish a basis for a quantitative study of the motion and equilibrium distribution of water in such mediums.

24. **Determination of frequency and damping of resonating circuits.** J. TYKOCINSKI-TYKOCINER, *University of Illinois*.—It was found as a further result of studies of thermionic oscillators (Phys. Rev. 33, 634 (1929); and Univ. of Ill. Eng. Exp. St. Bul. No. 194) that periodic variations of constants of a coupled circuit produce periodic variations of plate and grid current. This property of oscillators was investigated and applied for the determination of frequency and damping of circuits whose location or other conditions do not allow the insertion of a variable condenser, variometer or resonance indicator. The circuit is coupled with a calibrated circuit energized by a thermionic oscillator tube and with an aperiodic circuit, whose reactance or resistance may be varied periodically by means of an electromagnetic tuning fork, buzzer or by superposed a.c. When the oscillator is being tuned, variations of the plate and grid current are produced, which show a periodicity corresponding to that of the tuning fork or a.c. and a transient amplitude passing through two maxima and a sharp minimum placed between them. The M -curve of effective current values thus obtained is a curve of derivatives of the Bjerknes resonance curve. The minimum coincides with the fundamental frequency. The interval separating the two maxima is proportional to the decrement of the measured circuit. The maxima and minimum of the M -curve are audible in a telephone receiver. The complete curve is obtained by thermoelectric or thermionic instruments connected to amplifiers. The method was applied to closed circuits and antennae at frequencies from 100 to 100,000 kc.

25. **The amplification of small direct currents.** L. A. DUBRIDGE, *Washington University, St. Louis*.—A series of tests has been made by the author, under the supervision of Dr. Hull at the General Electric Laboratories, to investigate the possibilities of using a newly developed four-element thermionic tube, the FP-54 Pliotron, (described by Metcalf and Thompson, Phys. Rev. 36, 1489 (1930)) in place of an electrometer in the measurements of very small direct currents. Simple circuits of standard types were found suitable and a wide range of sensitivity obtained. (1) With a single-tube circuit, using a Type R galvanometer and an input

resistance of 10^{10} ohms, a current sensitivity of 10^{-14} amp/mm is readily obtained. (2) Greater stability is attained by using a balanced two-tube circuit, with which a sensitivity of 10^{-16} amp/mm can be reached. (3) By "floating" the two grids of this circuit and using the "rate of drift" method of measurement, it was found that currents as small as 5×10^{-18} amp could be detected. (4) To enable the output to be read on a microammeter a second stage of amplification was employed. A deflection of 4 micro-amp. was obtained for an input current of 10^{-18} amp. The circuits are all more stable and simpler to operate than an electrometer of equal sensitivity, and the highest attainable sensitivity is greater than for any type of electrometer except the Hoffman.

26. Studies in non-linear circuits. CHAUNCEY GUY SUITS, *General Electric Company, Schenectady.* (Introduced by A. W. Hull).—The fundamentally important series inductance, capacitance, resistance circuit

$$L'(i) \frac{di}{dt} + \frac{1}{C(i)} \int idt + iR(i) = f(t), \quad (1)$$

where the parameters are functions of the current, is discussed. The frequent occurrence and great practical importance of circuit elements which depend upon the current are noted. The particular cases of the series and parallel circuit with linear resistance, linear capacitance, and a non-linear iron-core inductance are studied in detail. For the *series circuit* it is shown that the abrupt rise in current with increase in voltage at a certain critical voltage for the circuit may be identified as a quasi-resonance condition, called *non-linear resonance*. The condition for resonance in the linear circuit,

$$-L' \frac{di}{dt} = \frac{1}{C} \int idt, \quad (2)$$

is generalized as

$$-L'(i) \frac{di}{dt} = \frac{1}{C(i)} \int idt \quad (3)$$

for non-linear cases. The relation (3) is satisfied in the steady state *during a portion of each cycle*, wherein the peak current may be calculated from Ohm's law. For the *parallel circuit non-linear resonance* similarly obtains, and is associated with a decrease in total effective current with increase in voltage (r.m.s.), a property unique in circuits. The fundamental analogy between the behavior of linear circuits to changing frequency and non-linear circuits to changing voltage follows from the predominating voltage dependence of impedance for the non-linear iron-core inductance. The paper will be accompanied by demonstration apparatus if time permits.

27. The effect of the temperature dependence of the work function on A and b in Richardson's equation. J. A. BECKER AND W. H. BRATTAIN, *Bell Telephone Laboratories, Inc., New York.*—The most general form of Richardson's equation is

$$i = AT^{-1/2} e^{\int (L_p/RT^2) dT} \quad (1)$$

where L_p represents the energy added to the system when one mole of electrons is "vaporized" at constant pressure. This equation follows necessarily from the first and second law of thermodynamics and from the generally accepted assumption that the electron vapor behaves like a perfect gas. In order that

$$i = AT^2 e^{-b_0/T} \quad (2)$$

it is necessary that

$$L_p = b_0 R + 5RT/2 \quad (3)$$

and to assume that b_0 is independent of T . $5RT/2$ represents the kinetic energy of the electron gas plus external work done per mole at constant pressure. It is generally assumed or deduced that the electrons in the metal receive negligible energy when T is increased. In that case, $L_p - 5RT/2$ represents work done per mole against various electrical forces. Call this bR . If bR depends on T , (1) becomes

$$i = AT^2 e^{\int (b/T^2) dT}. \quad (4)$$

If $b = b_0 + \alpha T$

$$i = AT^{2+\alpha} e^{-b_0/T}. \quad (5)$$

If the work function varies linearly with T , we conclude: 1. equation (5) replaces (2) which is invalid; 2. the mean slope of $\log i - 2 \log T$ vs. $1/T$ is $b_0 + \alpha T$ and not b_0 ; 3. the intercept of this plot is $\log (A e^{\alpha T})$ and not $\log A$ or $\log (A e^{-\alpha})$.

28. Conductivity of oxide cathodes. N. H. WILLIAMS AND W. S. HUXFORD, *University of Michigan*.—The conductive properties of oxide coatings used in the equipotential cathode type of radio tube have been investigated. The inner nickel sleeve served as one electrode, the second being a nickel strip in contact with the outer surface of the oxide. Currents through the coating as measured at constant potential vary with the frequency of the applied electromotive force. A decrease in conductivity of about forty percent occurs when the frequency is changed from 1500 to about 10,000 cycles per second. The decrease starts at lower frequencies for higher values of applied potential. These results indicate a transfer of electrical charges through the coating by ionic conduction, the process being inhibited at the higher frequencies. A method of estimating the relative thermionic activities of core metal and oxide surface is suggested. Fluctuations in the current through the coating were measured on an amplifier tuned to various frequencies from 200 to 40,000 cycles per second. An abnormal increase in "shot" voltage was found for frequencies below 10,000 cycles. This result is believed to confirm the hypothesis that positively charged ions are neutralized in the space charge produced by electrons which are emitted thermionically from the activated surface of the core metal.

29. The electrical polarization of electrets. MAURICE EWING, *Lehigh University*.—The internal electrical polarization of an electret was determined by breaking a piece of the electret along a plane normal to the direction of polarization and measuring the charge per unit area which appeared on the newly-formed surfaces. The polarization for this particular electret was found to be 2.0 ± 0.2 esu/cm². The theory of Adams (Frank. Inst. J., 204, 469 (1927)) seems to require that the polarization in an electret be of the order of 10^6 esu/cm².

30. Electrical characteristics of a viscous mineral insulating oil as functions of temperature and frequency. H. H. RACE, *General Electric Co., Schenectady*.—Data recently taken on the dielectric loss and the dielectric constant of good mineral insulating oils lead to the following conclusions: (a) At constant temperature the dielectric constant decreases by only a few percent as the frequency is increased from sixty to two million cycles per second. (b) At constant frequency the dielectric constant decreases with increased temperature and this change appears to be proportional to the decreasing density of the oil. (c) For a given temperature there is a critical frequency such that for all lower frequencies the A.C. loss is independent of the frequency and for all higher frequencies the loss increases with the frequency. Within the first frequency range the mechanism of D.C. conduction and of A.C. loss appear to be the same, and both are probably due to the migration of charged ions or larger particles in the oil. Within the second range, the loss per cycle, (after that resulting from D.C. conduction has been subtracted), shows resonance characteristics as a function of either temperature or frequency. (d) The higher the temperature, the higher the critical frequency below which the A.C. and D.C. losses are the same. Power factors as high as 1% have been observed under conditions for which the loss resulting from conduction would be negligible. These data have been studied from the point of view of Debye's theory of polar molecules, and a qualitative agreement has been found.

31. Dielectric constants of certain organic compounds. W. R. PYLE, *The Ohio State University*.—The dielectric constant of an organic compound is thought to be allied with its other physical properties such as solvent power and molecular complexity. Probably the future will reveal a more definite correlation between the dielectric constant and the other physical properties of a compound. The nulled heterodyne method of measurement of dielectric constants was made possible by the advent of the triode valve and it is employed in this work. For room temperature and at a frequency of 85.8 kilocycles the dielectric constant was determined for

each of the following: benzene, carbon tetrachloride, chloroform, cinnamic aldehyde, ethyl ether, methyl cyclohexane, methyl o-nitrobenzoate, nitrobenzene, oxalyl chloride, n-propyl ether, iso-propyl ether, o-xylene, m-xylene and p-xylene. The temperature coefficients of the dielectric constant for ortho-, meta-, and para-xylenes were determined over a range of about 25°C for both the linear formula and Abegg's formula. It seems reasonable to believe that the values of the dielectric constants determined in this work are relatively as accurate as the purity of the organic compounds.

32. **Maintaining direction in flight.** JAMES D. TEAR, *General Electric Co., Schenectady, N.Y.*—Accelerations due to changes in course cause the aircraft compass to be responsive to the vertical component of the earth's magnetic field and to be misleading as a direction instrument. North courses cannot be flown without other reference means. The potential generated by an electromagnetic compass is a function of the course setting θ , the course error $\Delta\theta$ and the product of angular velocity and speed or the angle of bank ϕ . A gyroscopic device, the sensitivity of which is controlled by the course setting mechanism, supplies a potential proportional to $\sin \phi$ and $\cos \theta$ compensating the acceleration error. An additional angular velocity effect independent of course is added. A null effect then requires an angular velocity toward the chosen course proportional to angular displacement, the condition for aperiodic steering. The adequacy of the system for maintaining direction in clouds has been verified in a series of experiments in which the rudder angle was automatically made proportional to the algebraic sum of the potentials in the compass circuit.

33. **A method of weather forecasting.** R. C. COLWELL, *West Virginia University*.—It has been shown before that when a high pressure area covers both Pittsburgh and Morgantown, the day signal from KDKA is stronger than the night signal, while for a low pressure area, the night signal is the stronger. Hence the ratio of the day to the night energy received from KDKA at Morgantown will give some indication of the atmospheric conditions between the two cities. In this method of forecasting, a fading curve is taken for about one hour before sunset and three hours after sunset. The area is measured with a planimeter and the ratio of the day to night energy is calculated for each day. If this ratio is greater than one, fair weather is indicated; whereas, if the ratio drops to one half, a storm is approaching. In addition to this ratio, barometer readings are taken and wind directions observed. A storm area passing north of Morgantown will cause a low barometer and a south wind. If the storm center passes to the south, the energy ratio from a station to the north is no longer reliable and readings must be taken upon a station to the south.

34. **Photoelectric properties of composite surfaces at various temperatures and potentials.** DIMITER RAMADANOFF, *Cornell University*. (Introduced by Ernest Merritt).—A large number of experiments were carried out with Ba photoelectric cells to determine the variation of photoelectric current with temperature and plate potential. In all cases the photoelectric current increased greatly at the higher temperatures, and reached maximum at 740°C. At this temperature the thermionic current was limited by space charge. By illuminating the photoelectric cell with interrupted light, the intensity of which was varied sinusoidally, it was possible to measure the photoelectric current with a new method which incorporates the use of a transformer coupled amplifier and a Bedell-Reich stabilized "Oscilloscope." With this apparatus the thermionic current, and sluggish currents which may be due to light in a secondary way, were completely eliminated and only the true photoelectric currents were measured. In this way a curve was obtained which represents the relation of photoelectric current vs. temperature at a constant applied voltage. This curve shows two distinct maxima at 560°C and 740°C the first of which is not observable with a galvanometer if constant illumination is used.

35. **Correlating the selective photoelectric effect with the selective transmission of electrons through a cathode surface.** A. R. OLPIN, *Bell Telephone Laboratories, Inc.*—The results of Fowler and others with respect to the penetration of α -particles into a model nucleus suggested the possibility of explaining the selective photoelectric effect by the selective transmission of electrons of a definite velocity through the cathode surface. These electrons must be

associated with waves of such length that they will form standing waves between abrupt potential discontinuities of like sign on the cathode surface. The existence of such a potential valley may be reasonably postulated, particularly for surfaces consisting of a layer of electro-negative atoms or molecules sandwiched between electropositive layers. By interpreting the width of the valley to be the distance between the nuclear boundaries in successive electro-positive layers and substituting these for d in the easily derivable equation $\nu_{\max.} = n^2 h / 8md^2$ [or $d = 0.0551 \lambda_{\max.}^{1/2}$ Angstroms, for the case of $n=1$], an extremely close correlation with experimental facts results. All the observed selective maxima in spectral photoelectric response curves for the hydrides, oxides and sulphides of the alkali metals have been checked by this equation with a higher degree of accuracy than has been obtained by any other theory.

36. Physical detectors of "Mitogenetic Radiation." OTTO GLASSER AND V. B. SEITZ, *Cleveland Clinic Foundation, Cleveland, Ohio.*—Experiments of Alexander Gurwitsch and co-workers in 1924 showed that some form of radiation from growing and dividing cells of various plants and tissues produced increased mitosis in other cells. Since then this observation has been experimentally substantiated by numerous other workers. An attempt is described to detect and classify these "mitogenetic radiations" by physical means and some results of these experiments are reported.

37. Thermoluminescence excited by exposure to radium. FRANCES G. WICK, *Vassar College.*—The experiments described in this paper were made at the Institute for Radium Research in Vienna and the method of observation is one which has been used there by Dr. Karl Przibram. Calcium sulphate plus manganese and specimens of fluorite were exposed to radium and the thermoluminescence excited by this exposure was measured by heating the specimens in front of a photo-electric cell connected with a Wulf electrometer. Observations were made from the beginning of heating until the light was exhausted. Subjecting the specimens to a pressure of 10,000 Kg/cm² either before or after exposure to radium was found to change the intensity of the light emitted. Calcium sulphate plus manganese shows a single maximum of intensity as the temperature rises. The effect of pressure applied either before or after exposure to radium is to diminish the height of this maximum. Powdered fluorite previously heated to remove all natural thermoluminescence, shows, after exposure to radium, a number of sharp maxima due to different rare earth impurities. These maxima are lowered as a result of pressure. A broad diffuse band in the blue upon which the sharp bands are superimposed is made stronger as a result of pressure.

38. Significance of wave-length in color vision. C. A. RINDE, *College of the Pacific.*—Helmholtz and Koenig showed all color sensations to be reproducible by mixing light of three specific wave-lengths. Ladd-Franklin suggested red and green, blue and yellow as primary; each pair belonging to a single sensitive mechanism. The author's measurements of the retinal areas sensitive to homogeneous light selected from various regions of the grating spectrum indicate that the four areas exist and are independent. The approximate wave-length range to which each is sensitive has been measured, and an additional area sensitive only to the shorter wave-lengths has been found.

39. Appearance of color bands in films of sputtered tin. LESTER I. BOCKSTAHLER AND C. J. OVERBECK, *Northwestern University.* Small circular cathodes of tin are used to sputter films on glass. These films show concentric rings of color similar in appearance to Newton's rings. When viewed with monochromatic light, the rings are alternately light and dark. In white light the films show several cycles of the colors of the visible continuous spectrum. The growth of a set of rings, when viewed with reflected white light, begins with the appearance of a blue center a few seconds after the discharge is started. This center gradually passes through a cycle of colors of increasing wave length until it is red. With the appearance of each new center color all preceding colors move outward and form surrounding bands. The red center then merges into blue and the cycle is repeated. The rate of growth of a set of bands depends on the nature of the gas as well as on its pressure and the current density. Under a given set of conditions the change of color of the center and the addition of another set of color bands takes place with very definite regularity. Work is in progress to determine the chemical nature of these films and the cause of the colors.

40. The transmission of visible light through fog. H. G. HOUGHTON, *Round Hill Research Division, Massachusetts Institute of Technology (Introduced by J. A. Stratton)*.—Measurements have been made on the transmission of visible light through artificial fog which was produced by condensing low pressure steam. Curves for various densities of fog were plotted and found to have definite maxima at about 4900Å. The relation between fog density and the transmission of light was found to be practically linear for all wave-lengths in the visible spectrum. The maxima obtained are not in agreement with the results of other investigators but it is thought that this is due to a difference in the particle size of the fogs. Measurements indicated that the particles of the fogs used were considerably smaller than those of the fogs employed by other experimenters.
41. Theoretical discussion of the transmission of light through fog. J. A. STRATTON AND H. G. HOUGHTON, *Massachusetts Institute of Technology*.—The transmission of light through fog has been studied from a theoretical standpoint in an attempt to explain the experimental results described in another paper. The treatment is based on the work of Debye, Mie, Jobst and others on the pressure of light and on the colors of colloidal solutions. The fog particles are considered to be perfect dielectric spheres having an index of refraction of 1.33 and a permeability of unity. The coefficient of absorption, which is a function of particle diameter, is obtained by direct summation of Jobst's expression. By proper selection of particle diameter a theoretical curve is arrived at which fits the experimental curve quite closely. This particle size checks the measured value within the accuracy of the measurements. The transmission of light through fog having larger particles may be readily computed in the same manner.
42. Ultraviolet energy radiated by General Electric type S-1 lamps in quartz bulbs. B. T. BARNES, *Nela Park Laboratory, Cleveland*. The energy flux density of the principal ultraviolet lines from General Electric S-1 lamps in fused quartz bulbs has been measured. The latter are made somewhat smaller than the glass bulbs so that with normal operation the temperature of the mercury pool will be the same in the two cases in spite of the lower absorption of the quartz in the infra-red between 2 and 4 μ . The gain in intensity by use of quartz bulbs is even greater than expected. With quartz bulbs the lines at 2650 and 2537Å are nearly as strong as those around 3000Å.
43. The General Electric photoflash lamp. W. E. FORSYTHE AND M. A. EASLEY, *Nela Park Laboratory, Cleveland*. The bulb of the new photoflash lamp contains about fifty milligrams of aluminum foil that has a surface of about three hundred sixty square centimeters. This lamp can be operated from a one and one half volt storage battery or from a one hundred fifteen volt line. As the lamps are now constructed they start about two hundredths of a second after they are turned on and from the beginning of the flash to the maximum is about sixteen thousandths seconds while the whole flash lasts about six hundredths seconds. The maximum flux amounts to well over one million lumens.
44. Recent Developments in Architectural Acoustics. PAUL E. SABINE, *Riverbank Laboratories*.
45. Some Physical Characteristics of Speech and Music. HARVEY FLETCHER, *Bell Telephone Laboratories, Inc.*
46. Concerning Some of the Problems Encountered in Recording and Reproducing Photographic Sound Records on Moving Picture Film. CLARENCE W. HEWLETT, *General Electric Company*.
47. Magnetostriction measurements using a heterodyne beat method. A. B. BRYAN AND C. W. HEAPS, *Rice Institute*.—The apparatus previously used in measuring discontinuous changes in length accompanying the Barkhausen effect in nickel has been employed for gross magnetostriction measurements in nickel and iron and in magnetite, hematite and bismuth crystals. Length changes in a direction parallel to the applied magnetic field are measured. The results for nickel and iron are similar to those previously obtained. Magnetite expands

for two orientations and contracts for a third and shows no hysteresis. Hematite shows a small expansion for each of two orientations. For bismuth a field of 2160 gauss produces no measurable change in length. It is estimated that $\Delta L/L$ is less than 2.2×10^{-9} . Additional measurements are to be made with larger magnetic fields and higher sensitivity.

48. Variation of magnetic susceptibilities with temperature in Sm^{+++} and Eu^{+++} . AMELIA FRANK, *University of Wisconsin*.—Calculation of susceptibilities in Sm^{+++} and Eu^{+++} , previously made at room temperature only (J. H. Van Vleck and A. Frank, *Phys. Rev.* **34**, 1494 (1929)) were extended to include values over a temperature range 14°K–1000°K using the theoretical expression previously given (l.c.). The value of the temperature coefficient $(1/\chi)(d\chi/dT)$ at 300°K was found to be -0.00187 for Eu^{+++} and only -0.00032 for Sm^{+++} in contrast with the normal Curie value -0.00333 . These values are in satisfactory agreement with existing experimental data. Cabrera finds -0.002 for Eu^{+++} while Freed and other observers report values in the neighborhood of -0.0006 for Sm^{+++} . The coefficient for Sm^{+++} is so abnormally small that accurate percentage agreement cannot be expected. The computed values show that Sm^{+++} should exhibit a curious behavior in that, while at low temperatures the susceptibility decreases quite rapidly with an increase in temperature, a minimum is reached at about 400°K.

49. On the theory of magnetic susceptibilities of salts of the iron group. J. H. VAN VLECK, *University of Wisconsin*. It is well known that the susceptibilities observed for these salts, in marked contrast to those of the rare earths, do not have the theoretical values for free ions, but instead conform to a formula $\chi = N(hc/2\pi mc)^2 S(S+1)/3kT$ obtained by assuming that only the spin S of the paramagnetic ion contributes freely to the susceptibility. As emphasized by Stoner, (*Phil. Mag.* **8**, 250), this demands that inter-atomic forces quench the magnetic effect of the orbital angular momentum, both in solids and solutions. The present paper aims to show that these forces can really do this. Following Bethe and Kramers, they may be approximately represented by a potential V whose series development usually begins with second order terms $Ax^2 + By^2 + Cz^2$. If $|(A-B)\bar{x}^2| \gg kT$ etc., or in general if V has no more than rhomboidal symmetry and is large compared to kT , these inter-atomic forces really quench the orbital moment. For the spin to be free, however, one must have $(h\Delta\nu_M)^2/h\Delta\nu_V \ll kT$, where $h\Delta\nu_M$ and $h\Delta\nu_V$ are respectively of the order of magnitude of the multiplet intervals for free ions and of the dissymmetry in V . These conditions require that $h\Delta\nu_V$ likely be of the order 0.1 to 1 volt. This agrees qualitatively with the coloring of iron salts in solution, which indicates that the ion is held in complexes whose binding energy is about 1 volt.

50. Magnetic susceptibilities of some binary alloys. F. L. MEARA, *Ohio State University*.—Gouy's method for measuring susceptibilities has been used to determine the susceptibilities of six series of binary alloys, tin-thallium, cadmium-zinc, antimony-cadmium, antimony-thallium, antimony-lead and antimony-tin. The specimens in the form of small cylindrical rods were made from the purest metals obtainable and were melted either in a vacuum or in an atmosphere of nitrogen. The difference in weight in and outside a magnetic field was determined by means of a Sartorius balance, which under favorable conditions gave the weight to one millionth of a gram. The maximum error did not exceed one percent. Curves showing the relation between susceptibility and concentration indicate the formation of the inter-metallic compound Sb-Cd in the cadmium-antimony series, and Sn-Tl in the tin-thallium series. With the addition of thallium to antimony the diamagnetic susceptibility passes through a minimum when the concentration of antimony is about eighteen percent. The lead antimony series shows a similar minimum at fifty percent. The susceptibility of the zinc-cadmium series indicates that zinc is slightly soluble in cadmium, and cadmium slightly soluble in zinc, and the remainder of this series of alloys mechanical mixtures.

51. The emission of positive ions from metals. H. B. WAHLIN, *University of Wisconsin*.—The positive ion emission from metals has been investigated by a mass spectrograph method. It has been found that most metals when first heated give off alkaline ions, as has been observed before. In addition, Cr, Mo, W, Ru, Rh, Nb, Ta, when heated to a temperature where vaporiza-

tion becomes appreciable, give off ions which are singly charged atoms of the electrode material itself. No indications of doubly charged atoms were obtained. Cu, Ag, Au, Zn, Mn, V, Fe, Co, Ni, Pd, Os, Ir, Pt, U, Th, Sb give only alkaline ions. Mn is doubtful. The work is being extended to temperatures above the melting point.

52. Residual ionization in air at new high pressures and its relation to the cosmic penetrating radiation. JAMES W. BROXON, *University of Colorado*.—Residual ionization measurements in air at pressures up to 170 atmospheres were made at 5400 ft. altitude in a spherical chamber of 11-23/32 in. diameter with lead and water shields. Values as low as 1.47 ions/c.c. sec. at 0.83 atmosphere were observed. At pressures above 140 atmospheres ionization-pressure curves obtained with the chamber shielded were parallel to the pressure axis, slopes in this region certainly not exceeding 0.02 ion/cc sec. atm. Increased shielding decreased the ionization, showing the existence of a penetrating radiation. Observations with water shields showed this radiation to have its origin above the level of the chamber. The calculated absorption coefficients are 0.0127 cm^{-1} lead, and 0.0010 or 0.0028 cm^{-1} water, the latter two values following respectively from the extreme assumptions that the radiation approached entirely from the vertical direction, or uniformly from all directions above the horizontal. If the ionization is considered to be due entirely to recoil electrons excited in the walls of the chamber, the pressure-ionization relation may be explained; and if the Compton theory is used, the absorption coefficient of the initial penetrating radiation as calculated from the observed range of the recoil electrons is found to be 0.0025 cm^{-1} water.

53. The effect of hydrogen upon the intensities of the spectra of zinc, cadmium and mercury. J. G. BLACK AND W. G. NASH, *University of Kentucky*.—When hydrogen is mixed with zinc vapor in a low voltage arc, some of the zinc lines change their intensities markedly. (Phys. Rev. 34, 1138, (1929)). Recent experiments with the related elements, cadmium and mercury, show similar changes. Hydrogen increases the number of transitions to the $2^3P_{0,1,2}$ configuration of all three elements and greatly reduces the number of transitions from the 2^3P_1 state by radiation. The configuration energy is approximately 4.7 volts in mercury, 4 volts in zinc, and 3.78 volts in cadmium. Hg' has more than enough energy to dissociate hydrogen. Zn' has almost exactly enough, which fact may account for the total absence of the 3075.8 line. Cd' does not have enough energy and probably loses its total energy to tube walls and electrodes after it has been made metastable by hydrogen impacts. An alternative explanation of the resonance quenchings is that they are due to the formation of metallic hydrides. It appears that the absence of a Raie Ultime does not insure the absence of an element in chemical spectroscopic analysis when hydrogen is present.

54. The ionization of hydrogen by positive ion impacts. MASON E. HUFFORD, *Indiana University*.—Positive ions of K, Na, Li and H have been accelerated between a filament and an earthed nickel cathode in an atmosphere of pure hydrogen. The cathode was surrounded by a second nickel screen and this in turn was enclosed by a similar screen in contact with the walls of the ionization tube. Ions were accelerated by potentials varying from zero to 2000 volts and retarded beyond the cathode by a potential 7.5 volts more than the accelerating potential. Current-accelerating potential curves show that the relation between ionization current and potential with K-ions is about linear. Increases can well be explained by the action of electrons from the cathode. With other ions the increase of current is much greater. With low pressures the increase in current is such as to indicate ionization by positive ions. At higher pressures distinct critical potentials are shown at voltages about 200 volts below that at which an arc is established.

55. On the fraction of current carried by electrons at the cathode of a mercury arc. K. T. COMPTON, *Massachusetts Institute of Technology*.—Ever since Schottky first pointed out that studies of heat balance afford a possibility of estimating what fraction of the current at arc cathodes is carried by escaping electrons, attempts have been made to do this in the hope of thereby testing theories of the arc. Such work has heretofore indicated that not much more than half this current is carried by electrons,—a conclusion which is difficult to reconcile with

any electron emission theory of the arc cathode because of the impossibility of accounting for a number of positive ions produced by an approximately equal number of electrons which had fallen through a cathode drop amounting to not more than one minimum ionizing potential. Revised estimates are now based on measurements of cathode drop and new considerations involving accommodation coefficients and the destination of electronic energy near the cathode. The conclusion is now reached that between 80% and 100% of the current of the cathode is carried by electrons. Thus it can no longer be said that arc theories based on electron emission from the cathode are disproved by measurements of heat balance.

56. Study of the afterglow in mercury vapor. HAROLD W. WEBB AND DAVID SINCLAIR, *Columbia University*.—The intensity of the afterglow in mercury vapor was studied in a side tube leading from a mercury arc as a function of vapor pressure, concentrations of ions and electrons and electron temperature. The intensity was found to vary roughly as the fourth power of the vapor pressure. Except at very low concentrations it was closely proportional to the first power of the electron concentration. With vapor pressure and concentration held constant, the intensity decreased very rapidly with increase in electron temperature, changing by a factor of 2500 as the temperature increased from 1300° to 5600°K. This change is too large to be explained by the theory of the simple recombination process. The results are well expressed in the form, that the intensity varies directly as the square of the total number of electrons and inversely as the number of electrons having energies greater than 1.2 volt. This suggests that we have a recombination process producing the afterglow, which takes place in two stages of which the second is responsible for the emission of the series lines, and that the effect of the fast electrons is to reionize from the first stage.

57. Problems in the design of a tube to withstand millions of volts. WILLARD H. BENNETT, *California Institute of Technology*.—It appears improbable that further increases in potential which can be produced in high voltage tubes can be hoped for until the mechanisms, themselves, of the causes of puncture have been carefully studied. A study of corona discharge over glass led to the conclusion that for further increases of potential, the potential must be generated in vacuum, and that the field must be roughly normal to the glass wall of the tube. The greatest difficulty in obtaining higher potentials in tubes is due to auto-electronic emission from electrode surfaces. A study of emission from unconditioned metal surfaces of radii of curvature large compared to the distance between the surfaces showed that loose microscopic particles adhering to the cathode can give emission indistinguishable from the emission following the usual breakdown. The metal used as anode was found to determine largely or entirely the field-current characteristics.

58. Experiments with high-voltage tubes. M. A. TUVE, L. R. HAFSTAD, AND O. DAHL, *Department of Terrestrial Magnetism, Carnegie Institution of Washington*.—Measurements have been obtained on the artificial β and γ -rays produced by the high-voltage cascade-tubes and Tesla coils previously described in the Physical Review. The $H\rho$ values of the fastest β -rays, measured by their deflection in a calibrated magnetic field, correspond in voltage-equivalents, using the standard β -ray tables, to the peak voltages applied to the tubes, measured as before by the capacity-potentiometer method. Using a Geiger-Müller tube-counter shielded by six inches of lead, the relative γ -ray intensities from the tubes have been measured through 1, 2, and 3 inches of lead. With the tube operating at about 1,300 kilovolts, the absorption coefficient after filtering through 1 inch of lead is the same (0.47) as that for the γ -rays from radium in equilibrium measured under the same conditions with the same instrument. These β and γ -ray measurements incidentally constitute a verification also of previous voltage-measurements. "Heat working" of the Pyrex, as previously described, has removed the voltage-limitation to such an extent that tubes have operated satisfactorily up to approximately 2,000 kilovolts, this limit (above ground) being set by corona or sparkover to the grounded oil-tank. Experiments are in progress on high-speed protons.

59. Multiplet separations and Zeeman effects. J. B. GREEN, *Ohio State University*.—The methods developed by Houston and Goudsmit are applied to the spectra of tin, lead, and antimony. Using the spectroscopic values of the multiplet separations it has been possible to

determine the g -values for the configuration p^2 of Sn I and Pb I, and for the configuration ^3P+s of Sb, in very satisfactory agreement with the experimental values of Green and Loring, and Back for these elements. Further agreement is found in the case of the 3P and 1P of Sn III. The multiplet separations and g -values calculated on Houston's theory adequately explain the anomalies found by Green and Loring in this spectrum.

60. Photometric study of the appearance of spectral lines in a condensed spark. H. V. KNORR, *Antioch College*.—The time interval between the appearance of spectral lines in a condensed spark has been studied by means of a Kerr cell used as an electro-optical shutter. Since there appears to be some question about the meaning of the time intervals measured in this way, photometric observations have been made on the rate of increase in the intensities of such lines. From the rate of increase of the intensity for a particular line, it is possible to find by extrapolation the time at which the intensity is zero, that is, the time of its first appearance. The results obtained by this method are compared with the results obtained by the visual method. Observations were made on the arc lines $2^3P_{012}-2^3S_1$ of zinc and for five air lines appearing in the zinc spark. These three zinc lines appear at nearly the same time. The five air lines also appear at nearly the same time but definitely at a time earlier than the zinc lines. These results are not in agreement with the results obtained by the visual method. The explanation of this discrepancy may be found in the failure of the visual method to take proper account of the threshold of visibility. These results indicate that neither of these methods give data on the life time of the zinc atoms in the excited state but only data on the characteristics of the spark discharge.

61. Spectra emitted in the initial stages of condensed discharges. J. W. BEAMS, *University of Virginia*.—Certain improvements in the Kerr cell method (Phys. Rev. 24, 35, (1930)), (Program O.S.A. Oct. 31, 1930) have made it possible to study the times of appearance of spectrum lines in condensed discharges as a function of pressure of the gas. In mercury vapor 5461($2^3P_1-2^3S$) was followed very closely (within less than the limit of precision at pressures above 10 cm) by 4358($2^3P_2-2^3S$) while 5791(2^1P-3^1D) appeared somewhat later. As the vapor pressure of the mercury was increased the time between the appearance of 5461 and 5791 decreased. In a discharge in air 5001 N II ($1^3D'_{1,2}-1^3F'_{2,3}$) appeared first. As the pressure was lowered from one atmosphere the time between the appearance of 5001 and 4631, 4643 N II ($1^3P_2'-2^3P_{2,1}$) was decreased while a slight increase was noted in the time between the appearance of 5001 and the group 5680, 5676, 5667, N II ($1^3P'_{2,0,1}-1^3D'_{3,1,2}$). In a mixture of equal amounts of air and helium the time between the appearance of 5001 N II and 5876 (2^3P-3^3D) increased with lowering of pressure. The results probably indicate that some of the above levels are excited in part at least by secondary processes.

62. The sixth spectrum of arsenic. D. BORG, *Uppsala University*, and J. E. MACK, *University of Wisconsin*.—The lines of the transition $3d^4s-3d^4p$ have been identified in As VI. In all respects the spectrum agrees with the expectations from extrapolation of the sequence Ni I—Ge V, unlike the As VI classification proposed by P. Pattabhiramiah and A. S. Rao (Zeits. f. Physik 53, 587, 1929), in which those authors point out anomalies.

63. Heterochromatic photographic photometry in the Schumann region. GEORGE R. HARRISON and PHILIP A. LEIGHTON, *Massachusetts Institute of Technology and Stanford University*.—The spectral energy responses of several of the fluorescent materials ordinarily used for coating photographic emulsions when used in vacuum spectroscopy have been investigated in the ultraviolet between 4000 and 2300 Å, and in certain easily reproducible cases the number of fluorescent quanta has been found strictly proportional to the number of incident quanta throughout this range. This fact, taken with the uniformity of contrast previously found under similar conditions (Jour. Opt. Soc. America 20, p. 313, 1930) appears to furnish a general method of photographic photometry which can be used throughout the extreme ultraviolet, where the sensitivity of most spectral apparatus is too low to permit the use of thermopiles for plate standardization. The method is now being checked directly with fluorite apparatus in the Schumann region, and is being applied in a 21 ft. vacuum spectrograph to the determination of electronic transition probabilities in multiply ionized atoms of the first long period.

64. Intermittent exposure in photographic spectrophotometry over wide intensity ranges.BRIAN O'BRIEN AND E. DICKERMAN O'BRIEN, *Institute of Optics, University of Rochester, N. Y.*

—Previous work on the compensation of reciprocity failure in photographic spectrophotometry by intermittency failure imposed on the light beam of higher intensity by interrupted exposure (Phys. Rev. 33, p. 640 (1929)) has been extended using sector discs with aperture ratio as low as 1/1200, using a mercury arc as source mounted on a carriage with range of movement of 50 meters for varying intensity. Emission of the arc was held constant within $\frac{1}{2}\%$ (measured radiometrically) by controlled ventilation and electrical input. Errors in measurement of sector apertures and exposure timing were less than $\frac{1}{2}\%$. Densities were measured with a thermoelectric microdensitometer. For intensities in ratio 1200:1 and sector disc opening 1/1200 running 28 flashes per sec., and comparing adjacent areas, the difference in density produced by continuous low intensity and interrupted high intensity (for $I t = \text{const}$) on Eastman Process plates developed to high gamma was less than 0.01 for all densities from threshold to 1.0 for all wavelengths from 4000Å to 2300Å for intensities from approximately optimal to 10^{-4} this value. For $\lambda < 2800\text{Å}$ correction was made for atmospheric absorption as measured by Dawson, Granath, & Hulburt (Phys. Rev. 34, p. 136 (1929)). Reciprocity and intermittency failure separately determined by continuous exposure of same total energy to the higher intensity were as great as 0.20 density units for intensity ratio 10^3 .

65. Band spectrum of sulphur. PAUL HUBER, *Ohio State University.*

—The band spectrum of S_2 has been investigated in both emission and absorption. An under-water spark was used as a source for the light absorbed by the vapor in a heated tube, while Geissler tubes were used for the emission spectra. The effect of predissociation is especially evident in emission, the $n' \rightarrow 0$ progression suddenly breaking off after the 8-0 band, ($\lambda 2828$), as reported by Von Iddekinge. The heat of dissociation of normal S_2 is therefore reduced to less than 4.39 volts, as compared with 4.9 volts given by the International Critical Tables. No improvement could be made in the accuracy of the heat of dissociation of excited S_2 , because of the extreme irregularities in intensity in emission. Five emission bands lying between $\lambda 2828$ and $\lambda 2980$ have been photographed at high dispersion using the second order of a 21-foot grating. The fine structure analysis of these bands is now in progress.

66. Distribution of intensity within the β and γ band systems of nitric oxide. OLIVER R.

WULF AND ERNEST J. JONES, *Bureau of Chemistry and Soils, Washington, D. C.*—Variations in the distribution of intensity within the β and γ bands of nitric oxide have been observed when the products from an oxygen discharge tube are allowed to interact with the products from an active nitrogen tube. In this connection attention is called to an abnormal excitation of the γ bands of nitric oxide as they are emitted from an ordinary high current atmospheric pressure arc. The character of the intensity distribution suggests that the excitation arises as a chemiluminescent phenomenon, the energy of excitation being derived from energy made available in reaction. There appears to be evidence for reaction involving metastable nitrogen molecule. If this is the case it illustrates the chemical reactivity in the homogeneous gas phase of one state of the neutral nitrogen molecule. The conditions leading to the alterations in intensity distribution within the band systems mentioned above suggest that the excitation of band spectra is apt to depend on chemiluminescent processes and that the intensity distribution will, therefore, frequently be abnormal.

67. CO bands in the region $\lambda 2220$ to $\lambda 3300$. HAROLD P. KNAUSS, *Ohio State University.*

—Microphotometer records covering the region from 2200 to 3300Å were made of CO band spectra obtained in the electrodeless ring discharge (Knauss and Cotton, Phys. Rev. 36, 1099, (1930)) and wave-lengths were measured. Unidentified bands at wave-lengths 2925, 3028, 3138, and 3253Å were identified as belonging to a new system, corresponding to transitions from $C'(\Sigma)$ to $a'(\Sigma)$. According to values for the known energy levels of the CO molecule quoted by Estey (Phys. Rev. 35, 309 (1930)), the equation for the new system should be

$$\nu = 34160 - (1173n'' - 9n''^2).$$

Comparison between the observed wave-lengths and those predicted from this formula is made in the following table.

Transition	ν (Calc.)	λ (Calc.)	λ (Obs.)
0-0	34160	2926.5	2925
0-1	32996	3029.8	3028
0-2	31850	3138.8	3138
0-3	30722	3254.1	3253

68. Infrared absorption bands of slightly asymmetric molecules. HAROLD H. NIELSEN, *Ohio State University*.—A set of theoretical curves (as yet unpublished) showing the properties of infrared bands of completely asymmetric molecules have been made by D. M. Dennison. As a complement to these, calculations have been made for molecules of only slight asymmetry. A_x , A_y and A_z have been chosen the three principal moments of inertia of the molecule, where $A_x < A_y < A_z$. Diagrams have been prepared of positions of lines and their respective intensities, determined from quantum mechanical solutions of asymmetric rotators, where the parameter $\rho = A_z/A_y$ varies by steps of 0.01 within the limits $\rho = 0$ and $\rho = 0.1$. Direct application of these will be made on the spectrum of Formaldehyde (H_2CO) now under observation.

69. Infrared absorption of formaldehyde vapor. JOHN R. PATTY AND HAROLD H. NIELSEN, *Ohio State University*.—Measurements of Formaldehyde vapor (H_2CO) have been made with a Hilger infrared spectrometer of the Wadsworth type from the visible to 7.0μ . The spectrometer is equipped with a rock salt prism and a Coblentz thermopile, and is used in conjunction with a Moll thermal relay and a Leeds and Northrup high sensitivity moving coil galvanometer. The bands reported by Salant and West have been confirmed and in addition a band of relatively strong intensity was found at 4.7μ and another faint band at 2.3μ . The bands listed in order of their intensities are, 4.7μ , 3.38μ , 1.8μ , 1.4μ , 2.3μ , and 1.25μ . Another faint maximum was found at 1.9μ , but it is believed that this may be a part of the 1.8μ band reported by Salant and West. The band at 3.38μ has been resolved into fine line structure by the aid of a prism-echelette grating spectrometer of the Sletor type. The general characteristics of the band are P , Q and R branches of which the Q branch is relatively weak and a fine line structure of 4.5 cm^{-1} .

70. The spectrum of strontium and barium hydride. W. R. FREDRICKSON AND A. L. WARTZ, *Syracuse University*.—Bands ascribed to the hydrides of the elements strontium and barium, as obtained by an arc between iron and the element in an atmosphere of hydrogen, lie in the far red end of the spectrum, degrade to the violet, but show no similarity. The strontium bands lie in the region $\lambda 7500$ to $\lambda 6800$ with double heads at 7350, 7323 and 7020, 6985, the latter being the more intense. At the far red end of spectrum there is a peculiar intensity distribution, showing no sharp heads and with large open spaces in the fine structure. At high dispersion the 7020 band shows four strong branches, indicating a $^2\Sigma - ^2\Sigma$ transition. The barium band lies in the region $\lambda 6925$ to $\lambda 6380$ and is a $^2\Pi - ^2\Sigma$ band, showing satellite series which are relatively strong in comparison with the customary P , Q , R series.

71. Comparison of x-ray diffraction intensities in liquid long chain compounds with intensities from computations based on a structure factor. G. W. STEWART AND ROSS D. SPANGLER, *The State University of Iowa*.—Quantitative determination of intensities of x-rays scattered from some liquid long-chain compounds are carried out and the results compared with values obtained from experiments. The determinations are based upon the idea of molecular grouping in liquids. A structure factor of the molecules is used to obtain the intensities. Computations are carried out and comparisons made in the case of eleven normal alcohols and twenty-two octyl alcohols. In the majority of cases, the agreement between experimental and computed values is very good, in a few it is fair, and, in a case or two it is poor. On the whole, the results give convincing evidence in favor of molecular grouping in liquids.

72. Useful accessories for the Siegbahn x-ray vacuum spectrograph. F. K. RICHTMYER, *Cornell University*.—To avoid registration on the photographic plate of minute surface imperfections of the crystal, it has been usual to rotate the crystal, by steps of a few minutes of arc, through a degree or so during an exposure. A device is described, consisting of a telechron

motor and reducing gear, for producing continuous, slow oscillations of the crystal through any desired small angular amplitude. To facilitate rapid identification of spectral lines by comparison with some known line, a special plate holder has been devised by means of which a linear scale may be printed on the photographic plate above the x-ray spectrum. The background due to scattered radiation from the crystal reaching the photographic plate frequently covers up faint lines or makes their measurement difficult. When one is interested in a narrow spectral region the intensity of this background can be materially reduced by placing a wedge a millimeter or two in front of the crystal, somewhat after the manner of the Seemann spectrograph. However, inequality of the x-ray brightness of the focal spot then necessitates that the (spiral) filament should be slowly rotated during exposure.

73. Formation of photographic images on cathodes of alkali metal photoelectric cells. A. R. OLPIN AND G. R. STILWELL, *Bell Telephone Laboratories, Incorporated*.—A method of forming both negative and positive photographic images on the cathodes of potassium and sodium photoelectric cells in vacuum is described. These images are sharp and clear in every detail and can be permanently "fixed" by proper treatment. Among the materials which have been successfully used in treating the exposed surfaces to bring out these images are sulphur vapor, air, oxygen and hydrogen in the ratio of 9 to 1, hydrofluoric acid and bromine. During the time the image is forming, the photoelectric sensitivity of the illuminated portions decreases approximately 30 per cent. After the image is fixed as a permanent record there is little difference between the sensitivity of the cathode area bearing the image and neighboring areas. Photographs of photoelectric cells are shown in which such photographic images are plainly visible.

74. The emission of positive ions from thoriated tungsten. H. B. WAHLIN, *University of Wisconsin*. An investigation of the emission of positive ions from thoriated tungsten shows that when heated to a temperature above 2000°C three types of ions are given off: a W ion of mass 184, a second ion of mass 232, and a heavier ion of mass 247 ± 1 . This heavy ion may be a mononitride or a monoxide of thorium. That it cannot be WO_4 is shown by the fact that it does not disappear when the wire is heated in an atmosphere of hydrogen. Outgassing of the wire at an estimated temperature of 1200°C for 100 hours in a vacuum of 10^{-6} mm does not cause the ion to disappear. Varying the gas pressure in the positive ray chamber from 10^{-6} mm to 10^{-5} mm has no effect on the ion. Prolonged heating at a temperature above 2000°C will cause the 247 ion to decrease with respect to the 232 ion which is assumed to be thorium. Neither the 232 ion nor the 247 ion appeared when unthoriated tungsten or thorium metal were used. An x-ray investigation of the L region of samples of thoria ores has so far failed to give any indication that the heavy ion may be of an elementary nature.

75. The dielectric constant of air at high pressures. JAMES W. BROXON, *University of Colorado*.—Measurements of the dielectric constant of dry air at zero frequency were made by a balance method, using a quadrant electrometer as an indicator. The dielectric constant was found to increase linearly with the pressure at the rate of 555×10^{-6} per atmosphere at 18°C., up to 170 atmospheres. The Clausius-Mossotti function passes through a minimum in this region.

76. A lens for use with the concave grating. J. B. GREEN, *Ohio State University*.—When the slit for a concave grating is placed on the circle of half the radius of curvature of the grating the focal plane is found to be on that circle for a vertical astigmatic image. In general, regardless of the position of the slit, the other focus is found to be hyperbola. This method of calculation yields a very simple result useful for the calculation of the lengths of the astigmatic images. For the study of individual lines a spherocylindrical lens may be used to correct this astigmatism with a resultant increase in the intensity available, and at the same time, a possibility of markedly increasing the dispersion. A preliminary study of several lines with such a lens has yielded promising results.

77. The anomalous scattering of alpha-rays. MORRIS MUSKAT, *Gulf Research Laboratory, Pittsburgh, Pa.*—The potential field causing the Rutherford-Chadwick anomaly in the alpha-

ray scattering by Mg and Al has been determined by inverting the wave-mechanical expression giving the amplitude of the wave scattered by a spherically symmetrical force as an integral over the potential field of the scattering atom. The anomaly was represented analytically in two different ways. The potential fields for both representations, as derived by the above inversion, are essentially the same, their form depending almost entirely on the single fact that the scattering curves show a marked minimum. In magnitude this potential field never exceeds 10% that of the Coulomb potential. It oscillates in sign and falls off very rapidly with distance from the scattering center, becoming negligible at distances greater than about 5×10^{-13} cm. Its small numerical value and oscillatory character are in marked contrast to the assumptions made heretofore, most of which have been that the potential has the form: $1/\rho^n$, $n \geq 2$, ρ being the distance from the scattering center. The classical charge equivalent of this potential field is a series of shells of alternating sign of charge, separated by approximately 1.5×10^{-13} cm. Rutherford and Chadwick originally suggested just this type of explanation.

78. Dispersion and refractive index of nitrogen measured as functions of pressure by displacement interferometry. CLARENCE E. BENNETT, *Brown University*.—A method of measuring simultaneously the dispersion and refractive index of a gas is discussed. It is justified on theoretical and experimental grounds and applied to the measurement of these quantities for nitrogen over a seven atmosphere range of pressures at two different temperatures, 30° and 0°C, with a high degree of precision. The results show that the Lorentz-Lorenz relation is followed, and that the dispersion is a linear function of pressure. The value of the Cauchy constant B is found to be 1.95×10^{-19} per cm of mercury pressure. The index of refraction is measured at atmospheric pressure for three wave-lengths, at 0° and 30°C, with a limiting error of one third of one percent in $(\mu-1)$. The dispersion information enables these values to be reduced to infinite wave-length, making possible the determination of the dielectric constant by Maxwell's law. The value 1.000585 so obtained differs by less than two-thirds of one percent in $(\epsilon-1)$ from that measured directly by Zahn. The values of the refractive index for nitrogen under N.T.P. conditions for the wave-lengths 4811Å, 5893Å, and 6362Å, are 1.0002921, 1.0002969, and 1.0002967, respectively.

79. The crystal structure of potassium permanganate. R. C. L. MOONEY, *University of Chicago*, (Introduced by Henry G. Gale).—The unit cell size and the space group of potassium permanganate were redetermined, and a structure assigned on the basis of intensity observations from photographic plates. The single crystal oscillation method was used, and the plates interpreted by the method of Bernal. Intensities were evaluated simply by visual estimation. The results indicate the crystal to be based on the simple orthorhombic lattice, having four molecules to the unit cell, and symmetry 2Di-16. The cell size was found to have the dimensions: $a=9.08\text{Å}$, $b=5.72\text{Å}$, $c=7.41\text{Å}$. The values check closely the results of other observers. Symmetry considerations and intensity observations indicated a structure having eleven parameters. By the assumption of a tetrahedral arrangement of oxygen about manganese, and by use of values of ionic radii as given by Goldschmidt, it was possible to determine the parameters. Comparative intensities were calculated for the structure. Hartree's figures for the scattering power at different angles were used. The theoretical values so obtained were found to agree fairly well with observed intensities.

80. Linear time scale for voltage range up to 1000 volts. C. K. STEDMAN, *Paul William Research Fellow, Purdue University*, (Introduced by K. Lark-Horovitz).—A circuit generating continuously a voltage wave rising linearly from V_1 to V_2 in time t_2-t_1 , and dropping from V_2 to V_1 in time small compared to t_2-t_1 , can be connected to the horizontal deflecting plates of an oscillograph to provide a linear time axis. The linear time axis circuit of Beddell and Reich (AIEE Journal 46, 563 (1927)) is limited to a voltage range as defined by the difference between the ignition and extinction voltages of the G-10 neon lamp of fifteen to twenty volts. It has been found that by substituting the Thyatron FG 17 for the neon lamp, voltage ranges from 60 to 1000 volts or more may be obtained. With the grid of the thyatron connected to its filament negative the range is 60 volts and every additional volt negative on the grid increases the range about 100 volts. Stabilization is easily effected by introducing about a tenth

of a volt into the Thyatron grid circuit from the circuit under investigation. The deflecting plates of even a very low sensitivity oscillograph can be connected directly across the current limiting tube (for which a VT 14 is very satisfactory) with no intervening amplifier. The frequency range is approximately the same as that of a neon lamp. A magnetic field parallel to the axis of the Thyatron improves operation at high frequencies by preventing the discharge from redistributing itself over the electrodes.

81. Apparent fatigue and aging phenomena in the active nitrogen afterglow. CHAS. T. KNIPP AND L. N. SCHEUERMAN, *University of Illinois*.—Last July a 5-liter Pyrex bulb was heat-treated, then primed with dried tank nitrogen to a pressure of 0.2 mm Hg and sealed off. The bulb was energized by a motor-generator high frequency set for intervals of time varying from a flash (about 0.1 sec.) up to 50 or more seconds, and the duration of the afterglow noted. A surprising result was observed. The duration of the afterglow fell off apparently exponentially with increase of time of energizing. To further check this point a 12-liter bulb was prepared (last August) and placed in an ice bath. The curve obtained still dropped off, but less abruptly. The maximum duration of the afterglow was about 11 minutes. Just recently, December 22, this same bulb was placed in an ice bath at 1°C and again subjected to progressively increasing periods of excitation. The maximum was now about 47 minutes, which, when the excitation was prolonged to 50 sec., was reduced to 26 minutes. The reduction in duration seems to be of the nature of a fatigue. It seems unlikely that it is wholly due to the evolution of water vapor since special precautions were taken to free the bulb and nitrogen of moisture, while the increase in duration on flash seems to be an aging effect favorable to the formation of the active aggregates. A 24-liter bulb after aging 3 months glowed, on flash, for 110 minutes.

82. A preliminary report on a new method of x-ray powder diffraction. T. M. HAHN, *University of Kentucky*, (Introduced by William S. Webb).—A preliminary report on a method employing the use of a conical beam of x-rays incident upon powdered crystals arranged in a circular form about the central axis of the cone, normal to the axis. All rays diffracted through an angle θ will be brought together at a common point upon the axis of the cone. A photographic film along this axis receives the record of the diffraction pattern, from which the spacing of the planes of the crystal may be readily determined. Advantages of this method are reduced time of exposure and increased separation of diffraction spots.

THE PHYSICAL REVIEW

ON SOME SOLAR AND LUNAR SPECTRA TAKEN IN LITTLE AMERICA, ANTARCTICA*

BY MALCOLM P. HANSON** AND E. O. HULBURT

NAVAL RESEARCH LABORATORY

(Received January 26, 1931)

ABSTRACT

Solar spectra were taken with a small quartz spectrograph at noon on November 13, 1929, and January 25, 1930, in Little America, Antarctica, by Malcolm P. Hanson of the Byrd Antarctic Expedition. The ultraviolet limit of these spectra was at about 304μ which was the same as the ultraviolet limit of noon solar spectra taken at Washington, D.C., in December and January. Assuming that the ultraviolet limit of the solar spectra was due to ozone in the upper atmosphere and that the amount of ozone in Washington was the same as that measured by Dobson, Harrison, and Lawrence at Oxford, England, it came out that the effective thickness of the ozone at N.T.P. above Little America was about 0.28 cm on November 13, 1929, and January 25, 1930.

The ultraviolet limit of lunar spectra taken at Little America on April 24, 1929, two days after the Antarctic winter night set in, and on July 18, 1929, thirty-five days before the night ended, was at about 305μ .

AMID the stress of final preparations for the departure of the Byrd Antarctic Expedition it was decided to take along a small quartz spectrograph, Hilger, Type E3. An experiment was hurriedly planned which consisted simply in photographing spectra of the sun and the moon in Antarctica with exposures long enough to bring out the ultraviolet region around 300μ . Meanwhile similar spectra were made with a similar spectrograph at the Naval Research Laboratory, Washington, D.C. By a comparison of the two sets of spectra it was hoped to learn something about the ozone in the upper atmosphere of Antarctica. The dispersion of the spectrographs was about 4μ per mm at wave-length 300μ .

November 13, 1929, was clear and solar spectra were obtained at Little America, latitude 78.6° south, with a slit width of about 0.02 mm, being purposely over-exposed in the visible part of the spectrum in order to bring out the ultraviolet end. The ultraviolet limit of spectra taken at noon, local time, was at about 304μ . The same limit was given by similar spectra at noon on January 25, 1930. The midnight sun spectrum of January 25, 1930, ended at about 320μ ; the sun was about 9° above the horizon at that time.

* Published with the permission of the Navy Department.

** In charge of radio of the Byrd Antarctic Expedition.

The noon solar spectra at the Naval Research Laboratory for November and December, 1929, and January, 1930, ended at about 303 , 304 and $304\mu\mu$, respectively; the same values were found, respectively, for November and December, 1930, and January, 1931. The noon spectra for June, 1930, ended at about $299\mu\mu$. It is seen that the solar ultraviolet limit was the same on November 13, 1929, and January 25, 1930, at Little America as it was in December or January at Washington. The altitude of the sun was approximately the same at the two places, being about 30° from the horizon at Little America and 27° to 30° at Washington. Therefore, since the ultraviolet end of the solar spectrum is limited by the ozone in the upper atmosphere the measurements indicated that the ozone in November, 1929, and January, 1930, was of about the same thickness in Little America as it was in Washington in December and January. It is due to the fortunate circumstance that both the elevations of the sun and the ultraviolet solar spectrum limits were about the same at Little America and at Washington that one can say that the ozone thicknesses were the same at the two places. If, for example, the spectrum limits had been the same and the solar elevations different, or vice versa, the program of observations could probably not have been used with safety to derive an exact conclusion about the relative amounts of ozone in the two regions.

We do not know what the thickness of the ozone was in Washington but we may assume it to be roughly the same as that in Oxford, England, observed by Dobson, Harrison, and Lawrence¹ in 1925 and 1926. The justification of this assumption is found in the fact that the seasonal variation, with the maximum in August, of the intensity of the therapeutic solar wave-lengths 290 to $310\mu\mu$, observed by Clark,² in 1927 and 1928 in Baltimore, Md., U.S.A., agreed fairly well with the intensity calculated² from the ozone absorption coefficients of Fabry and Buisson,³ the 1925 and 1926 ozone thickness¹ at Oxford and the solar zenith distance at Baltimore. Clark's⁴ further observations showed that the curve of the seasonal variation of the solar radiations from 290 to $310\mu\mu$ was approximately the same in the years 1929 and 1930 as it was in the years 1927 and 1928.

Interpolating among the Oxford measurements (ref. 1, Table 3) gives the values for December and January to be 0.27 and 0.29 cm of ozone, respectively. Accordingly, the average of these, or 0.28 cm was the value of the effective thickness of the ozone in Little America on November 13, 1929, and January 25, 1930. It need hardly be said that the present method of determining ozone by means of the ultraviolet limit of the solar spectrum can not be depended upon to give great accuracy. It is to be hoped that future polar expeditions may be equipped to carry out much better determinations of ozone.

The value 0.28 cm of ozone in midsummer at Little America is in keeping

¹ Dobson, Harrison and Lawrence, *Proc. Roy. Soc. A* **114**, 521 (1927).

² Clark, *Amer. Jr. Hygiene* **9**, 646 (1929).

³ Fabry and Buisson, *Journ. de Phys.* **3**, 196 (1913).

⁴ Clark, *Amer. Jr. Hygiene* **12**, 690 (1930).

with the probable average values in north polar regions in midsummer, namely, 0.290 cm for July and 0.265 for August, estimated by Dobson.⁵ Dobson^{1,5} concluded that the ozone values found by various stations scattered over the earth would be most simply accounted for by the hypothesis that corpuscular radiation from the sun is "the chief ozone forming agent at the poles and possibly for the rest of the world" (ref. 5, page 431). We do not think that the observations call for any such extreme hypothesis. Maris⁶ calculations of the temperatures of the high atmosphere indicate wind movements in the high atmosphere which, combined with the hypothesis that ozone is formed by certain wave-lengths of the ultraviolet portion of the solar spectrum and is decomposed by other wave-lengths, would lead, qualitatively at any rate, to an ozone distribution in agreement with observation. One cannot make an exact calculation of the matter for the photochemical quantum efficiencies of the formation and destruction of ozone by the various ultraviolet wave-lengths are not yet known.

Fig. 1. Spectrum of the moon taken at Little America on July 18, 1929.

Spectra of the moon were taken at Little America on April 24, 1929, and on July 18, 1929. It will be remembered that the sun's last official appearance at Little America was on April 22 and his official reappearance was on August 22. Thus the moon spectrum of April 24 was obtained two days after the beginning of the Antarctic winter night and the one of July 18 was obtained thirty-five days before the end of the Antarctic night. The spectrograph was mounted outside on the snow, aimed at the moon and shifted by hand from time to time. The moon was focussed on the slit by a quartz lens 5 cm in diameter and 20 cm in focal length. The spectra of April 24 were taken with a slit width of 0.3 mm and exposures from 1 to 15 minutes. With such a wide slit the ultraviolet limit of the spectrum was not sharply defined, and the only safe conclusion that could be drawn was that the ultraviolet limit was between 310 and 300 μ .

On July 18 the moon was about 40° from the horizon and the temperature was -50° Fahrenheit. A good spectrum, reproduced as a positive in Fig. 1, was obtained with an exposure of one hour at midnight, local time, and a slit width of 0.05 mm. Eastman Commercial Panchromatic cut film was

⁵ Dobson, Proc. Roy. Soc. A129, 412 (1930).

⁶ Maris, Terr. Mag. and Atmos. Elec. 33, 233, (1928); 34, 45 (1929).

used. The spectrum extended to about 305μ , the last solar absorption line being at this wave-length. It is doubtful whether the solar absorption lines, which are clear enough on the original negative, can be seen in the reproduction of Fig. 1.

The film was somewhat fogged throughout and the bright lunar spectrum of Fig. 1 is seen to be surrounded by a region relatively darker than the general fogged field. The dark halo around the spectrum is thought to be due to the Eberhard photographic effect. If a plate or film be uniformly exposed to light of moderate intensity and if a small area be then given an additional heavy exposure, on development a region of abnormally lowered density will be noted around the dense portion. This is caused by the large quantity of soluble bromide thrown off from the heavily exposed area of emulsion during the development which acts as a restrainer and slows up the development of the surrounding regions. It is not known whether the low temperature during the exposure had anything to do with the rather unusual appearance of the negative of Fig. 1. The development of the film, which was done about three days after the exposure, was effected under approximately normal conditions. The solar spectra and the moon spectra of April 22, as well as the Washington spectra, in general showed the Eberhard effect to a slight degree, but none to the extent of the negative of Fig. 1.

Since the lunar spectra ended at about 305μ it is concluded that the ozone in the high atmosphere of Little America during the winter night was not greatly different from ozone in other parts of the world. Rosseland⁷ also found that stellar spectra photographed in midwinter at 71° north latitude ended around 300μ .

In conclusion it is a pleasure to mention the assistance of Mr. R. B. Carleton in taking the long series of solar spectra at this laboratory.

DIRECTED VALENCE IN POLYATOMIC MOLECULES

By J. C. SLATER

MASSACHUSETTS INSTITUTE OF TECHNOLOGY

(Received January 22, 1931)

ABSTRACT

The interactions of atoms in polyatomic molecules are described qualitatively. Particular attention is paid to atoms of the types of F, O, N, C, where the valences come from p electrons. Directional effects are discussed, namely that the two valences of O, and the three of N, tend to be mutually at right angles, and the four of C have tetrahedral symmetry. Numerous examples are given, from the structure of metals and of organic and inorganic compounds. Mathematical treatment is postponed until a later paper.

IT HAS already been noticed by Born¹ that the method applied by the writer to the problem of complex atomic spectra is equally adaptable to molecular structure. The writer² has used the method in one problem of atomic interaction, the problem of cohesive forces in univalent metals. When applied to molecular problems in general, however, it yields not only the familiar results for diatomic molecules, but also information regarding valence in polyatomic molecules, particularly in the matter of directional properties, which seems to be new and which is capable of correlating a good deal of experimental material. In this paper, we give the results of the discussion in a qualitative way, postponing mathematical justification to a later paper.

The general ideas described in the paper were outlined in an informal talk at the Washington meeting of the American Physical Society last April, and I wish to thank several members of the society for valuable discussion at that time. I also wish to acknowledge valuable assistance and suggestions from several of my colleagues, particularly Dr. Warren, Dr. Ashdown, and Dr. Scatchard.

Two atoms containing all their electrons in closed shells repel each other. But if each atom has one wave function containing only one electron, rather than two of opposite spins, attraction is possible. This actually occurs if the spins of the electrons in question in the two atoms are oppositely directed. The attraction pulls the atoms together until the wave functions from which electrons are missing overlap as much as possible, when equilibrium occurs. In consequence of resonance, the charge concentrates at the place where the functions are overlapping, and in an approximate way we may consider that the two electrons, of opposite spin, spending their time in this region, form a closed shell. This is a homopolar valence bond, and two electrons forming such a bond are inactive in forming further bonds, just as if they were in closed shells within a single atom.

¹ M. Born, *Zeits. f. Physik* **64**, 729 (1930).

² J. C. Slater, *Phys. Rev.* **35**, 509 (1930).

The simplest and most familiar example of a single valence bond is found in H_2 ,³ where each atom contains a single $1s$ electron, so that the $1s$ shell is not completed, and if the spins are oppositely directed, the electrons are shared and form a molecule. But almost equally simple is, for example, I_2 . Here each atom lacks a single p electron from its outer shell. If the remaining electron in that particular p wave function in one atom has a spin opposite to that in the other, there will be attraction, which will proceed until the two wave functions overlap as much as possible. We meet at once the question, how does the degeneracy of the p shell affect the problem. And we can answer definitely from perfectly general considerations.

To get the lowest possible energy, we wish in a rough way the greatest possible overlapping of the p functions from the two atoms. This demands first that each of these functions be as concentrated as possible. Now the wave functions corresponding to the three p levels, in the ordinary axial system of coordinates, can be written

$$\begin{aligned} p^+ &: (x + iy) f(r) \\ p^0 &: z f(r) \\ p^- &: (x - iy) f(r). \end{aligned}$$

The charge densities corresponding to these are

$$\begin{aligned} p^+ &: (x^2 + y^2) f^2(r) \\ p^0 &: z^2 f^2(r) \\ p^- &: (x^2 + y^2) f^2(r). \end{aligned}$$

As shown in Fig. 1, made by a very ingenious method by Dr. Langer, the first and third are great in the x - y plane, in a sort of ring-shaped region; the second

Fig. 1. Charge distribution of p^+ and p_0 , with s for comparison.
I am indebted to Dr. Langer for this photograph.

is great along the z axis, and is more concentrated than the others. But we are allowed to use any three orthogonal linear combinations of these functions. If we take $(r \cdot u_1) f(r)$, $(r \cdot u_2) f(r)$, $(r \cdot u_3) f(r)$, when u_1 , u_2 , u_3 are three orthogonal unit vectors, these functions will be great, respectively, along the

³ Heitler and London, *Zeits. f. Physik* **44**, 455 (1927).

axes of these three vectors, and each will be as concentrated as the p_0 before. These functions evidently give as concentrated a density as we can get, and hence are most suitable for use in discussing binding.

Let us now consider our I_2 molecule. We take the vector u_1 in each atom as the vector pointing toward the other atom. Then plainly the functions $(r \cdot u_1) f(r)$ for the two atoms, since they correspond to distributions pointing along the line of centers, and hence stretching out toward the other atom, can overlap. The other functions, on the other hand, are large in the planes normal to the line of centers, and do not overlap appreciably. We can visualize the atoms as the hubs of two wheels connected by an axle. The functions which overlap are extending along the axle, the others along the spokes of the two wheels. For binding, then, we assume an electron missing from this function $(r \cdot u_1) f(r)$ in each atom, and we can be confident that in this way we shall get the most stable molecule. In the usual description, if the z axis is taken as the axis of the molecule and at the same time the axis for axial wave functions for the electrons, an electron with function p_0 is missing from each atom. This coincides with the conventional description of this case.

Next let us consider an atom which lacks two electrons of having a complete shell, as for example O. Suppose we have another atom, as H, which can be bound to it. We choose our vectors u_1, u_2, u_3 so that one of them, say u_1 , points along the line from O to H. Then by the previous argument we must have one electron missing from the state which we may symbolize by u_1 , to form the bond with the H. The other missing electron must then be lacking from either the state u_2 or u_3 , and hence must have its density along the direction at right angles to the line joining the O and H. A second hydrogen attempting to become bound to form a water molecule, would move so that its charge would overlap in place of this missing one. It would then take up a position so that the lines joining the centers of the oxygen and the two hydrogen atoms would form right angles. Of course, the interactions between the two hydrogen atoms would modify this; it is difficult to say in which direction. But in a general way we should expect a triangular model, as is shown in Fig. 2, and that of course is observed.

The same sort of argument would indicate that the two valences of a divalent atom like oxygen should always be at right angles, and we can obtain many actual examples of this. The atoms of this sort are O, S, Se, Te. In the elements Se and Te in the solid state the atoms form chains of an interesting helical form, as shown in Fig. 3, so that if we look along the axis of the helix every third atom lies in a corresponding position. But just such a spiral is formed if atoms are arranged in a chain with the lines joining successive atoms making right angles with each other, these lines pointing in succession along the x, y, z, x, y, z, \dots , axes, which is the structure which our theory would suggest. Another illustration, less definite, is furnished by the crystal structure of the silicates. These are presumably in general ionic compounds. But some features of them resemble valence compounds: each silicon is surrounded by four oxygens, suggesting the valence of four and tetrahedral structure which we shall discuss in a later paragraph; and where an

oxygen is shared between tetrahedra, is shared by two only, as if it had just two valences for the two silicons. These features are both illustrated in Fig. 4. Now it is observed that in such a shared oxygen, the lines joining the oxygen to the silicons always form an angle with each other, as if there were

Fig. 2.

Fig. 2. NH_3 and H_2O . The angles here, and in the other figures, are taken to be just 90° , rather than adjusted to agree with experiment.

Fig. 3.

Fig. 3. Chain of atoms from Te. The actual chain continues indefinitely in both directions. The crystal is made of many chains packed together parallel to each other.

valences which tended to be at right angles to each other, rather than being parallel as one would otherwise expect.

The trivalent atoms, N, P, As, Sb, Bi, can be discussed by just the same principles: their three valences tend to be mutually at right angles, one elec-

Fig. 4.

Fig. 4. $(\text{Si}_2\text{O}_7)^{4-}$ group from a silicate. The lighter atoms represent Si. Two tetrahedra are joined by sharing an O. In the actual case, the valences of this shared O are more nearly parallel than we have shown.

Fig. 5.

Fig. 5. Sheet of atoms from Bi. This consists of two layers of atoms, each atom being joined to three neighbors in the other sheet. The whole crystal consists of piles of these sheets.

tron being shared from each of the three functions with the factors $(r \cdot u_1)$, $(r \cdot u_2)$, $(r \cdot u_3)$. The most obvious example is ammonia, NH_3 , which has the pyramidal structure which we should expect from this model, as is shown in Fig. 2. Then in the metals, As, Sb, Bi, we find good illustrations of the princi-

ple. The atoms in these metals form plates, which appear, when we look down on them, like hexagonal lattices, each atom being surrounded by three others symmetrically placed. But really alternate atoms are displaced above or below the plane, as shown in Fig. 5, so that each atom above the plane is at the apex of a pyramid whose base is formed by three atoms below the plane, and vice versa; and the three lines joining an atom with its neighbors are very nearly at right angles. The whole crystal is formed by piling these plates together in such a way as to approximate a simple cubic lattice.

Other examples can be found in organic compounds containing nitrogen, in which the nitrogen is connected to something else by a double bond. In the oximes, as shown in Fig. 6, it is connected in this way to a carbon atom; in the azo compounds as in Fig. 7, to another nitrogen. The double bond we visualize simply as the sharing of two electrons, so that the two bonds and the center of the atom determine a plane. The third valence of the nitrogen

Fig. 6.

Fig. 6. Two isomeric forms of an oxime compound. A nitrogen and carbon are joined by a double bond. The two forms arise from the two possible orientations of the third valence of the nitrogen.

Fig. 7.

Fig. 7. Two isomeric forms of an azo compound. Two nitrogens are joined by a double bond.

should then, according to our picture, be at right angles to this plane, but it could point out in either of the two normal directions. If the rest of the molecule were not symmetrical about this plane, we should then expect two forms of the molecule, depending on which normal were chosen; and as a matter of fact, both these groups of compounds show isomerism which is attributed to just this sort of effect.

The tetravalent atoms, C, Si, Ge, Sn, Pb, demand a different treatment. If we assume that four electrons are removed from the group of six p 's, this leaves none in one of the three wave functions, and one each in the remaining two. Thus there are two electrons to be shared, as in O, and we have divalent atoms as we observe for example in CO. But to obtain a valence of four, we must plainly have only three p 's removed, leaving one electron each in these states; and the other missing electron must then be an s . This latter, having a spherical distribution of charge, has no directional properties. Thus in CH_4 , for example, we should tentatively expect that the three hydrogens attached

to p valences would form a pyramid, as in NH_3 , and the remaining hydrogen, bound to an s , and free to wander, would set itself opposite the apex of the pyramid to avoid the others, forming a rough tetrahedron. This would not be a symmetrical tetrahedron, however; and by a slight change in the conditions we can arrive at a really symmetrical one, which would undoubtedly have a lower energy, and which we consider to be the real form for a tetra-valent compound.

To arrive at this symmetrical arrangement, we set up four linear combinations of the three p wave functions and the one s function, having a tetrahedral symmetry. We take four unit vectors, u_1, u_2, u_3, u_4 , pointing to the four corners of a regular tetrahedron. Then the four functions $(r \cdot u_1) f(r), \dots, (r \cdot u_4) f(r)$ are, as we have seen, linear combinations of the three p functions, but of course they are not orthogonal. If however we take the s wave function, say $\phi(r)$, we can form combinations $(r \cdot u_1) f(r) + \alpha \phi(r), \dots, (r \cdot u_4) f(r) + \alpha \phi(r)$, where α is a parameter, and we can choose α to make the four

Fig. 8. Diamond lattice.

Fig. 9. CH_4 .

functions orthogonal. These are then the required tetrahedral wave functions. The density of each one is great along one of the axes of a regular tetrahedron; the addition of the s function results in having the density much larger in one direction than in the opposite one. If now each of these wave functions lacks one electron, and other atoms share with the remaining ones, they will take up a tetrahedral arrangement about the central atom.

The tetrahedral structure for the valence of C and the other atoms of this group is too well known to require extensive comment; a very great number of observations of the organic chemists have led to it. But we may mention a few examples. The solids as diamond, forms of Pb and Si, form the diamond lattice shown in Fig. 8, in which each atom is surrounded by four others in tetrahedral arrangement. The gas CH_4 , shown in Fig. 9, is undoubtedly tetrahedral, as shown by the absence of electric moment. The double carbon bond is explained very easily by the sharing of two electrons, meaning that two tetrahedra join by an edge. The remaining four valences then all lie in a plane, as shown in Fig. 10, and the isomerism of the derivatives of ethylene, $\text{H}_2\text{C}=\text{CH}_2$, is readily explained: given two unlike radicals attached to each atom, there will be two different compounds depending on the two possible

assignments of one pair to the two electrons of the corresponding atom. This explanation seems much more convincing than the ingenious theory of Hückel,⁴ based wholly on *p* electron valence.

The weakness of Hückel's theory is that he does not consider carefully the nature of the other bonds than the double one, and hence does not notice the fact which we point out, that the *s* valence must be combined with the *p*'s to obtain a symmetrical arrangement. If one followed his argument through, each of the carbons in ethylene would have one *p* valence and one *s* free to join to hydrogens, and the latter would then hardly be equivalent.

Similarly the triple bond would correspond to the sharing of a whole face of two tetrahedra. The remaining valences would then point out along the line of centers, so that acetylene, $\text{HC}\equiv\text{CH}$, shown in Fig. 11, should be a linear molecule, as is observed from its lack of dipole moment.

Fig. 10.

Fig. 10. Two isomeric forms of a substituted ethylene. Two carbons joined by a double bond. Two isomers if at least two sorts of radicals are attached to the carbon: trans form (at left) with like radicals opposite; cis form (right) with like radicals adjacent.

Fig. 11.

Fig. 11. C_2H_2 . A linear molecule with a triple bond.

An ordinary chain compound is shown in Fig. 12. The zig-zag structure of the compound, observed for example by Müller,⁵ is well shown in the figure.

The atoms beyond the tetravalent ones appear generally in ionic compounds rather than with valence bonds, and so do not concern us in this paper. But we should discuss one point: in a great many compounds there is ambiguity as to whether the bonds are homopolar or ionic. We have mentioned the silicates; other examples are $\text{H}-\text{Cl}$ (which could be written also H^+Cl^-) and $\text{H}-\text{O}-\text{H}$ (which could be written $\text{H}^+(\text{OH})^-$ or $\text{H}^+\text{O}=\text{H}^+$). Even such a compound as Al_2O_3 can be written in either way $(\text{Al} \begin{smallmatrix} \diagup \text{O} \diagdown \\ \diagdown \text{O} \diagup \end{smallmatrix} \text{Al})$ or $(\text{Al}^{+++})_2(\text{O}^-)_3$. Very general principles of wave mechanics tell us the outline of the treatment in these cases. The two explanations constitute two unperturbed states, from which the true one is to be found by linear combination, so that the real situation is intermediate between the two. If the energies of the two

⁴ E. Hückel, *Zeits. f. Physik* 60, 423 (1930).

⁵ A. Müller, *Proc. Roy. Soc. A* 114, 542 (1927).

models are approximately the same, the real state will lie roughly half way between, while if one has a much lower energy than the other, that will fairly accurately represent the real situation. Moreover, if the two are combined, there will be a resonance effect in the energy, which will generally bring the real energy lower than that computed from either model separately. This may well explain the unusual stability of the silicates, and of the other compounds we mentioned: their energy is lower on account of the two explanations of the binding.

It is important to consider the relation of our models, say for H_2O , to those of Debye,⁶ based on the assumption of ionic compounds in which the polarizability of the O^- is considered. Debye has been able to give alternative explanations even of the triangular form of H_2O and the pyramidal form of NH_3 . From the discussion of the last paragraphs, we see that both these explanations are to be regarded as legitimate starting points, with the true

Fig. 12.

Fig. 12. A chain compound, C_7H_{16} . The zig-zag arrangement of carbons, and the elongated cross-section of the chain, result from having the valences of carbon inclined at definite angles to each other.

Fig. 13.

Fig. 13. Benzene, C_6H_6 . The Kekulé model.

state of affairs somewhere between them. The two descriptions, ionic and homopolar, are not as a matter of fact very different in fundamentals. Consider for example HCl . In the homopolar valence explanation, the electron from H , and one from Cl , are shared on the line joining the two atoms, and the net effect is that some of the hydrogen electron's charge has shifted toward the chlorine. In the ionic explanation, we start by assuming that the hydrogen electron is wholly transferred to the chlorine. But then we assume that polarization pulls some of it back again, and we are left in very much the same situation as before. The principal advantages of the homopolar method, with these ambiguous problems, are first that it seems rather nearer the real solution, as is shown, for example, by the small dipole moments of the hydrogen halides; and second that it is better able to deal in a general way with directional properties.

Another point connected with valence should be mentioned similar to the

⁶ P. Debye, "Polar Molecules," Chemical Catalog Co.

ambiguity between the ionic and homopolar valence descriptions of a compound. In some cases there may be several ways of drawing valence bonds in a given compound. In such cases, the real situation is again a combination of the various possibilities, and on account of resonance the energy is lower than it would otherwise be. We can not then draw the valence bonds in an unambiguous way; we must rather imagine them shared between several atoms. Such cases of shared valence may well be commoner than is usually supposed. The writer has already explained the cohesion in monovalent metals as coming from this effect, and it probably persists through most of the metals other than those specifically discussed in this page; for in all of these, each atom has more neighbors than it has electrons to share, and hence than it has valence bonds in the ordinary sense. Another example is probably found in the benzene ring. Here the Kekulé model, shown in Fig. 13, allows either the structure

By wave mechanics we should have a combination of these two possible structures, resulting in a complete equivalence of the carbons of the ring, a shared valence (essentially $1\frac{1}{2}$ bonds between each pair), and an added stability for the structure on account of the resonance effect on the energy. Still another case presumably comes in the existence of shared valences where ordinarily we suppose no valence at all to act. In H_2O , there is probably a little valence attraction between the two H's, just as if they were forming a H_2 molecule, and as a consequence the angle between the lines to the two H's should be slightly acute. And even between molecules we may expect this shared valence to act. In crystals like Te and Sb we have spoken as if all valence forces acted within the chains or plates of which the crystals are formed, but this undoubtedly is not the case. In complicated organic compounds, probably the valence forces between one molecule and another are nearly as strong as within a molecule. Substances where this is true will hang together to form solids, and it will be nearly as difficult to separate the molecules as to break up the individual molecules, so that an attempt to vaporize them by heating will be very likely to disrupt the whole structure instead, a common phenomenon with these complicated compounds. Many examples of polymerization may well be cases where valences formerly operative within a molecule have partly changed over to the role of intermolecular forces. It seems, then, that this phenomenon of shared valence is of common occurrence, and that an understanding of it, as well as of the relation between ionic and homopolar binding, is essential.

THE ROTATIONAL ANALYSIS OF THE S_2 BANDS

BY S. MEIRING NAUDÉ AND ANDREW CHRISTY
 RYERSON PHYSICAL LABORATORY, UNIVERSITY OF CHICAGO

(Received January 23, 1931)

ABSTRACT

The emission spectrum of S_2 has been obtained by means of a Geissler tube, the plates being taken in the third order of a 21 foot concave grating giving a dispersion of 0.878 Å per mm. The following bands have been studied; 9-1(λ 2857.36), 7-0(λ -2860.13), 8-1(λ 2887.84), 9-2(λ 2917.38) and 7-1(λ 2920.28). Each band consists of three R and three P branches. For small values of K each band appears to have a weak and a strong R branch and a weak and a strong P branch. The lines of the strong branches separate into two components for $K \geq 25$. This structure is similar to that of the Schumann-Runge bands of O_2 . It is concluded that the S_2 bands investigated are due to a ${}^3\Sigma_u^- \rightarrow {}^3\Sigma_g^-$ transition (like O_2). The values of B_v'' and B_v' (by extrapolation) are 0.409 and 0.319 cm^{-1} , respectively, the nuclear separation of the lower state being $r_v'' = 1.603 \times 10^{-8}$ cm and of the upper state $r_v' = 1.814 \times 10^{-8}$ cm. It is shown that the rotational levels with odd K values are missing in the upper state and those with even K values in the lower state. The fact that alternate levels are missing shows that the internal angular momentum of the S^{32} nucleus is zero.

INTRODUCTION

THE band spectrum due to the S_2 molecule extends from about λ 6000 to λ 2300 Å. The spectrum consists of a large number of overlapping bands which degrade toward the red. These bands have been studied by various investigators. Henri¹ divides the spectrum into four regions according to the frequency equations which fit most accurately the heads obtained in absorption. Rosen² has shown, however, that all these bands belong to the same band system, and from the vibrational analysis obtained the following equation for the heads:

$$\nu = \nu_e + 427.1(v' + \frac{1}{2}) - 2.7(v' + \frac{1}{2})^2 - 727.4(v'' + \frac{1}{2}) + 2.91(v'' + \frac{1}{2})^2 \quad (1)$$

Henri¹ found the bands to become diffuse at λ 2794.2, a phenomenon which he termed "predissociation."

Henri and Teves³ using plates taken in absorption with relatively small dispersion, attempted a rotational analysis of the S_2 spectrum. They state that each band consists of P , Q , and R branches, giving the values of the nuclear separations for the upper and lower states as $r' = 0.70$ Å and $r'' = 0.73$ Å. Teves⁴ continued this work in fluorescence obtaining results similar to those of Henri and Teves. Recently Swings⁵ and Rompe⁶ also working with the

fluorescence spectrum of S_2 , have tried to bring their results into agreement with those of Henri and Teves, but found it impossible to interpret completely the complex patterns obtained.

It has been shown that the molecules F_2 , Cl_2 , Br_2 , and I_2 have similar electronic states. The same has also been found in the molecules Li_2 , Na_2 , and K_2 .⁷ One would therefore expect a corresponding similarity to hold for O_2 and S_2 . In particular it seems probable that the S_2 bands mentioned above are analogous to the Schumann-Runge bands of O_2 . Recently E. V. Martin and F. A. Jenkins⁸ have also found the SO bands lying between $\lambda 2500$ and $\lambda 3500$ to correspond to the Schumann-Runge bands. The analysis of Henri and Teves, however, would indicate that S_2 differs fundamentally from O_2 . Furthermore, the values of r_e'' and r_e' found for the O_2 Schumann-Runge bands^{9,10} are 1.204 and 1.609 Å, respectively. Irrespective of the similarity of the S_2 and O_2 bands, the values of the nuclear separations for the two states obtained by Henri are too small, since the r_e values for S_2 are surely greater than those for O_2 , whereas, according to Henri, the reverse is the case.

The purpose of the present work was to check Rosen's results by studying the spectrum of the S_2 bands photographed with greater dispersion than he used, and to obtain the rotational analysis. The work dealing with the vibrational analysis, perturbations, predissociation, etc., will be discussed in a later paper, and only that concerning the rotational structure will be given here. It will suffice to state that, except for the revision of the vibrational quantum numbers of a number of band heads and the discovery of numerous perturbations, mainly in the upper electronic state, our results agree with those of Rosen, so that his analysis with a few modifications can be made use of in the present paper.¹¹

EXPERIMENTAL PROCEDURE

The spectrum of S_2 was excited in a Geissler tube (see Fig. 1) of Pyrex, having large cylindrical aluminum electrodes, so that as much as 0.7 amps. could be passed through the tube. The current was supplied by a 5 KW transformer. The tube was provided with a quartz window W sealed on to one end of a quartz tube, the other end of which was ground flat. This end of the quartz tube was sealed onto the Pyrex tube with sealing wax. Considerable difficulty was experienced in keeping the quartz window from fogging due to sulphur condensing on it. The best results were obtained when the sulphur was introduced into the tube in the form of H_2S ¹² which streamed continuously through the tube in the direction away from the window, thus opposing the diffusion of sulphur towards the window. In case the window did get fogged with sulphur, heating it gently with a bunsen burner restored

¹¹ P. Huber, *Amer. Phys. Soc. Meeting*, Paper No. 65, Cleveland, Dec. 30, 1930, has apparently also found that Rosen's vibrational analysis is fundamentally correct.

¹² H. H. Van Iddekinge (*Nature* **125**, 858 (1930)) has independently used the same method.

its transparency. The H_2S was dried over P_2O_5 before introduction into the tube. In the discharge tube the H_2S dissociated, giving sulphur and hydrogen.¹³ The other end of the tube was connected to a liquid air trap in which the sulphur and H_2S were frozen out. This trap in turn was connected to a Megavac oil pump which was kept running while the discharge was going on. The pressure of the sulphur in the discharge tube could be regulated by controlling the flow of H_2S by means of a stopcock sealed on to a capillary tube.

Another method used for introducing the sulphur into the above discharge tube was by distilling the sulphur in vacuo into the side tube *T* (see Fig. 1). By heating *T* while the discharge was running pure sulphur could be introduced directly into the discharge tube. In this case a mercury diffusion pump was used to evacuate the discharge tube beforehand. More sulphur condensed on the window when this method was used and therefore the former method was preferred for long exposures. The spectrum obtained by

Fig. 1. Discharge tube used for obtaining the S_2 emission spectrum in the region $\lambda 2850$ – $\lambda 2950$ with great intensity. *W* is a quartz window sealed into a quartz tube which is in turn sealed on to the discharge tube with sealing wax. When sulphur is used instead of H_2S to obtain the spectrum the tube *T* with the dotted outline contains pure sulphur.

this method agreed with that obtained by introducing H_2S , as was determined by comparing plates taken in the second order of the 21 foot grating in both cases.

The photographs of the bands in the region $\lambda 2850$ – $\lambda 2950$ used for the analysis were taken in the third order of the 21 foot Rowland grating giving a dispersion of 0.878 Å per mm. A red purple filter of the Corning Glass Company was used to cut out the second order between $\lambda 4250$ and $\lambda 4450$ Å which would otherwise overlap the spectrum obtained. Eastman 33 plates were used. The time of exposure was about 30 hours.

The plates were measured on a comparator with an accuracy of 0.003 mm. The iron arc was used as comparison spectrum, the wave-lengths of which were taken from Kayser's "Hauptlinien" (1926). The iron standards agreed to within 0.003 Å, so that the wave-lengths of the sulphur band lines

¹³ In the region $\lambda 2850$ – $\lambda 2950$, which we studied for this work, the sulphur spectrum was very intense as compared with the weak continuous spectrum obtained from the hydrogen molecule.

may be assumed to be correct to 0.01Å. The wave-lengths (in air) were converted to wave-numbers (in vacuo) by means of Kayser's "Schwingungszahlen."

DATA AND ROTATIONAL ANALYSIS

The bands due to S_2 are very numerous so that there is practically no region of the emission spectrum in which overlapping does not occur. In the region between $\lambda 2828$ and $\lambda 2950$ the overlapping is the least. Therefore the bands: 9-1, with its head at $\lambda 2857.36$; 7-0, $\lambda 2860.13$; 8-1, $\lambda 2887.84$; 9-2, $\lambda 2917.38$ and 7-1, $\lambda 2920.28$, have been chosen for the rotational analysis. Even with the large resolution used a large number of lines could not be separated, a few unresolved groups having a width as large as 1 cm^{-1} . The lines of the 9-1 and 9-2 bands could not be followed very far due to the overlapping of the 7-0 and 7-1 bands, the latter being considerably more intense than the former. Other weaker bands are partially superposed on the 8-1, the 7-1 and probably on the 7-0 band, making the assignment of the lines into series extremely difficult.

It was noticed that in the clear regions of the 9-1 and 9-2 bands the strong lines in each band could be assigned into two distinct series. For every strong line in the above bands there is a line of about half the intensity on the short wave-length side of the former, the interval between the strong and the weak lines remaining approximately constant. The same type of series, i.e. two strong and two weak series, has been found in each of the remaining bands. In the two bands, 7-0 and 7-1, in which the series could be followed to a considerable distance from the head, it was seen that each line of the strong series splits into two lines, the components of this doublet having equal intensity. The distance between each line of the weak series and the center of the corresponding doublet in the strong series, after its lines had split, is the same as before splitting occurred. In this region the three lines, i.e. the lines of the weak series and the two corresponding lines into which each line of the strong series splits, are approximately of the same intensity. It is evident, therefore, that each band consists of six series: A , A_y , A_z , B_x , B_y and B_z . In the 9-1 and 9-2 bands, where the overlapping by other bands is least, all lines but two have been assigned to the various branches.

The two sets of combinations which are given in Tables IV and V were obtained by performing the subtraction $A(\alpha) - B(\beta)$ and $A(\alpha) - B(\beta+1)$, where α and β are arbitrary numbers assigned to the series A and B respectively. Since the S_2 bands are those of a homopolar molecule (S^{32}_2), we may expect alternate band lines to be either missing or weak.¹⁴ But if the latter were the case we would have noticed it. If, however, all lines are present in the series, the above combinations would correspond to $R(K) - Q(K) \approx \Delta_1 F'(K)$ and $R(K) - Q(K+1) \approx \Delta_1 F''(K)$, [or $Q(K) - P(K) \approx \Delta_1 F'(K)$ and $Q(K) -$

¹⁴ F. W. Aston (Proc. Roy. Soc. A115, 487 (1927)) has estimated that about 97 percent of the atomic weight of sulphur is due to the S^{32} isotope. Consequently these S_2 bands must be due to (S^{32})₂. The bands due to $S^{32}S^{34}$ and $S^{32}S^{33}$ have not been observed. These bands will be very much weaker and, furthermore their calculated positions lie within the bands investigated thus making their observation more difficult.

$P(K+1) \approx \Delta_1 F''(K)$]. The A_x , A_y , and A_z series would then be three R (or three Q) branches and the B_x , B_y and B_z series would be three Q (or three P)

* These lines are made up of two components which become resolvable at $K=25$. They are referred to in the text as R_{xy} and P_{xy} , and when they become resolvable R_x , R_y , P_x and P_y . The remaining values are then R_z and P_z . It will be shown later in the text that R_x , R_y and R_z correspond to R_1 , R_3 and R_2 , respectively, and similarly for the P branches.

¹ Smoothed values, the observed lines being composite.

branches. But if alternate lines are missing, the combinations correspond to $R(K) - P(K) = \Delta_2 F'(K)$ and $R(K) - P(K+2) = \Delta_2 F''(K+1)$. The equations for $\Delta_1 F$ and $\Delta_2 F$ are:

$$\Delta_1 F = \text{constant} + 2(B + 3D)K + 4DK^3 \quad (2)$$

$$\Delta_2 F = \text{constant} + 4(B + 3D)K + 8DK^3 \quad (3)$$

where $B = h/8\pi^2\mu cr^2$ and $D = -4\bar{B}^3/\omega_e^2$, μ being the reduced mass of the molecule. If we assume the first alternative, i.e. no lines missing, we obtain from our data $B'' = 0.818 \text{ cm}^{-1}$, while the second gives $B'' = 0.409 \text{ cm}^{-1}$. From the empirical formula¹⁵ $B = (27.7/\mu) (3000/\omega'')^{-2/3}$ which holds within a few per cent for all known molecules composed of atoms of equal or nearly equal mass, we obtain $B'' = 0.404 \text{ cm}^{-1}$. Furthermore, if we assume that all lines are present, the value of D calculated from the theoretical relation $D_e = -4B_e^3/\omega_e^2$ is sixteen times as large as the value actually obtained from our data, whereas if we assume alternate lines missing, the value of D obtained from our data agrees within experimental error with the above theoretical value. These comparisons show that we must adopt $\Delta_2 F$ and alternate missing lines. The series A and B therefore correspond to three R and three P branches.

In Tables I, II, and III, listed under their respective headings, R or P , are given the lines of the five bands investigated. The lines indicated by asterisks are the strong lines made up of two components which become resolvable at about $K = 25$. The values with superscript (1) are assumed values, the observed lines being composite. $\delta\nu_R$ and $\delta\nu_P$ are the intervals between the weak and the strong lines in the R and P branches, except that where the strong lines are separated into two components, $\delta\nu$ is the interval between the weak line and the center of gravity of the doublet. It is seen that these intervals are the same within experimental error for all the bands investigated.

The values of $\Delta_2 F''(K) = R(K-1) - P(K+1)$, which should agree for the 7-1, 8-1 and 9-1 bands are given in Table IV B. In Tables IV A and IV C the corresponding $\Delta_2 F'''$'s of 7-0 and 9-2 are tabulated. The values of $\Delta_2 F'(K)$ which should agree for the 7-1 and 7-0, and for the 9-1 and 9-2 bands are given in Table VA and VC. The corresponding $\Delta_2 F'(K)$'s for the 8-1 bands are given in Table VB. It will be seen that all the expected agreements are fulfilled within experimental error.

The absence of strong Q branches indicates that we are dealing with a transition for which $\Delta\Lambda = 0$. Furthermore, the great intensity of the entire system makes it evident that the transition is between two states of equal multiplicity, i.e. $\Delta S = 0$. From the structure of the band, three R and three P branches, we conclude that the electronic states involved are triplets. The possible transitions are $^3\Sigma \rightarrow ^3\Sigma$, $^3\Pi \rightarrow ^3\Pi$ and perhaps $^3\Delta \rightarrow ^3\Delta$.¹⁶ The fact that

¹⁵ P. M. Morse, Phys. Rev. **34**, 57 (1929).

¹⁶ In a $^3\Pi \rightarrow ^3\Pi$ or $^3\Delta \rightarrow ^3\Delta$ transition we would expect three strong R and three strong P branches present, spaced approximately as in a $^3\Sigma \rightarrow ^3\Sigma$ transition, if we have case (b) for both upper and lower electronic states, or if we had case (a) in which A is approximately the same in both the upper and the lower states (cf. TiO bands: A. Christy, Phys. Rev. **33**, 701 (1929)). For these transitions, however, we would expect all lines to be present and also the so called staggering effect, the magnitude of which would depend on λ type doubling.

¹ Smoothed values, the observed lines being composite.

$^3\Sigma \rightarrow ^3\Sigma$ transition, presumably analogous to that of the Schumann-Runge bands of O₂. We also know that the final $^3\Sigma$ state is the normal state, because these bands are observed with great intensity in absorption.^{18,1,2}

¹⁷ RQ and PQ band lines would probably be too weak to detect.

¹⁸ We have found that this system of S₂ appears with great intensity in absorption.

* These values are obtained from the stronger R and P branches before the lines become resolvable, and are referred to in the text as $\Delta_2 F_{xy}$. The bracketed values are then $\Delta_2 F_x$ and $\Delta_2 F_y$. The remaining values are $\Delta_2 F_z$. As will be shown later in the text $\Delta_2 F_x$, $\Delta_2 F_y$ and $\Delta_2 F_z$ correspond to $\Delta_2 F_1$, $\Delta_2 F_2$ and $\Delta_2 F_3$, respectively.

Where J is the total angular momentum of the molecule, its values being $J=K+S$, $K+S-1, \dots, K-S$. S is the resultant electronic spin. For a

triplet state $S=1$, hence $J=K+1$, K and $K-1$. Due to the three values of J , we shall have, in general, three closely spaced energy states for each value of K . These energy states are designated by F_1 , F_2 and F_3 , where F_1 corresponds to $J=K+1$, F_2 to $J=K$ and F_3 to $J=K-1$.

As has been shown by Kramers,²⁰ $f_i(K, J-K)$ for $^3\Sigma$ states is made up of two parts, one of which is due to the interaction of the resultant electronic spin S^* with the rotational angular momentum K^* , and is equal to

$$(1/2)\gamma[J(J+1) - K(K+1) - S(S+1)] \\ = (1/2)\gamma[(J(J+1) - K(K+1) - 2)] \quad (5)$$

while the other part is due to the interaction between the individual spins of the electrons and is designated by $w_i(K, J-K)$. $f_i(K, J-K)$ then becomes

$$f_i(K, J-K) = (1/2)\gamma[J(J+1) - K(K+1) - 2] + w_i(K, J-K) \quad (6)$$

It has been shown²⁰ that $w_i(K, J-K)$ has the following form for the three values of J :

$$J = K+1, \quad w_1 = -\epsilon(1 - 3/2K + 3) \quad (7)$$

$$J = K-1, \quad w_3 = -\epsilon(1 + 3/2K - 1) \quad (8)$$

$$J = K, \quad w_2 = +2\epsilon. \quad (9)$$

We can neglect terms in ϵ/K for moderate and large values of K , since ϵ is usually small. $f_i(K, J-K)$ then is:

$$J = K+1, \quad f_1 = -\epsilon + \gamma K \quad (10)$$

$$J = K-1, \quad f_3 = -\epsilon - \gamma(K+1) \quad (11)$$

$$J = K, \quad f_2 = 2\epsilon - \gamma \quad (12)$$

The lines of the R and P branches are given by:

$$R_i(K) = \nu^0 + F_i'(K+1) - F_i''(K) \quad (13)$$

$$P_i(K) = \nu^0 + F_i'(K-1) - F_i''(K) \quad (14)$$

Hence, for the three components of the triplet,

$$\Delta_2 F_i'(K) = R_i(K) - P_i(K) = F_i'(K+1) - F_i'(K-1) \text{ is:}^{21}$$

$$J = K+1, \quad \Delta_2 F_1'(K) = 2(B_v' + 2D_v' + \gamma') + 4(B_v' + 3D_v')K + 8D_v'K^3 \quad (15)$$

$$J = K-1, \quad \Delta_2 F_3'(K) = 2(B_v' + 2D_v' - \gamma') + 4(B_v' + 3D_v')K + 8D_v'K^3 \quad (16)$$

$$J = K, \quad \Delta_2 F_2'(K) = 2(B_v' + 2D_v') + 4(B_v' + 3D_v')K + 8D_v'K^3 \quad (17)$$

For the lower electronic state,

²⁰ H. A. Kramers, Zeits. f. Physik 53, 422 (1929).

²¹ We should include in these equations an additional term $+12 D_v K^2$; but D_v is of the order of magnitude of 10^{-7} , so that, for values of K in which this term will become appreciable, the contribution of the cubic term will be much greater than that of the squared term, and hence the latter may be neglected.

$\Delta_2 F_i''(K) = R_i(K+1) - P_i(K-1) = F_i''(K+1) - F_i''(K-1)$ has exactly the same form as in the above equations, except that the $(')$ is replaced by the $('')$.

In Tables IV and V the $\Delta_2 F$ values with asterisks, $\Delta_2 F_{xy}$, are obtained from the lines of the strong R and P branches. When these lines are resolvable, the bracketed values, $\Delta_2 F_x$ and $\Delta_2 F_y$, for any one K , are obtained from the corresponding components of the doublets. The remaining value $\Delta_2 F_z$ for every K is obtained from the weak R and P branches. As will be shown later, $\Delta_2 F_z$ corresponds to $\Delta_2 F_2$, cf. Eq. (17). The sets of values $\Delta_2 F_{xy}$ correspond to the mean of Eqs. (15) and (16), i.e. $\overline{\Delta_2 F_{13}(K)} = 2(B_v + 2D_v) + 4(B_v + 3D_v)K + 8D_v K^2$ which is the same as Eq. (17). If we assume γ negative (the justification will be discussed below) $\Delta_2 F_1$ and $\Delta_2 F_3$, cf. Eqs. (15) and (16), correspond to $\Delta_2 F_x$ and $\Delta_2 F_y$, respectively.

The values of the molecular constants obtained from the data are listed in Table VI. The values of B were obtained from the slopes of our graphs corresponding to Eqs. (15), (16) and (17). The value of D_e was obtained from the equation $D_e = -4B_e^3/\omega_e^2$, which agrees within experimental error with the value obtained from Eqs. (15), (16), and (17).

$$B_e = B_0 + \frac{1}{2}\alpha_e \quad \text{and} \quad \alpha_e = \frac{B_0 - B_v}{v}$$

TABLE VI. Values of molecular constants.

		B (cm^{-1})	D_e (cm^{-1})	$\alpha_e B_e$ and r_e^{22}	ϵ and γ^{23}
$^3\Sigma_g^-$	$v''=0$	0.408 ₈	$D_e'' = -5.2 \times 10^{-7}$	$\alpha_e = 0.000_7$ $B_e'' = 0.409 \text{ cm}^{-1}$ $r_e'' = 1.603 \times 10^{-8} \text{ cm}$	$\epsilon' - \epsilon'' = 0.47$ $\gamma' \approx \gamma'' \approx -0.1$ $\gamma - \gamma'' = \pm 0.014 \pm 0.003$
	$v''=1$	0.407 ₇			
	$v''=2$	0.407 ₀			
$^3\Sigma_u^-$	$v'=0$	0.318 ₅ (extrapolated)	$D_e' = -7.2 \times 10^{-7}$	$\alpha_e = 0.001_5$ $B_e' = 0.319 \text{ cm}^{-1}$ $r_e' = 1.814 \times 10^{-8} \text{ cm}$	
	$v'=7$	0.308			
	$v'=8$	0.306			
	$v'=9$	0.305			
		0.341			

The experimental values of $\Delta_2 F$ for $v'=9$ obtained from the 9-1 and 9-2 bands do not fall upon a straight line as one would expect. In order to represent these points we had to draw two straight lines, one fitting the points for lower values of K giving $B_9' = 0.305 \text{ cm}^{-1}$ and the other fitting the points for higher values of K giving $B_9' = 0.341 \text{ cm}^{-1}$. It is thought that this effect is due to the perturbation of the rotational levels. This seems plausible, for

²² In our letter, Phys. Rev. **36**, 1800 (1930), the values of r_e are incorrectly given due to an arithmetical error in obtaining the r_e values from the values of B_e .

²³ The constants ϵ and γ are discussed in the following section. From our data we are only able to determine the accuracy of $(\gamma' - \gamma'')$ and not of either γ' or γ'' , so that the values given for these constants may be off by several percent.

it is known from our work to be published in a later paper that predissociation occurs at $v' = 10$. All bands with $v' = 10$ are diffuse in absorption and absent in emission.

The exact value of the quantum numbers K was obtained by extrapolating the $\Delta_2 F_i$ curves given in Eqs. (15), (16), and (17) to $\Delta_2 F_i = 0$. It has thus been found that the levels with *even* K values are missing in the *lower state*, and those with *odd* K values are missing in the *upper state*.

Exactly the same results have been found in the Schumann-Runge bands of O_2 investigated by Ossenbrüggen⁹ and Lochte-Holtgreven and Dieke.¹⁰ As Mulliken²⁴ has shown, the normal state of the oxygen molecule is in all probability $^3\Sigma_g^-$, this being the lower state of the Schumann-Runge bands. According to the selection rules for $^3\Sigma^- \rightarrow ^3\Sigma$, the upper state must then be $^3\Sigma_u^{+10,24}$. We conclude, therefore, that the S_2 here investigated are due to a $^3\Sigma_u^- \rightarrow ^3\Sigma_g^-$ transition.

Since alternate levels are missing we conclude that the internal angular momentum of the S^{32} nucleus is zero.

SPIN FINE STRUCTURE OF ROTATIONAL LEVELS

As we have seen above, the splitting of the rotational levels of a $^3\Sigma$ state into three components is due firstly, to the interaction of the resultant electronic spin with the rotational angular momentum (see Eq. (5)), and secondly to the interaction of the individual spins of the electrons (see Eqs. (7), (8) and (9)). In the expression for the first interaction the constant γ enters and in that, for the second, the constant ϵ . As these constants have only been determined in a few band spectra, namely, O_2 ^{20,10} and PH²⁵, it will be of value to determine them as accurately as possible from the data for S_2 given above.

In order to obtain the values of γ , we have to correlate $\Delta_2 F_1$, $\Delta_2 F_2$ and $\Delta_2 F_3$ given in Eqs. (15), (16) and (17) above with one of the three sets of $\Delta_2 F$ values for $K \geq 25$, $\Delta_2 F_x$, $\Delta_2 F_y$ and $\Delta_2 F_z$ given in Tables IV and V. By examining these $\Delta_2 F$ values it is clear that γ must be small since the $\Delta_2 F$ values for the same value of K are almost the same within experimental error. By averaging all the $\Delta_2 F_x$, $\Delta_2 F_y$ and $\Delta_2 F_z$ separately for the upper state, we find that these values can be represented by $(N-0.1)$, $(N+0.1)$ and N cm.⁻¹ respectively. The same result holds for the lower state. These results can now be explained by correlating the $\Delta_2 F_x$ values with $\Delta_2 F_2$, and the $\Delta_2 F_z$ and $\Delta_2 F_y$ values with either $\Delta_2 F_1$ or $\Delta_2 F_3$ where $|\gamma'| \approx |\gamma''| \approx 0.1$. It is impossible, however, to determine definitely from our data alone whether $\Delta_2 F_1$ should be correlated with $\Delta_2 F_x$ or $\Delta_2 F_y$, as we do not know whether γ is positive or negative.

It has been shown that the value of γ'^{26} in the normal $^3\Sigma_g^-$ state of the O_2 molecule is negative ($= -0.025$).²⁰ The value of γ'^{26} for the excited $^3\Sigma_u^-$ state of the Schumann-Runge bands has also been found to be negative ($= -0.048$).¹⁰ We would, therefore, expect the value of γ for the normal $^3\Sigma_g^-$

²⁴ R. S. Mulliken, Phys. Rev. **32**, 880 (1928); **36**, 700 (1930).

²⁵ R. W. B. Pearse, Proc. Roy. Soc. **A129**, 328 (1930).

²⁶ The γ used here corresponds to $(-B)$ in Kramer's terminology (cf. ref. 20) and $(-D)$ in that of Lochte-Holtgreven and Dieke (cf. ref. 10).

and probably for the excited ${}^3\Sigma_u^-$ states of S_2 also to be negative.²⁷ Hence, if we assume γ negative $\Delta_2 F_1$ and $\Delta_2 F_3$ correspond to $\Delta_2 F_x$ and $\Delta_2 F_y$, respectively, in Tables IV and V. Hence R_1 (or P_1) R_3 (or P_3) and R_2 (or P_2) correspond to R_x (or P_x), R_y (or P_y) and R_z (or P_z), respectively, in Tables I, II and III.

A schematic drawing of the rotational levels of the S_2 molecule is given in Fig. 2, with the theoretical separation of each level from the dotted line

Fig. 2. A schematic representation of the structure of the rotational energy levels of S_2 . The groups with rotational quantum numbers $K+1$ and $K-1$ refer to the upper ${}^3\Sigma_u^-$ state, and the group with quantum number K to the lower ${}^3\Sigma_g^-$ normal state. The dotted line represents the position of the rotational level if no interaction between K and S existed, its approximate energy value being given directly above it. The full lines represent the actual levels resulting from the interaction of the resultant electronic spin S^* with the rotational angular momentum K^* (see Eq. (5)) and the interaction between the individual spins of the electrons (see Eqs. (7), (8) and (9)). The calculated separation of these levels from the dotted line is given on the right. The lines joining the upper and the lower levels represent the observed transitions and are named accordingly. The K in the diagram is the value of K'' .

for every K value given on the right. The equations for the separations of the three components in the triplet in the R and P branches, as may be seen with the help of Fig. 2, are²⁸

²⁷ According to J. H. van Vleck (Phys. Rev. 33, 467, 1929), $\gamma = \sum_K C_K A_K B_K / \nu_K$. The summation is to be taken over all the Π states. It is likely, however, that there will be one Π state whose influence is much greater than that of all others. ν_K then will be the interval between this Π state and the Σ state in question. $C_K A_K$ is the coefficient at the magnetic interaction in this Π state. B has the usual meaning. We would expect this Π state to be similar in O_2 and S_2 . Hence the sign at γ for both molecules would in all probability be the same.

²⁸ The values in ϵ/K have not been omitted in these equations.

$$R_1 - R_3 = -6\epsilon'(2K + 3/4K^2 + 12K + 5) + 6\epsilon''(2K - 1/4K^2 + 4K - 3) - (3\gamma' - \gamma'') - 2(\gamma' - \gamma'')K \quad (18a)$$

$$R_2 - R_1 = (3\epsilon' - 3\epsilon'') - (3\epsilon'/2K + 5) + (3\epsilon''/2K + 3) - 2\gamma' + \gamma'' - (\gamma' - \gamma'')K \quad (19a)$$

$$R_2 - R_3 = (3\epsilon' - 3\epsilon'') + (3\epsilon'/2K + 1) - (3\epsilon''/2K - 1) + \gamma' + (\gamma' - \gamma'')K \quad (20a)$$

$$P_1 - P_3 = -6\epsilon'(2K - 2/4K^2 - 8K + 3) + 6\epsilon''(2K - 1/4K^2 + 4K - 3) + \gamma' + \gamma'' - 2(\gamma' - \gamma'')K \quad (18b)$$

$$P_2 - P_1 = (3\epsilon' - 3\epsilon'') - (3\epsilon'/2K + 1) + (3\epsilon''/2K + 3) + \gamma'' - (\gamma' - \gamma'')K \quad (19b)$$

$$P_2 - P_3 = (3\epsilon' - 3\epsilon'') + (3\epsilon'/2K - 3) - (3\epsilon''/2K - 1) - \gamma' + (\gamma' - \gamma'')K. \quad (20b)$$

The average of Eqs. (19a) and (19b) is:

$$\approx (3\epsilon' - 3\epsilon'') - (3\epsilon' - 3\epsilon'')/(2K + 3) - (\gamma' - \gamma'') - (\gamma' - \gamma'')K \quad (21)$$

and the average of Eqs. (20a) and 20b) for $K \geq 5$:²⁹

$$\approx (3\epsilon' - 3\epsilon'') + (3\epsilon' - 3\epsilon'')/(2K - 1) + (\gamma' - \gamma'')K. \quad (22)$$

The interval between R_2 and the mean of R_1 and R_3 is for $K \geq 3$:²⁹

$$3(\epsilon' - \epsilon'') + \frac{1}{2}(\gamma' - \gamma''). \quad (23)$$

This interval is the same as that obtained from the P branches.

Eqs. (18a) to (23) may now be used to correlate definitely the branches designated by R_x , R_y and R_z (or P_x , P_y and P_z) with R_1 , R_3 and R_2 (or P_1 , P_3 and P_2). The average of the experimental values $\delta\nu_R$ and $\delta\nu_P$ given in Tables I, II, and III are plotted in Fig. 3, Graph A. It is recalled that $\delta\nu_R$ and $\delta\nu_P$ are the intervals between the weak R_z (or P_z) and the corresponding strong lines R_{xy} (or P_{xy}). When the components of the strong lines become resolvable, $\delta\nu_R$ ($\delta\nu_P$) are the intervals between R_z (or P_z) and the center of the resulting doublet. The values of the average intervals between the weak lines R_z (or P_z) and the corresponding short wave-length component of the doublet R_x (or P_x), i.e. the average of $(R_z - R_x)$ and $(P_z - P_x)$ are plotted below Graph A. The values of the average intervals between the weak line R_z (or P_z) and the long wave-length component of the doublet R_y (or P_y), i.e. the average of $(R_z - R_y)$ and $(P_z - P_y)$ are plotted above graph A.

We see that the plotted values of $\delta\nu_R$ and $\delta\nu_P$ (graph A) are approximately constant, and independent of K . Further, as can be seen from Fig. 3, the average of the intervals $\delta\nu_R - (R_z - R_x)$ and $\delta\nu_P - (P_z - P_x)$ is approximately equal but of opposite sign to the intervals $\delta\nu_R - (R_z - R_y)$ and $\delta\nu_P - (P_z - P_y)$.

²⁹ These equations contain approximations which hold only for the values of K as given.

Considering the results obtained above by comparing the experimental values of $\Delta_2 F$ and Eqs. (15), (16) and (17) and also Fig. 3, we see that the only possible correlation (assuming γ negative) is that R_x (or P_x) corresponds to R_1 , (or P_1), R_y (or P_y), to R_3 , (or P_3) and R_z (or P_z), to R_2 , (or P_2).

From Eq. (23) and Graph A, $3\epsilon' - 3\epsilon'' + \frac{1}{2}(\gamma' - \gamma'') = -1.41$ from which we obtain $\epsilon' - \epsilon'' = -0.47^{30}$ if we put $(\gamma' - \gamma'') = 0.014$ (see below).

The points below and above graph A in Fig. 3, can now best be represented by graphs B and C, respectively, which are the graphs of Eqs. (21) and (22), if we take $(3\epsilon' - 3\epsilon'') = -1.42$ and $(\gamma' - \gamma'') = 0.014$. We have seen above that $\gamma' \approx \gamma'' \approx -0.1$ and from $(\gamma - \gamma'') = 0.014$, we conclude $|\gamma''| > |\gamma'|$.

Fig. 3. Graphs showing the average observed separations of the triplets. The circular points represent the intervals between the weak R_x (or P_x) series and the strong R_{xy} (or P_{xy}) or the center of the doublets R_x and R_y (or P_x and P_y), when R_{xy} (or P_{xy}) become resolvable for $K \geq 25$. These points are represented by Graph A. The triangles represent the intervals between the weak R_x (or P_x) series and the long wave-length component of the doublet R_y (or P_y) and the inverted triangles represents the intervals between the weak R_x (or P_x) series and the short wave-length component of the doublet R_x (or P_x). The triangles may best be represented by C which is the graph of Eq. (22), and the inverted triangles by B which is the graph of Eq. (21) where $3(\epsilon' - \epsilon'') = -1.42$ and $\gamma' - \gamma'' = +0.014$. The plotted values are the averaged intervals for the R and P series.

From our data we are not able to determine the values of ϵ' and ϵ'' separately. This will be possible if the rotational structure of the S_2 bands similar to the O_2 atmospheric bands could be determined. These bands of S_2 which would lie in the infrared, have as yet not been discovered.

DISCUSSION OF PREVIOUS WORK

With regard to previous work on the rotational analysis of S_2 there is every indication that the analysis of Henri and Teves³ is probably incorrect, since the resolution used could not be sufficient to separate all the lines in the bands and thus to assign the lines correctly into series. The complexity of the patterns obtained in fluorescence by Teves⁴, Swings,⁵ and Rompe⁶ are undoubtedly due to the following causes:

³⁰ In the O_2 Schumann-Runge bands ϵ' and ϵ'' were both found to be positive and also $\epsilon'' > \epsilon'$. If we assume ϵ' and ϵ'' are also positive in the S_2 bands, then $\epsilon'' > \epsilon'$.

- (1) All the lines of the mercury arc have been used to excite fluorescence.
- (2) As Rompe points out Swings' arc was not sufficiently cooled, giving him broad exciting lines, whereas Rompe states that he himself was unable to obtain step to step fluorescence in mercury vapour with his own source, indicating that his exciting lines were also too broad.
- (3) The rotational lines of the S_2 bands lie close together.

Due to these facts and the small dispersion used by these investigators, it is extremely difficult, if not impossible, to interpret the results which have been obtained by them. It will be interesting, however, if the fluorescence spectrum could be investigated using single line excitation and somewhat larger dispersion than that used by previous investigators.

Note added in proof: We have received a letter from Mons. P. Swings in which he states that according to results derived from an investigation of the fluorescence spectra of S_2 (obtained with a Crony spectrograph with 11 prisms giving a dispersion of 1 Å per mm at $\lambda 3000$) he found $I'' = 70 \times 10^{-40}$ gm cm² corresponding to a value of $B'' = 0.396$ cm⁻¹. This value of B'' agrees within experimental error with our value $B_e'' = 0.409$ cm⁻¹ given above. His results will be published in the *Mém. Soc. royale Sciences, Liège*.

The authors wish to express their appreciation to Professor R. S. Mulliken for his interest and advice in connection with this work.

ORBITAL VALENCY*

BY JAMES H. BARTLETT, JR.

DEPARTMENT OF PHYSICS, UNIVERSITY OF ILLINOIS

(Received January 15, 1931)

ABSTRACT

The interaction of two atoms, each with one $2p$ electron, is studied by a method similar to that used by Kemble and Zener. An atomic wave function whose radial part is of the form $\text{const. } re^{-kr/2}$ (that is, with no nodes) is used. Complete potential energy curves are obtained for the twelve possible states, which are ${}^1\Delta_g$, ${}^3\Delta_u$, ${}^1\Pi_g$, ${}^1\Pi_u$, ${}^3\Pi_g$, ${}^3\Pi_u$, ${}^1\Sigma_u^-$, ${}^3\Sigma_g^-$, two ${}^1\Sigma_g^+$, and two ${}^3\Sigma_u^+$. The most stable states are ${}^3\Sigma_u^+$ (lowest) and ${}^1\Sigma_g^+$, which arise from $m_{la}=0$ and $m_{lb}=0$, and in which there is the maximum overlapping of charge. The states with least overlapping of charge are those where $m_{la}=\pm 1$ and $m_{lb}=\pm 1$, resulting in ${}^1\Delta_g$, ${}^3\Delta_u$, ${}^1\Sigma_g^+$, ${}^1\Sigma_u^-$, ${}^3\Sigma_g^-$, ${}^3\Sigma_u^+$, which are all repulsive. The Π states lie in between, and are attractive. The present work gives precision to the ideas of Heitler on orbital valency, yields a positive exchange energy integral for the lowest states, and may be taken as supporting the conceptions of Slater about directed valency.

OUR knowledge of the rules underlying the formation of stable diatomic molecules from their constituent atoms is still very limited, in spite of the successes achieved by Heitler and London,¹ and by Kemble and Zener.² The idea of spin valency is quite useful, but its general inadequacy has been recognized by Heitler,³ who has therefore proposed an "orbital" valency. Two atoms can exert on each other forces due not only to the coupling between the spins, but also to the coupling between the orbits, and the two types of interaction may give rise to effects of the same order of magnitude.⁴ One must in general take the orbital valency into consideration, and it is highly desirable to formulate rules concerning the order of the resulting molecular states. This is the purpose of the present investigation.

The special problem here studied is that of the interaction of two similar atoms, each with one $2p$ valence electron. For simplicity, a hydrogenic wave function for the atom has been assumed, and the possible influence of internal s electrons has been neglected. Zener⁵ has shown that it is legitimate, as an approximation, to assume such a wave function. The method is essentially the same as used by Kemble and Zener,² except that in the actual evaluation

* This work was done largely with the aid of a Parker Travelling Fellowship from Harvard University.

³ W. Heitler, *Naturwiss.* **17**, 546 (1929).

⁴ This statement is rather inexact, but the precise formulation will be made later.

⁵ C. Zener, *Phys. Rev.* **36**, 51 (1930).

of the integrals the procedure of Zener and Guillemin⁶ has been followed. Without doubt, one could improve upon the energy values by using a variational method, but it will be assumed that their order would be the same, and it is primarily the order which is the object of this investigation.

We assume, therefore, the radial part of the atomic wave function to be of the form $R = \text{const } re^{-\kappa r/2}$, where κ is an arbitrary constant.

Notation. $a(nlm_1/1)$ = wave function for electron 1 on nucleus a , with quantum numbers m, l, m_1 . (Similarly for nucleus b).

For one electron, a = distance from nucleus a

b = distance from nucleus b .

For two electrons a_1 = distance of electron one from nucleus a , etc.

R = internuclear distance

r = interelectronic distance

θ_{a1} = angle from internuclear axis to line joining a and 1.

In the case under consideration, it is unnecessary to write explicitly n and l , which are 2 and 1, respectively, for each electron. Accordingly, we shall abbreviate the notation to $a(m_11)$.

Thus

$$a(11) = c_1 a_1 e^{-\kappa a_1/2} \sin \theta_{a_1} e^{i\phi_1}$$

$$b(02) = c_2 b_2 e^{-\kappa b_2/2} \cos \theta_{b_2}.$$

Kemble and Zener show how one may set up a secular equation for the two-quantum excited states of H_2 , and then separate it according to the constants of the motion, the spin-orbit interaction being supposed to be negligible. The same may be done in the present case, and one obtains a secular equation of the twelfth degree, which has eight linear factors, and two quadratic factors. The results are tabulated. The energy is measured from the "unperturbed" value, namely that for infinite separation. $^1\Sigma_g^+$ means that the electronic factor of the wave function is unchanged on reflection in a plane through the internuclear axis (+), and on reflection in the midpoint of this axis (g). The notation of Kemble and Zener is also given.

⁶ C. Zener and V. Guillemin, Phys. Rev. 34, 999 (1929).

WAVE FUNCTIONS AND ENERGY LEVELS

m_{1a}	m_{1b}	States Symmetry	Wave Function	"Diagonal" Energy
1	1	$^1\Delta_g(S^N)$	$a(11)b(12)+a(12)b(11)$	$\frac{1}{1+S_{11}}(I_1+I_2)$
1	1	$^3\Delta_u(A^N)$	$a(11)b(12)-a(12)b(11)$	$\frac{1}{1-S_{11}}(I_1-I_2)$
1	0	$^1\Pi_g(S^N)$	$a(11)b(02)+a(12)b(01)+a(01)b(12)+a(02)b(11)$	$\frac{1}{1+S_{10}}(I_3+I_4+I_5+I_6)$
1	0	$^1\Pi_u(A^N)$	$a(11)b(02)+a(12)b(01)-a(01)b(12)-a(02)b(11)$	$\frac{1}{1-S_{10}}(I_3-I_4-I_5+I_6)$

1	0	$^3\Pi_u(A^N)$	$a(11)b(02)-a(12)b(01)+a(01)b(12)-a(02)b(11)$	$\frac{1}{1-S_{10}}(I_3-I_4+I_5-I_6)$
1	-1	$^1\Sigma_u^-(A^N)$	$a(11)b(-12)+a(12)b(-11)-a(-11)b(12)-a(-12)b(11)$	$\frac{1}{1-S_{11}}(I_1-I_2-I_7+I_8)$
1	-1	$^3\Sigma_g^-(S^N)$	$a(11)b(-12)-a(12)b(-11)-a(-11)b(12)+a(-12)b(11)$	$\frac{1}{1+S_{11}}(I_1+I_2-I_7-I_8)$
1	-1	$^1\Sigma_g^+(S^N)$	$a(11)b(-12)+a(12)b(-11)+a(-11)b(12)+a(-12)b(11)$	$\frac{1}{1+S_{11}}(I_1+I_2+I_7+I_8)$
0	0	$^1\Sigma_g^+(S^N)$	$a(01)b(02)+a(02)b(01)$	$\frac{1}{1+S_{00}}(I_9+I_{10})$
1	-1	$^3\Sigma_u^+(A^N)$	$a(11)b(-12)-a(12)b(-11)+a(-11)b(12)-a(-12)b(11)$	$\frac{1}{1-S_{11}}(I_1-I_2+I_7-I_8)$
0	0	$^3\Sigma_u^+(A^N)$	$a(01)b(02)-a(02)b(01)$	$\frac{1}{1-S_{00}}(I_9-I_{10})$

where

$$I_1 = \int H' [a(11)]^2 [b(12)]^2 dv$$

$$I_2 = \int H' a(11)b(11)a(12)b(12)dv$$

$$I_3 = \int H' [a(11)]^2 [b(02)]^2 dv$$

$$I_4 = \int H' a(11)b(11)a(02)b(02)dv$$

$$I_5 = \int H' a(01)a(11)b(02)b(12) \cos(\phi_1 - \phi_2) dv$$

$$I_6 = \int H' a(11)b(01)a(12)b(02) \cos(\phi_1 - \phi_2) dv$$

$$I_7 = \int H' [a(11)]^2 [b(12)]^2 \cos 2(\phi_1 - \phi_2) dv$$

$$I_8 = \int H' a(11) b(11) a(12) b(12) \cos 2(\phi_1 - \phi_2) dv$$

$$I_9 = \int H' [a(01)]^2 [b(02)]^2 dv$$

$$I_{10} = \int H' a(01) b(01) a(02) b(02) dv$$

$$I_{11} = \int H' a(01) a(12) b(11) b(02) \cos(\phi_1 - \phi_2) dv$$

where H' is the "perturbative" part of the energy, e.g.,

$$H' = \frac{2}{R} + \frac{2}{r} - \frac{2}{a_2} - \frac{2}{b_1}, \text{ using atomic units.}$$

$$(S_{11})^{1/2} = \int a(11) b(11) dv_1, (S_{00})^{1/2} = \int a(01) b(01) dv_1, S_{10} = (S_{11} S_{00})^{1/2}.$$

There remain to be solved two two-degree secular equations, namely

$$(1) \quad \begin{vmatrix} I_1 + I_2 + I_7 + I_8 - E(1 + S_{11}) & 2(I_5 + I_{11}) \\ -I_5 + I_{11} & I_9 + I_{10} - E(1 + S_{00}) \end{vmatrix} = 0$$

and

$$(2) \quad \begin{vmatrix} I_1 - I_2 + I_7 - I_8 - E(1 - S_{11}) & 2(-I_5 + I_{11}) \\ +I_5 + I_{11} & I_9 - I_{10} - E(1 - S_{00}) \end{vmatrix} = 0$$

The solution of (1) gives us two states of the $^1\Sigma, S^N$ type, and the solution of (2) two states of the $^3\Sigma, A^N$ type. It turns out that the influence of the non-diagonal terms is negligible.

EVALUATION OF THE INTEGRALS

General formulae. One may classify the integrals according to whether it is necessary to use the Neumann expansion or not in their evaluation. One does not need to do so for the integrals I_1, I_3, I_9, I_5 , and I_7 . The only term in the Hamiltonian which offers difficulty is the $2/r$ term. The integrals involving the Neumann expansion are termed "exchange," and the others "Coulomb."

Before proceeding, the notation needs explanation. That used by Zener and Guillemin⁶ will be adopted.

$$\Gamma_n = \int_0^\infty e^{-u} u^{n-1} du \quad \Gamma_n(\alpha) = \int_\alpha^\infty e^{-u} u^{n-1} du, \quad \gamma_n(\alpha) = \Gamma_n - \Gamma_n(\alpha)$$

$$A_n(\sigma, \alpha) = \int_\alpha^\infty e^{-\alpha x} x^n dx = \frac{1}{\alpha^{n+1}} \Gamma_{n+1}(\sigma\alpha)$$

$$B_n(\alpha) = \int_{-1}^1 e^{-\alpha x} x^n dx = A_n(-1, \alpha) - A_n(1, \alpha)$$

$$f_\tau(m, \alpha) = \int_1^\infty e^{-\alpha x} x^m Q_\tau(x) dx$$

where

$$Q_0 = \frac{1}{2} \ln \left(\frac{x+1}{x-1} \right), \quad x > 1, \quad \text{and} \quad Q_1 = xQ_0 - 1.$$

One may readily establish, by partial integration, the following recursion formulae:

$$A_{m+1}(1, \alpha) - A_m(1, \alpha) = \frac{1}{\alpha} \{ (m+1)A_m(1, \alpha) - mA_{m-1}(1, \alpha) \}$$

$$A_{m+1}(1, \alpha) + A_m(1, \alpha) = \frac{1}{\alpha} \{ 2e^{-\alpha} + (m+1)A_m(1, \alpha) + mA_{m-1}(1, \alpha) \}$$

$$A_{m+2}(1, \alpha) - A_m(1, \alpha) = \frac{1}{\alpha} \{ (m+2)A_{m+1}(1, \alpha) - mA_{m-1}(1, \alpha) \}$$

$$f_0(n+2, \alpha) - f_0(n, \alpha) = \frac{1}{\alpha} \{ -A_n(1, \alpha) + 2f_0(n+1, \alpha) + n[f_0(n+1, \alpha) - f_0(n-1, \alpha)] \}$$

$$\begin{aligned} f_1(n+2, \alpha) - f_1(n, \alpha) &= \frac{1}{\alpha} \{ 3f_1(n+1, \alpha) - f_0(n, \alpha) + n[f_1(n+1, \alpha) - f_1(n-1, \alpha)] \} \\ &= \frac{1}{\alpha} \{ 2f_1(n+1, \alpha) - A_{n-1}(1, \alpha) \\ &\quad + (n+1)[f_1(n+1, \alpha) - f_1(n-1, \alpha)] \} \end{aligned}$$

We have here used the relations

$$(x^2 - 1) \frac{dQ_n}{dx} = nxQ_n - nQ_{n-1}, \quad n > 0$$

and

$$f_1(m, \alpha) = f_0(m+1, \alpha) - A_m(1, \alpha).$$

Now let

$$F(n, \lambda) = \int_{-1}^1 \frac{e^{-\rho\mu} d\mu}{(\mu - \lambda)^n}$$

then $F(1) = e^{-\rho\lambda} [-E_i(\rho(1+\lambda)) + E_i(-\rho(1+\lambda))]$ where

$$-E_i(-x) = \int_x^\infty \frac{e^{-u}}{u} du.$$

In general,

$$F(n) = -\frac{1}{n-1} \left[\frac{e^{-\rho}}{(1-\lambda)^{n-1}} - \frac{e^{\rho}}{(-1-\lambda)^{n-1}} \right] - \frac{\rho}{n-1} F(n-1), n \neq 1$$

and

$$\frac{dF(n)}{d\lambda} = nF(n+1).$$

Abbreviating,

$$F_1(n) = -\frac{1}{n-1} \left[\frac{e^{-\rho}}{(1-\lambda)^{n-1}} - \frac{e^{\rho}}{(-1-\lambda)^{n-1}} \right]$$

and

$$F(n) = -\frac{\rho}{n-1} F(n-1) + F_1(n)$$

$$\begin{aligned} \int_1^{\infty} f(\lambda) F(n+1) e^{-\rho\lambda} d\lambda &= \int_1^{\infty} f(\lambda) \frac{1}{n} \frac{dF(n)}{d\lambda} e^{-\rho\lambda} d\lambda = \frac{1}{2n} f(\lambda) F(n) e^{-\rho\lambda} \Big|_1^{\infty} \\ &\quad - \frac{1}{2n} \int_1^{\infty} e^{-\rho\lambda} \left\{ F(n) \frac{df(\lambda)}{d\lambda} - f(\lambda) \frac{dF_1(n)}{d\lambda} \right\} d\lambda. \end{aligned} \quad (3)$$

For the most part, two kinds of coordinate systems have been employed. One, with a, b , and ϕ as coordinates, and $(1/R)adabdbd\phi$ as volume element, is most convenient for integrals such as $\int e^{-\kappa a} f(a, b) dv$, since one can integrate over b first and avoid the occurrence of integral logarithms in the final integrand (using a wave function with radial part $R = cre^{-\kappa r/2}$). The other, with λ, μ , and ϕ as coordinates, where $a = (R/2)(\lambda + \mu)$ and $b = (R/2)(\lambda - \mu)$, and $(R/2)^3(\lambda^2 - \mu^2)d\lambda d\mu d\phi$ is the volume element, is best for integrals such as $\int e^{-\kappa(a+b)} f(a, b) dv$, the integration over μ being performed first. The transformation is as follows:

$$\begin{aligned} \cos \theta_a &= \frac{\lambda\mu + 1}{\lambda + \mu} & \cos \theta_b &= \frac{\lambda\mu - 1}{\lambda - \mu} & \sin^2 \theta_a &= \frac{(\lambda^2 - 1)(1 - \mu^2)}{(\lambda + \mu)^2}, \\ \sin^2 \theta_b &= \frac{(\lambda^2 - 1)(1 - \mu^2)}{(\lambda - \mu)^2}. \end{aligned}$$

Normalization. The normalized atomic wave functions are $u = c_1 e^{-\kappa r/2} r \sin \theta e^{\pm i\phi}$ and $u = c_2 e^{-\kappa r/2} r \cos \theta$, where $2\pi c_1^2/\kappa^5 = 1/32$ and $2\pi c_2^2/\kappa^5 = 1/16$. Let $\alpha = \kappa R$.

$$\begin{aligned} (S_{11})^{1/2} &= 2\pi c_1^2 \int e^{-(\kappa/2)(a+b)} a \sin \theta_a b \sin \theta_b adabdb \\ &= \frac{2\pi c_1^2}{\kappa^5} \left(\frac{\alpha}{2} \right)^5 \int_1^{\infty} d\lambda \int_{-1}^1 d\mu e^{-\alpha\lambda/2} (\lambda^2 - 1)(\lambda^2 - \mu^2)(1 - \mu^2) \\ &= 1/24 \cdot (\alpha/2)^5 \{ A_4(1, \alpha/2) - (6/5)A_2(1, \alpha/2) + (1/5)A_0(1, \alpha/2) \} \end{aligned}$$

$$\begin{aligned} (S_{00})^{1/2} &= (2\pi c_2^2/\kappa^5)(\alpha/2)^5 \int_1^{\infty} d\lambda \int_{-1}^1 d\mu e^{-\alpha\lambda/2} (\lambda^2\mu^2 - 1)(\lambda^2 - \mu^2) \\ &= 1/24 \cdot (\alpha/2)^5 \{ A_4(1, \alpha/2) - (18/5)A_2(1, \alpha/2) + A_0(1, \alpha/2) \} \end{aligned}$$

The integrals I_1, I_3, I_5, I_6, I_7 .

Let

$$\begin{aligned} i_1 &= \int \frac{2}{r} [a(11)]^2 [b(12)]^2 dv = \int \frac{2}{r} c_1^4 a_1^2 b_2^2 \sin^2 \theta_{a_1} \sin^2 \theta_{b_2} e^{-\kappa(a_1+b_2)} dv \\ i_3 &= \int \frac{2}{r} [a(11)]^2 [b(02)]^2 dv = \int \frac{2}{r} c_1^2 c_2^2 a_1^2 b_2^2 \sin^2 \theta_{a_1} \cos^2 \theta_{b_2} e^{-\kappa(a_1+b_2)} dv \\ &= \int \frac{2}{r} [a(01)]^2 [b(12)]^2 dv = \int \frac{2}{r} c_1^2 c_2^2 a_1^2 b_2^2 \cos^2 \theta_{a_1} \sin^2 \theta_{b_2} e^{-\kappa(a_1+b_2)} dv \\ i_5 &= \int \frac{2}{r} [a(01)]^2 [b(02)]^2 dv = \int \frac{2}{r} c_2^4 a_1^2 b_2^2 \cos^2 \theta_{a_1} \cos^2 \theta_{b_2} e^{-\kappa(a_1+b_2)} dv \\ i_5 &= \int \frac{2}{r} a(01) a(11) b(02) b(12) \cos(\phi_1 - \phi_2) dv \\ &= \int \frac{2}{r} c_1^2 c_2^2 a_1^2 b_2^2 \sin \theta_{a_1} \cos \theta_{a_1} \sin \theta_{b_2} \cos \theta_{b_2} e^{-\kappa(a_1+b_2)} \cos(\phi_1 - \phi_2) dv \\ i_7 &= \int \frac{2}{r} [a(11)]^2 [b(12)]^2 \cos 2(\phi_1 - \phi_2) dv \\ &= \int \frac{2}{r} c_1^4 a_1^2 b_2^2 \sin^2 \theta_{a_1} \sin^2 \theta_{b_2} e^{-\kappa(a_1+b_2)} \cos 2(\phi_1 - \phi_2) dv. \end{aligned}$$

We can now expand $2/r$ as usual:—

$$\begin{aligned} \frac{2}{r} &= \frac{2}{b_1} \left\{ 1 + \frac{b_2}{b_1} \cos \gamma + \left(\frac{b_2}{b_1} \right)^2 P_2(\cos \gamma) + \dots \right\} \quad b_2 < b_1 \\ &= \frac{2}{b_2} \left\{ 1 + \frac{b_1}{b_2} \cos \gamma + \left(\frac{b_1}{b_2} \right)^2 P_2(\cos \gamma) + \dots \right\} \quad b_2 > b_1 \end{aligned}$$

where γ is the angle between the lines b_1 and b_2 , and

$$\begin{aligned} P_n(\cos \gamma) &= P_n(\cos \theta_{b_1}) P_n(\cos \theta_{b_2}) \\ &\quad + 2 \sum_{m=1}^n (-1)^m \frac{(n-m)!}{(n+m)!} P_n^m(\cos \theta_{b_1}) P_n^m(\cos \theta_{b_2}) \cos m(\phi_1 - \phi_2) \\ \int_0^{2\pi} P_n(\cos \gamma) \cos m(\phi_1 - \phi_2) d(\phi_1 - \phi_2) &= 2\pi P_n(\cos \theta_{b_1}) P_n(\cos \theta_{b_2}), \quad m = 0 \\ &= 2\pi (-1)^m \frac{(n-m)!}{(n+m)!} P_n^m(\cos \theta_{b_1}) P_n^m(\cos \theta_{b_2}), \quad m \neq 0. \end{aligned}$$

On performing the integrations, one obtains, letting

$$\begin{aligned} g_{5,1} &= \frac{\gamma_5(\kappa b)}{\kappa b} + \Gamma_4(\kappa b) \\ g_{7,3} &= \frac{\gamma_7(\kappa b)}{(\kappa b)^3} + (\kappa b)^2 \Gamma_2(\kappa b), \end{aligned}$$

the following expressions:—

$$i_1 = (16\pi c_1^4/3\kappa^4) \int a^2 \sin^2 \theta_a e^{-\kappa a} [g_{5,1} - (1/5)P_2(\cos \theta_b)g_{7,3}] dv$$

$$i_3 = (8\pi c_1^2 c_2^2/3\kappa^4) \int a^2 \sin^2 \theta_a e^{-\kappa a} [g_{5,1} + (2/5)P_2(\cos \theta_b)g_{7,3}] dv$$

$$= (16\pi c_1^2 c_2^2/3\kappa^4) \int a^2 \cos^2 \theta_a e^{-\kappa a} [g_{5,1} - (1/5)P_2(\cos \theta_b)g_{7,3}] dv$$

$$i_9 = (8\pi c_2^4/3\kappa^4) \int a^2 \cos^2 \theta_a e^{-\kappa a} [g_{5,1} + (2/5)P_2(\cos \theta_b)g_{7,3}] dv$$

$$i_5 = - (8\pi c_1^2 c_2^2/5\kappa^4) \int a^2 \sin \theta_a \cos \theta_a \sin \theta_b \cos \theta_b e^{-\kappa a} g_{7,3} dv$$

$$i_7 = - (8\pi c_1^4/5\kappa^4) \int a^2 \sin^2 \theta_a \sin^2 \theta_b e^{-\kappa a} g_{7,3} dv$$

$$\int a^2 \sin^2 \theta_a e^{-\kappa a} (\Gamma_5/\kappa b) dv = (8\pi\Gamma_5/3\kappa^5) [g_{5,1}(\alpha) - (1/5)g_{7,3}(\alpha)]$$

$$\int a^2 \cos^2 \theta_a e^{-\kappa a} (\Gamma_5/\kappa b) dv = (4\pi\Gamma_5/3\kappa^5) [g_{5,1}(\alpha) + (2/5)g_{7,3}(\alpha)]$$

$$\begin{aligned} \int a^2 \sin^2 \theta_a e^{-\kappa(a+b)} [(\kappa b)^3 + 6(\kappa b)^2 + 18\kappa b + 24] (1/\kappa b) \cdot dv \\ = (2\pi/\kappa^5)(\alpha/2)^4 \{ (\alpha/2)^3 [(4/3)(A_6 - A_4) - (4/35)(A_2 - A_0)] \\ + 6(\alpha/2)^2 [(4/3)(A_5 - A_3) - (4/15)(A_3 - A_1)] + 18(\alpha/2) [(4/3)(A_4 - A_2) \\ - (4/15)(A_2 - A_0)] + 24(4/3)(A_3 - A_1) \} \end{aligned}$$

$$\begin{aligned} \int a^2 \cos^2 \theta_a e^{-\kappa(a+b)} [(\kappa b)^3 + 6(\kappa b)^2 + 18\kappa b + 24] (1/\kappa b) \cdot dv \\ = (2\pi/\kappa^5)(\alpha/2)^4 \{ (\alpha/2)^3 [(2/3)(A_6 - A_4) + (46/35)A_2 - (2/5)A_0] \\ + 6(\alpha/2)^2 [(2/3)A_5 + (4/15)A_3 + (2/15)A_1] + 18(\alpha/2) [(2/3)A_4 + (8/5)A_2 \\ - (2/3)A_0] + 24[(2/3)A_3 + (10/3)A_1] \} \end{aligned}$$

$$\Gamma_7 \int a^2 \sin^2 \theta_a e^{-\kappa a} P_2(\cos \theta_b) (1/\kappa b)^3 dv$$

$$= (8\pi\Gamma_7/\kappa^5) [\gamma_5/3\alpha^3 - \Gamma_2/15 - 2\gamma_7/5\alpha^5]$$

$$\Gamma_7 \int a^2 \cos^2 \theta_a e^{-\kappa a} P_2(\cos \theta_b) (1/\kappa b)^3 dv$$

$$= (4\pi\Gamma_7/\kappa^5) [\gamma_5/3\alpha^3 + 2\Gamma_2/15 + 4\gamma_7/5\alpha^3 - \alpha^2 e^{-\alpha}/2]$$

$$\begin{aligned} & \int a^2 \sin^2 \theta_a e^{-\kappa a} (1/\kappa b)^3 P_2(\cos \theta_b) [\Gamma_7(\kappa b) - (\kappa b)^5 \Gamma_2(\kappa b)] dv \\ &= (2\pi\alpha^2/4\kappa^5) [(\alpha/2)^5 \{-(4/3)(A_6 - A_4) + (64/7)(A_4 - A_2) - (12/7)(A_2 - A_0)\} \\ & \quad + (\alpha/2)^4 \{-8(A_5 - A_3) + 40(A_3 - A_1)\} \\ & \quad + 15\alpha^3 \{2(A_6 - A_4) - (76/15)(A_4 - A_2) + (62/15)(A_2 - A_0)\} \\ & \quad + 90\alpha^2 \{-8(A_5 - A_3) + (34/3)(A_3 - A_1)\} \\ & \quad + 360\alpha \{(15/2)A_4 - (71/6)A_2 + (10/3)A_0\}] \end{aligned}$$

$$\begin{aligned} & \int a^2 \cos^2 \theta_a e^{-\kappa a} (1/\kappa b)^3 P_2(\cos \theta_b) [\Gamma_7(\kappa b) - (\kappa b)^5 \Gamma_2(\kappa b)] dv \\ &= (2\pi\alpha^2/4\kappa^5) [(\alpha/2)^5 \{(4/3)A_6 - (220/21)A_4 + (124/7)A_2 - 4A_0\} \\ & \quad + (\alpha/2)^4 \{8A_5 - 64A_3 + 88A_1\} \\ & \quad + 15\alpha^3 \{-2A_6 - (14/15)A_4 + (6/5)A_2 + (10/3)A_0\} \\ & \quad + 90\alpha^2 \{8A_5 + (14/3)A_3 - (26/3)A_1\} \\ & \quad + 360\alpha \{-(23/2)A_4 - (25/6)A_2 + 2A_0\} \\ & \quad + 720 \{8A_3 + 2A_1\}] \end{aligned}$$

$$\begin{aligned} & \int a^2 \sin^2 \theta_a e^{-\kappa a} (1/\kappa b)^3 [\Gamma_7(\kappa b) - (\kappa b)^5 \Gamma_2(\kappa b)] dv \\ &= (2\pi\alpha^2/4\kappa^5) [5(\alpha/2)^5 \{(4/3)(A_6 - A_4) - (4/35)(A_2 - A_0)\} \\ & \quad + 30(\alpha/2)^4 \{(4/3)(A_5 - A_3) - (4/15)(A_3 - A_1)\} \\ & \quad + 15\alpha^3 \{(4/3)(A_4 - A_2) - (4/15)(A_2 - A_0)\} \\ & \quad + 120\alpha^2 \{A_3 - A_1\} + 960(A_2 - A_0)] \end{aligned}$$

$$\begin{aligned} & \Gamma_7 \int a^2 \sin \theta_a \cos \theta_a \sin \theta_b \cos \theta_b e^{-\kappa a} (1/\kappa b)^3 dv \\ &= (2\pi\Gamma_7/15\kappa^5\alpha^3) [-16\gamma_7(\alpha)/\alpha^2 + 4\alpha^3\Gamma_2(\alpha)] \\ & \int a^2 \sin \theta_a \cos \theta_a \sin \theta_b \cos \theta_b e^{-\kappa a} (1/\kappa b)^3 [\Gamma_7(\kappa b) - (\kappa b)^5 \Gamma_2(\kappa b)] dv \\ &= (2\pi\alpha^2/4\kappa^5) [(\alpha/2)^5 \{(4/3)(A_6 - A_4) - (152/21)(A_4 - A_2) + (1/15)(A_2 - A_0)\} \\ & \quad + (\alpha/2)^4 \{8(A_5 - A_3) - 40(A_3 - A_1)\} \\ & \quad + 20\alpha^3 \{A_6 - A_4 - (1/5)(A_4 - A_2) - 2(A_2 - A_0)\} \\ & \quad - 480\alpha^2 \{A_5 - A_3\} + 360\alpha \{(23/3)A_4 - 5A_2 - 2A_0\} - 240 \{16A_3 - 8A_1\}] \end{aligned}$$

Evaluation of the integral

$$\int a^2 \cos^2 \theta_a e^{-\kappa a} P_2(\cos \theta_b) (1/\kappa b)^3 dv = J$$

This is a conditionally convergent integral,⁷ the value of which depends upon the particular coordinate system used. Since the companion integral has been evaluated in the λ, μ system (merely for convenience), this procedure must be followed here, even though much more laborious than the evaluation in the a, b , system. Setting $\rho = \alpha/2$,

$$\begin{aligned} J &= \int \int e^{-\alpha(\lambda+\mu)/2} (2\pi/\kappa^5) (\alpha/2)^2 (\lambda\mu + 1)^2 (1/(\lambda - \mu)^3) (\lambda^2 - \mu^2) \\ &\quad \{1 - 3(\lambda^2 - 1)(1 - \mu^2)/2(\lambda - \mu)^2\} d\lambda d\mu \\ &= (2\pi\alpha^2/4\kappa^5) \left[\int \int e^{-\rho(\lambda+\mu)} (\lambda\mu + 1)^2 (\lambda + \mu)/(\lambda - \mu)^2 \cdot d\lambda d\mu \right. \\ &\quad - (3/2) \int \int (\lambda^2 - 1) e^{-\rho(\lambda+\mu)} (\lambda\mu + 1)^2 \{ (1 - \lambda^2)(\lambda + \mu)/(\lambda - \mu)^4 \\ &\quad \left. + (\lambda + \mu)^2/(\lambda - \mu)^3 \} d\lambda d\mu \right] \\ &= (2\pi\alpha^2/4\kappa^5) \int_1^\infty e^{-\rho\lambda} d\lambda [I_0 - (3/2)(\lambda^2 - 1) \{ (1 - \lambda^2)I_1 + I_2 \}] \end{aligned}$$

where

$$I_0 = \int_{-1}^1 d\mu e^{-\rho\mu} (\lambda\mu + 1)^2 (\lambda + \mu)/(\lambda - \mu)^2$$

$$I_1 = \int_{-1}^1 d\mu e^{-\rho\mu} (\lambda\mu + 1)^2 (\lambda + \mu)/(\lambda - \mu)^4$$

$$I_2 = \int_{-1}^1 d\mu e^{-\rho\mu} (\lambda\mu + 1)^2 (\lambda + \mu)^2/(\lambda - \mu)^3$$

$$I_0 = 2\lambda \{ \lambda^2 F(0) + 2\lambda(\lambda^2 + 1)F(1) + (\lambda^2 + 1)^2 F(2) \} + \lambda^2 F(-1) \\ + 2\lambda(\lambda^2 + 1)F(0) + (\lambda^2 + 1)^2 F(1)$$

$$I_1 = 2\lambda \{ \lambda^2 F(2) + 2\lambda(\lambda^2 + 1)F(3) + (\lambda^2 + 1)^2 F(4) \} + \lambda^2 F(1) \\ + 2\lambda(\lambda^2 + 1)F(2) + (\lambda^2 + 1)^2 F(3)$$

$$I_2 = -4\lambda^2 \{ \lambda^2 F(1) + 2\lambda(\lambda^2 + 1)F(2) + (\lambda^2 + 1)^2 F(3) \} - 4\lambda \{ \lambda^2 F(0) \\ + 2\lambda(\lambda^2 + 1)F(1) + (\lambda^2 + 1)^2 F(2) \} - \{ \lambda^2 F(-1) + 2\lambda(\lambda^2 + 1)F(0) \\ + (\lambda^2 + 1)^2 F(1) \}$$

$$\begin{aligned} J &= (2\pi\alpha^2/4\kappa^5) \int_1^\infty e^{-\rho\lambda} d\lambda \{ 3\lambda(1 - \lambda^4)^2 F(4) + (3/2)(1 - \lambda^4)(1 - 9\lambda^4)F(3) \\ &\quad + (24\lambda^7 - \lambda^5 - 14\lambda^3 - \lambda)F(2) + (21\lambda^6 - 5\lambda^4/2 - 6\lambda^2 - 1/2)F(1) \\ &\quad + (9\lambda^5 - 2\lambda^3 - \lambda)F(0) + (3\lambda^4/2 - \lambda^2/2)F(-1) \}, \end{aligned}$$

⁷ This was not realized at first, and the a, b coordinate system was used. This gave a wrong result, and I wish to thank Mr. H. M. Mott-Smith, Jr. for his kindness in helping to locate the error.

Applying formula (3), one obtains

$$J = (4\pi/\kappa^5)(\gamma_8/3\alpha^3 + 2\Gamma_2/15 + 4\gamma_7/5\alpha^5 - \alpha^2 e^{-\alpha/2}).$$

This differs from the result using the a, b coordinate system in that the last term here does not occur in that result.

The integrals $i_2, i_4, i_6, i_8, i_{10}$, and i_{11} .

$$i_2 = c_1^4 \int dv_1 dv_2 a_1 \sin \theta_{a_1} b_1 \sin \theta_{b_1} a_2 \sin \theta_{a_2} b_2 \sin \theta_{b_2} e^{-(\kappa/2)(a_1+a_2+b_1+b_2)} (2/r)$$

$$i_4 = c_1^2 c_2^2 \int dv_1 dv_2 a_1 \sin \theta_{a_1} b_1 \sin \theta_{b_1} a_2 \cos \theta_{a_2} b_2 \cos \theta_{b_2} e^{-(\kappa/2)(a_1+a_2+b_1+b_2)} (2/r)$$

$$i_6 = c_1^2 c_2^2 \int dv_1 dv_2 a_1 \sin \theta_{a_1} b_1 \cos \theta_{b_1} a_2 \sin \theta_{a_2} b_2 \cos \theta_{b_2} \cos(\phi_1 - \phi_2) e^{-(\kappa/2)(a_1+a_2+b_1+b_2)} (2/r)$$

$$i_8 = c_1^4 \int dv_1 dv_2 a_1 \sin \theta_{a_1} b_1 \sin \theta_{b_1} a_2 \sin \theta_{a_2} b_2 \sin \theta_{b_2} \cos 2(\phi_1 - \phi_2) e^{-(\kappa/2)(a_1+a_2+b_1+b_2)} (2/r)$$

$$i_{10} = c_2^4 \int dv_1 dv_2 a_1 \cos \theta_{a_1} b_1 \cos \theta_{b_1} a_2 \cos \theta_{a_2} b_2 \cos \theta_{b_2} e^{-(\kappa/2)(a_1+a_2+b_1+b_2)} (2/r)$$

$$i_{11} = c_1^2 c_2^2 \int dv_1 dv_2 a_1 \cos \theta_{a_1} b_1 \sin \theta_{b_1} a_2 \sin \theta_{a_2} b_2 \cos \theta_{b_2} \cos(\phi_1 - \phi_2) e^{-(\kappa/2)(a_1+a_2+b_1+b_2)} (2/r).$$

We use Neumann's expansion:

$$\frac{1}{r} = \frac{2}{R} \sum_{\tau=0}^{\infty} \sum_{\nu=0}^{\tau} D_{\tau\nu} P_{\tau}^{\nu} \left(\frac{\lambda_1}{\lambda_2} \right) Q_{\tau}^{\nu} \left(\frac{\lambda_2}{\lambda_1} \right) P_{\tau}^{\nu}(\mu_1) P_{\tau}^{\nu}(\mu_2) \cos \nu(\phi_1 - \phi_2)$$

the upper arguments for $\lambda_2 > \lambda_1$, and the lower for $\lambda_2 < \lambda_1$

$$D_{\tau\nu} = (-1)^{\nu} \epsilon_{\nu} (2\tau + 1) \left[\frac{(\tau - \nu)!}{(\tau + \nu)!} \right]^2, \quad \epsilon_0 = 1, \quad \epsilon_1 = \epsilon_2 = \dots = 2.$$

One does not need to concern oneself as to whether the above series converges rapidly or not (for the integrals in question), for orthogonality relations reduce the number of terms to three or four. In general, but not always, the second term is so small compared with the first that its contribution may be neglected.

Let us denote the terms arising from $\tau=0$ by $i_2^{(0)}, i_4^{(0)}$, etc. Also, let

$$\begin{aligned} \sigma_{\tau}(m, n, \alpha) &= \int_1^{\infty} Q_{\tau}(\lambda) e^{-\alpha\lambda/2} \lambda^m A_n \left(\lambda, \frac{\alpha}{2} \right) d\lambda \\ &= \sum_{\nu=0}^n (n!/\nu!) f_{\tau}(m + \nu, \alpha) (\alpha/2)^{\nu-n-1} \\ s_{\tau}(m, n, \alpha) &= \int_1^{\infty} Q_{\tau}(\lambda_1) e^{-\alpha\lambda_1/2} \lambda_1^m d\lambda_1 \int_1^{\lambda_1} e^{-\alpha\lambda_2/2} \lambda_2^n d\lambda_2 \\ &= f_{\tau}(m, \alpha/2) A_n(1, \alpha/2) - \sigma_{\tau}(m, n, \alpha) \end{aligned}$$

Tables of σ_r , s_r , etc. are given later.

$$\begin{aligned}
 i_2^{(0)} &= 2c_1^4(2\pi)^2(R/2)^9 \int (\lambda_1^2 - 1)(1 - \mu_1)^2(\lambda_2^2 - 1)(1 - \mu_2^2)(\lambda_1^2 - \mu_1^2) \\
 &\quad (\lambda_2^2 - \mu_2^2) Q_0 \left(\frac{\lambda_2}{\lambda_1} \right) e^{-\kappa R (\lambda_1 + \lambda_2)/2} d\mu_1 d\mu_2 d\lambda_1 d\lambda_2 \\
 &= (2\kappa/1024)(\alpha/2)^9 \int (\lambda_1^2 - 1)(\lambda_2^2 - 1)(4/3)^2(\lambda_1^2 - 1/5) \\
 &\quad (\lambda_2^2 - 1/5) Q_0 \left(\frac{\lambda_2}{\lambda_1} \right) e^{-\kappa R (\lambda_1 + \lambda_2)/2} d\lambda_1 d\lambda_2 \\
 &= (\kappa/144)(\alpha/2)^9 \{s_0(00)/25 + 36s_0(22)/25 + s_0(44) - 6[s_0(02) + s_0(20)]/25 \\
 &\quad + [s_0(04) + s_0(40)]/5 - 6[s_0(24) + s_0(42)]/5\} \\
 i_4^{(0)} &= (\kappa/144)(\alpha/2)^9 \{s_0(00)/5 + 108s_0(22)/25 + s_0(44) - 24[s_0(02) + s_0(20)]/25 \\
 &\quad + 3[s_0(04) + s_0(40)]/5 - 12[s_0(42) + s_0(24)]/5\} \\
 i_{10}^{(0)} &= (\kappa/16)(\alpha/2)^9 [\{s_0(00) + s_0(04) + s_0(40) + s_0(44)\}/9 + 36s_0(22)/25 \\
 &\quad - 2\{s_0(02) + s_0(20) + s_0(42) + s_0(24)\}/5]
 \end{aligned}$$

Let

$$\begin{aligned}
 t_2(2m, 2n, \alpha) &= \int_1^\infty Q_2(\lambda_1) e^{-\alpha\lambda_1/2} \lambda_1^{2m} d\lambda_1 \int_1^{\lambda_1} P_2(\lambda_2) e^{-\alpha\lambda_2/2} \lambda_2^{2n} d\lambda_2 \\
 &= (3/2)s_2(2m, 2n + 2) - (\frac{1}{2})s_2(2m, 2n).
 \end{aligned}$$

Then

$$\begin{aligned}
 i_2^{(2)} &= 10c_1^4(2\pi)^2(R/2)^9 \int (\lambda_1^2 - 1)(1 - \mu_1)^2(\lambda_2^2 - 1)(1 - \mu_2^2)(\lambda_1^2 - \mu_1^2) \\
 &\quad (\lambda_2^2 - \mu_2^2) e^{-\alpha(\lambda_1 + \lambda_2)/2} \cdot Q_2 \left(\frac{\lambda_2}{\lambda_1} \right) P_2 \left(\frac{\lambda_1}{\lambda_2} \right) P_2(\mu_1) P_2(\mu_2) d\mu_1 d\mu_2 d\lambda_1 d\lambda_2 \\
 &= 10c_1^4(2\pi)^2(R/2)^9 \int (4/15)^2(\lambda_1^2 - 1)(\lambda_2^2 - 1)(\lambda_1^2 + 1/7) \\
 &\quad (\lambda_2^2 + 1/7) Q_2 \left(\frac{\lambda_2}{\lambda_1} \right) P_2 \left(\frac{\lambda_1}{\lambda_2} \right) e^{-\alpha(\lambda_1 + \lambda_2)/2} d\lambda_1 d\lambda_2 \\
 &= (\kappa/720)(\alpha/2)^9 [t_2(00)/49 + 36t_2(22)/49 + t_2(44) + 6\{t_2(02) + t_2(20)\}/49 \\
 &\quad - \{t_2(04) + t_2(40)\}/7 - 6\{t_2(24) + t_2(42)\}/7] \\
 i_4^{(2)} &= -(\kappa/120)(\alpha/2)^9 [-t_2(00)/21 + 12t_2(22)/49 + t_2(44)/3 \\
 &\quad - 6\{t_2(02) + t_2(20)\}/49 + \{t_2(04) + t_2(40)\}/7 - 2\{t_2(24) + t_2(42)\}/7] \\
 i_{10}^{(2)} &= (\kappa/20)(\alpha/2)^9 [\{t_2(00) + t_2(04) + t_2(40) + t_2(44)\}/9 + 4t_2(22)/49 \\
 &\quad - 2\{t_2(02) + t_2(20) + t_2(42) + t_2(24)\}/21]
 \end{aligned}$$

Let

$$u_4(2m, 2n) = \int_1^\infty Q_4(\lambda_1) e^{-\alpha \lambda_1^{1/2} \lambda_1^{2m}} d\lambda_1 \int_1^{\lambda_1} P_4(\lambda_2) e^{-\alpha \lambda_2^{1/2} \lambda_2^{2n}} d\lambda_2 \\ = (1/8) [35s_4(2m, 2n + 4) - 30s_4(2m, 2n + 2) + 3s_4(2m, 2n)]$$

Then

$$i_2^{(4)} = 18c_1^4(2\pi)^2(R/2)^9(16/315)^2 \int (\lambda_1^2 - 1)(\lambda_2^2 - 1) e^{-\alpha(\lambda_1 + \lambda_2)/2} Q_4\left(\frac{\lambda_2}{\lambda_1}\right) P_4\left(\frac{\lambda_1}{\lambda_2}\right) d\lambda_1 d\lambda_2 \\ = \kappa(1/105)^2(\alpha/2)^9 [u_4(00) - u_4(02) - u_4(20) + u_4(22)].$$

The other integrals for $\tau=4$ will be somewhat similar. Since the contributions from $\tau=2$ are small with respect to those from $\tau=0$, the influence of $\tau=4$ has been neglected.

$$i_6^{(1)} = -c_1^2 c_2^2 (2\pi)^2 D_{11}(R/2)^9 \int \frac{dP_1}{d\lambda} \left(\frac{\lambda_1}{\lambda_2}\right) \frac{dQ_1}{d\lambda} \left(\frac{\lambda_2}{\lambda_1}\right) (\lambda_1^2 - 1)(\lambda_2^2 - 1)(4/3)^2 \\ (\lambda_1^2 - \frac{1}{5})(\lambda_2^2 - \frac{1}{5}) e^{-\alpha(\lambda_1 + \lambda_2)/2} d\lambda_1 d\lambda_2 \\ = (\kappa/96)(\alpha/2)^9 [\{s_1(12) - s_1(10) - s_0(02) + s_0(00)\}/25 + \{s_1(34) \\ - s_1(32) - s_0(24) + s_0(22)\} - (\frac{1}{5})\{s_1(14) - s_1(12) + s_1(32) - s_1(30) \\ - s_0(04) + s_0(02) - s_0(22) + s_0(20)\}] \\ i_6^{(2)} = (3\kappa/160)(\alpha/2)^9 [\{s_2(24) - s_2(22) - s_1(14) + s_1(12)\}/49 + \{s_2(46) - s_2(44) \\ - s_1(36) + s_1(34)\}/9 - (1/21)\{s_2(26) - s_2(24) - s_1(16) + s_1(14) \\ + s_2(44) - s_2(42) - s_1(34) + s_1(32)\}] \\ i_{11}^{(1)} = -c_1^2 c_2^2 (2\pi)^2 D_{11}(R/2)^9 \int (\lambda_1 \mu_1 - 1)(\lambda_2 \mu_2 - 1)(\lambda_1^2 - 1)(\lambda_2^2 - 1) \\ (\lambda_1^2 - \mu_1^2)(\lambda_2^2 - \mu_2^2) e^{-\alpha(\lambda_1 + \lambda_2)/2} \frac{dP_1}{d\lambda} \left(\frac{\lambda_1}{\lambda_2}\right) \frac{dQ_1}{d\lambda} \left(\frac{\lambda_2}{\lambda_1}\right) \\ P_1'(\mu_1) P_1'(\mu_1) P_1'(\mu_2) P_1'(\mu_2) d\lambda_1 d\lambda_2 \cdot d\mu_1 d\mu_2 \\ = -i_6^{(1)} \quad i_{11}^{(2)} = i_6^{(2)}, \text{ etc.}$$

For the evaluation of $i_8^{(2)}$, we use the formula

$$(\lambda^2 - 1)^2 \frac{d^2 Q_2}{d\lambda^2} = 2[(\lambda^2 - 1)Q_2 - \lambda Q_1 + Q_0] \\ i_8^{(2)} = 3c_1^4(2\pi)^2 D_{22}(R/2)^9 \int (\lambda_1^2 - 1)^2 (\lambda_2^2 - 1)^2 \frac{d^2 Q_2}{d\lambda^2} \left(\frac{\lambda_2}{\lambda_1}\right) (16/5)^2 \\ (\lambda_1^2 - 1/7)(\lambda_2^2 - 1/7) e^{-\alpha(\lambda_1 + \lambda_2)/2} d\lambda_1 d\lambda_2 \\ = (\kappa/480)(\alpha/2)^9 [s_2(44) + (1/7)\{s_2(04) + s_1(14)\} + s_0(24) - 8s_2(24)/7 \\ - s_1(34) - s_0(04)/7 - (8/7)\{s_2(42) + (1/7)\{s_2(02) + s_1(12)\} + s_0(22) \\ - 8s_2(22)/7 - s_1(32) - s_0(02)/7\} + (1/7)\{s_2(40) + (1/7)\{s_2(00) + s_1(10)\} \\ + s_0(20) - 8s_2(20)/7 - s_1(30) - s_0(00)/7\}].$$

RESULTS

The results have been tabulated in Tables I–XV. The values are based partly on integral logarithm tables given by Jahnke–Emde, and the accuracy

is limited thereby. The tables are, therefore, subject to revision on this account. Except for this, they are accurate up to a possible change of the last figure. In this connection, it is urged that the tabular method is the economical one, in that the calculations may be checked easily.

In order not to make the labor prohibitive in other cases, some more straightforward method should be employed to obtain the entries for $s_2(m, n, \alpha)$ and similar quantities. As it is, the accuracy for small values of α is quite small. This is not serious, however, for the approximation method itself can be expected to give good results only for large values of the internuclear distance.

DISCUSSION

Fig. 1 shows the relative energies plotted as a function of the internuclear distance. The lowest term,⁸ for intermediate values of κR , is the $^3\Sigma_u^+$. For hydrogen, we may set $\kappa=1$, and the minimum of this curve lies at about 2.0A. The value of the heat of dissociation is 2.9 volts, approximately.

Fig. 1. Relative energies.

It is not possible to say, to the degree of approximation used here, whether the $^3\Pi_g$ state has a weak minimum or is repulsive. For the same reason, the relative positions of $^1\Sigma_g^+$ and $^1\Pi_u$ may actually be somewhat different. The

⁸This result has been predicted for B_2 by J. E. Lennard-Jones, Trans. Faraday Soc. 25, 681 (1929).

reason for this uncertainty lies partly in the fact that we have neglected $i_6^{(3)}$ and $i_6^{(4)}$, and partly in the low degree of accuracy to which s_2 may be given.

Apart from these minor details, it is safe to assert that the curves do represent the interaction of two hydrogen-like atoms, each with one $2p$ electron, insofar as this interaction is to be found by a first order perturbation calculation of the Kemble and Zener type.

Heisenberg⁹ has shown that there is reason to believe that the behavior of ferromagnetic substances may some day be understood, when it becomes possible to carry through detailed calculations. A necessary condition for ferromagnetism seems to be that the exchange integral for the lowest states be positive. This was found to be likely for $n \geq 3$, where n is the principal quantum number. From our results, it is seen that a positive exchange energy integral is obtained for $n=2$, $l=1$, so that the possibility of ferromagnetism does not seem to be governed by the principal quantum number in so simple a fashion. The sufficient conditions for ferromagnetism have yet to be given.

One also sees from the curves in the figure that the "Coulomb" integrals are in general more important than the "exchange" integrals. The states arising from $m_{1a}=0$, $m_{1b}=0$ lie the lowest, those from $m_{1a}=0$, $m_{1b}=\pm 1$ are next higher, and those from $m_{1a}=\pm 1$, $m_{1b}=\pm 1$ are highest. This means that the most stable configuration is that in which there is the maximum overlapping of charge, in accordance with the ideas of Slater¹⁰ on directed valency. Orbital valency may be associated with the "Coulomb" integrals, and spin valency with the exchange integrals. The latter concept may, however, be misleading.

Though this analysis is strictly applicable only to the case where two excited hydrogen atoms interact (leaving out of account the influence of the s orbits) one might expect that similar conditions would obtain for boron, or excited lithium. Unfortunately, the band spectrum of B_2 has not been analyzed, so that a direct check of the theory is wanting. The inner s electrons would probably have some influence, but whether the order of the energy levels would be affected or not is open to question.

In conclusion, I wish to express my deep appreciation to the many people with whom the problem has been discussed. It was suggested by Professor Heisenberg, whom I also wish to thank for his help on previous problems. Acknowledgment must also be made to Dr. Dirac for discussion of allied problems. The work was continued at the Eigenössische Technische Hochschule, Zürich, and completed in Urbana. Thanks are due Mr. W. H. Furry for assistance in checking part of the calculations.

Note added to proof, Feb. 17, 1931: The influence of the inner $2s$ electrons is now being studied, and will be made the subject of a later paper.

THE MASS ABSORPTION COEFFICIENT OF THE *K* SHELL
ACCORDING TO THE DIRAC RELATIVISTIC
THEORY OF THE ELECTRON*

BY LOUIS C. ROESS

CORNELL UNIVERSITY

(Received January 19, 1931)

ABSTRACT

Taking as model an atom containing two non-interacting electrons and a fixed nucleus with charge Ze , the mass absorption coefficient is calculated by use of the proper functions of the Dirac relativistic equation. Z is determined so as to make the lowest energy level agree with the experimental value determined from the *K* absorption edge. The numerical calculation presented difficulty because of lack of tables of complex gamma functions. The relativistic coefficient is found to be from 0 to 40 per cent smaller than the non-relativistic coefficient calculated by Nishina and Rabi, the greatest difference occurring for the heavy elements and short wave-lengths; it agrees slightly worse with experiment than the non-relativistic coefficient. The difference between theory and experiment is least for the heavy atoms, as would be expected, since for the heavy atoms (large Z) the neglected electronic interaction-field is small in comparison with the nuclear field. The variation of the relativistic coefficient with wave-length is complicated, but in the range $\frac{3}{2}\lambda_k$ to λ_k (λ_k = wave-length of *K* absorption edge) it is more nearly linear with λ^3 than the non-relativistic coefficient. The importance of using the relativistic equation for heavy atoms and short x-ray wave-lengths is emphasized by these results, which also show that the model chosen is too approximate, even for the heavy elements.

The general normalizing factors for the discrete and continuous spectrum proper functions of a hydrogen-like atom are given.

INTRODUCTION AND RESULTS

SEVERAL attempts¹ have been made, with classical or semi-classical theories, to calculate the atomic absorption coefficient for the *K* shell. More recently Wentzel² and Oppenheimer³ obtained approximate formulae using non-relativistic quantum mechanics, while Nishina and Rabi⁴ have given the explicit formula which follows from the Schrödinger theory. The comparison with experiment made by the latter authors shows fairly good agreement for the heavy elements and poor agreement for the light elements.

The purpose of the present paper is to calculate the mass absorption coefficient by use of the Dirac relativistic equation, and to compare the results

with experiment and with the non-relativistic theory. One can readily see from correspondence principle arguments that for the K electrons of the heavy atoms the relativity corrections should be important, and this is confirmed by the results.

The atom model used here as in the non-relativistic calculations consists of two non-interacting electrons in the field of a fixed nucleus with charge

Fig. 1. The mass absorption coefficient for lead. The curves marked Allen and Richtmyer are plots of the experimental data.⁷

Z^*e , where Z^* is that charge (smaller than the true charge Z) which makes the lowest energy level of the atom model agree with the experimental value. It is obvious that this model will be most nearly correct when the interaction of the K electrons with the nucleus is large compared with their interaction with each other and with the outer electrons, i.e., for the heavy elements.

Fig. 2. The mass absorption coefficient for tin. The curves marked Allen and Richtmyer are plots of the experimental data.⁷

The calculation proceeds as follows: by use of the Dirac radiation theory⁵ combined with the Dirac relativistic equation⁶ the general formula for the absorption probability is derived. This formula contains a certain matrix element which is then evaluated for the case of the transition between the K

⁵ P. A. M. Dirac, Roy. Soc. Proc. A114, 243 and 710, (1927).

⁶ P. A. M. Dirac, Roy. Soc. Proc. A117, 610, (1928).

level and a state of the continuous spectrum corresponding to the removal of one of the K electrons. The resulting formula for the mass absorption coefficient of the K shell is then calculated numerically. The last two operations constitute what is new in the paper. The final formula is quite complicated so that the numerical calculation is very laborious, especially because of lack of tables of the gamma function of complex argument.

The results of the present calculation are collected in the Table I and Figs. 1-3. The relativistic theory gives values of the absorption coefficient which are consistently lower than those of the non-relativistic theory, the difference varying from about 40 percent for Pb at $\frac{1}{2}\lambda_k$ to less than 1 percent for Al at λ_k . The calculated absorption coefficients for Al cannot be compared with experiment because of lack of data for the long wave-lengths, but show how closely the two quantum-mechanical theories agree for the light elements.

Fig. 3. The mass absorption coefficient for zinc. The curve marked Allen is a plot of the experimental data.⁷

It is found experimentally⁷ that the mass absorption coefficient varies linearly with λ^n where n ranges from 2.9 to 3 and apparently changes in value with the wave-length. The classical and semi-classical theories referred to above all give a linear variation with λ^3 . The quantum-mechanical theories predict a more complicated variation with λ , the non-relativistic theory indicating an exponent⁸ 2.87 at $\lambda = \frac{1}{2}\lambda_k$ and $8/3$ at $\lambda = \lambda_k$ (λ_k = wave-length of K edge). The relativistic theory here developed gives an exponent which is somewhat closer to three for the heavy elements over the range $\frac{1}{2}\lambda_k$ to λ_k . For example, for Pb the exponent is 2.86 at $\lambda = \lambda_k$ and 3.13 at $\lambda = \frac{1}{2}\lambda_k$. For the light elements the two theories agree closely for wave-lengths which are not too short.

There are a number of reasons, aside from the inadequacy of the model, for the disagreement between theory and experiment.⁹ In the first place, the

⁸ As pointed out to me by Professor Kennard, the expression of the theoretical results in terms of these exponents is misleading, since the relation given by the quantum mechanics may be written $C(\lambda)\lambda^n(\lambda)$, not $K\lambda^n(\lambda)$ (K independent of λ).

⁹ I wish to thank Professor F. K. Richtmyer for helpful discussions on these points.

† The values of λ_K are taken from the article by Grebe in Geiger-Scheel's Handb. d. Phys., XXI, p. 336.

†† The percent difference is calculated from the Dirac value as base.

true absorption coefficient is not measured experimentally, since scattering is always present. The scattering coefficient, though small in comparison with the true absorption coefficient over the range $\frac{1}{2}\lambda_K$ to λ_K , varies in an un-

known¹⁰ manner with the wave-length. In the second place, the experimenter measures the absorption coefficient for all the electrons in the atom, so that one must extrapolate the absorption curve for the $L+M+N+\dots$ electrons down to wave-lengths below the K edge and then subtract this from the total absorption in this range to get the absorption coefficient for the K electrons. Such an extrapolation, while it may introduce only a small error in the magnitude of the absorption coefficient, can easily change its variation with wave-length. Finally, even an exact model of an *isolated* atom would be incorrect, since the experimental measurements are usually made upon atoms in crystals. In the writer's opinion the above effects are not large enough to account for the discrepancy which, as already suggested by Nishina and Rabi,⁴ must be due to the inadequate model. The results obtained here show clearly that for the K shell of the heavy elements the relativistic theory must be used in conjunction with the correct model.

It should be possible to use a much better model for which the discrete proper functions are obtained by the variational method which has recently been used with such success, but how one can obtain more nearly correct proper functions for the continuous spectrum remains a difficult problem.

THE PROBABILITY OF ABSORPTION

According to Dirac⁶ the motion of an electron in an electromagnetic field with the vector potential A and scalar potential V is described by the wave-equation

$$\left[\frac{W + eV}{c} + \rho_1 \delta \left(\mathbf{p} + \frac{e}{c} \mathbf{A} \right) + \rho_3 mc \right] \psi = 0, \quad (1)$$

in which W is the energy parameter, \mathbf{p} the momentum vector-operator with components $(\hbar/2\pi i)(\partial/\partial x)$, \dots , and ρ_1 , ρ_3 , and δ are certain matrices having four rows and columns. The probability amplitude ψ is also a matrix having four rows and only one column. We shall let V represent the field of the fixed nucleus, and choose the vector potential A of the external field so that its scalar potential vanishes.

From Eq. (1) we obtain for the Hamiltonian function of the electron

$$H_e = H_0 - e\rho_1 \delta A \quad (2)$$

with

$$H_0 = -c\rho_1 \delta \cdot \mathbf{p} - \rho_3 mc^2 - eV.$$

H_0 is the Hamiltonian for the motion in the nuclear field alone. We now suppose the electromagnetic field to be quantized according to the Dirac⁵ scheme, and obtain with Waller,¹¹ taking retardation into account, the following Hamiltonian for the system atom plus field:

$$H = H_0 + \sum_r N_r \hbar \nu_r - \sum_r \rho_1 (\delta \mathbf{u}_r) \left\{ N_r^{1/2} e^{2\pi i / \hbar [\Theta_r - (\mathbf{K} \cdot \mathbf{r}_x)]} + e^{-2\pi i / \hbar [\Theta_r - (\mathbf{K} \cdot \mathbf{r}_x)]} N_r^{1/2} \right\} \quad (3)$$

¹⁰ This variation is very difficult to determine experimentally. For the most recent data see E. N. Coade, Phys. Rev. **36**, 1109, (1930).

¹¹ I. Waller, Zeits. f. Physik **58**, 75, (1929).

where N_r and Θ_r are operators which obey the relation

$$N_r e^{2\pi i \Theta_r / \hbar} - e^{2\pi i \Theta_r / \hbar} N_r = e^{2\pi i \Theta_r / \hbar},$$

\mathbf{x} is a vector with origin at the nucleus which gives the position in space, and

$$\mathbf{u}_r = \left(\frac{c^2 \hbar \nu_r}{2\pi c \sigma_r} \right)^{1/2} \mathbf{r}; \quad \kappa_r = \frac{\hbar \nu_r}{c} \mathbf{n}_r, \quad (3')$$

where $\sigma, d\nu, d\omega_r$ is the number of components r of the radiation field with given polarization \mathbf{r} in the frequency interval $d\nu$, and with direction of motion in the element of solid angle $d\omega_r$ about \mathbf{n}_r .

If the stationary states of the atom are specified by the J'' 's, while N_r' is the number of photons in the component r , we obtain from the general transformation theory the Schrödinger equation corresponding to the Hamiltonian (3)¹²

$$\begin{aligned} & \left[\frac{\hbar}{2\pi i} \frac{\partial}{\partial t} + W(J'') + \sum_r N_r' \hbar \nu_r \right] \Phi(J''; N_1', \dots, N_r', \dots) \\ &= \sum_{J'} \sum_s \mathbf{u}_s [N_s'^{1/2} A^s(J''J') \Phi(J'; N_1' \dots N_{s-1}', N_s' - 1, N_{s+1}' \dots) \\ & \quad + (N_s' + 1)^{1/2} B^s(J''J') \Phi(J'; N_1' \dots N_{s-1}', N_s' + 1, N_{s+1}' \dots)] \end{aligned} \quad (4)$$

with

$$\left. \begin{aligned} A^s(J''J') &= \int \psi_{J''}^*(\mathbf{x}) \rho_1 \delta \psi_{J'}(\mathbf{x}) e^{-2\pi i (\kappa_s \cdot \mathbf{x}) / \hbar} d\mathbf{x} \\ B^s(J''J') &= \int \psi_{J''}^*(\mathbf{x}) \rho_1 \delta \psi_{J'}(\mathbf{x}) e^{+2\pi i (\kappa_s \cdot \mathbf{x}) / \hbar} d\mathbf{x} \end{aligned} \right\} \quad (4')$$

where $\psi_{J'}(\mathbf{x})$ and $W(J')$ are the characteristic function and characteristic value for the motion of the electron in the nuclear field. $|\Phi(J'; N')|^2$ gives the probability for the state $(J'; N')$ of the system, atom plus field.

In Eq. (4) the sum with respect to J' is to include an integral over the continuous spectrum if one is present. In this case the probability of finding the atom in the range $d\epsilon'$ about ϵ' is given by $|\Phi(\epsilon'; N')|^2 d\epsilon'$, where for the continuous spectrum ϵ' is used for J' .

It should be noted that the sum over J' in Eq. (4) includes the negative energy states of the atom. They do not cause difficulty in our application to absorption because here we can restrict ourselves to transitions between states having positive energy. Waller¹² has shown the importance of the negative energy states in calculating scattering and dispersion.

We want to calculate the transition probability $w d\epsilon''$ for an absorption process in which the atom jumps from an initial discrete state J' to a final state in the range $d\epsilon''$ about ϵ'' in the continuous spectrum, with absorption of a photon of definite direction (in $d\omega_s$) and definite polarization, regardless

¹² I. Waller, *Zeits. f. Physik* **61**, 837 (1930).

of what the final frequency state of the field may be. We suppose for the moment that the atomic states are non-degenerate.

The initial state of the field is to be taken as follows: only photons having a direction of motion within a solid angle $d\omega_s$ about n_s , a definite polarization s , but arbitrary frequency ν_{sr} , where r expresses the variation in frequency of the component s , are to be present. For physically interesting results, the range of variation of ν_{sr} about the frequency corresponding to the atomic transition must be at least as great as the natural line breadth.

Following the well-known method,⁵ we calculate the probability of the above-mentioned atomic transition with absorption of a photon of frequency ν_{sr} , and then sum over all such frequencies, obtaining finally for a time t which is large compared with the atomic period but small compared with the mean life time of the state under consideration

$$w d\epsilon'' = \frac{2\pi e^2 c^2 t}{h^2 \nu^2} |s \cdot B^s(\epsilon''; J')|^2 \rho(\nu) d\omega_s d\epsilon'' \quad (5)$$

where

$$h\nu = W(\epsilon'') - W(J'), \quad (6)$$

and $\rho(\nu)$ is the spectral energy density per unit frequency range per unit solid angle for a definite polarization.

Our temporary assumption that the atomic states are non-degenerate is not true. According to the general theory of quantum mechanics, as presented by Born and Jordan,¹³ when the assembly of atoms is in thermal equilibrium before the absorption process occurs, we merely add together those transition probabilities relating to transitions between the degenerate states. Therefore we obtain finally for the transition probability $w d\epsilon''$

$$w d\epsilon'' = d\omega_s \frac{2\pi e^2 c^2 t}{h^2 \nu^2} \sum |s \cdot B^s(\epsilon''; J')|^2 \rho(\nu) d\epsilon'' \quad (7)$$

where the sum is to be taken over all initial states having the same energy and over all final states having the same energy.

In many practical applications we are interested in the absorption probability for arbitrary direction of motion and polarization of the absorbed photon. We can obtain this from Eq. (7) by summing over all directions of motion $d\omega_s$ and all polarizations s . When the wave-length of the incident light is long compared with atomic dimensions, so that we can replace the exponential factor in the matrix element B^s in Eq. (4') by unity, we can easily carry out this summation, obtaining for the absorption probability $w' d\epsilon''$ per unit time for arbitrary direction of motion and polarization of the absorbed photon

$$w' d\epsilon'' = \frac{16\pi^2 e^2 c^2}{3h^2 \nu^2} \sum |P(\epsilon''; J')|^2 \rho(\nu) d\epsilon'' \quad (8)$$

¹³ M. Born and P. Jordan, "Elementare Quantenmechanik," pp. 299, 321, and 329.

where

$$|P|^2 = |B_x|^2 + |B_y|^2 + |B_z|^2. \quad (8')$$

SOLUTIONS OF THE DIRAC EQUATION

The solutions of Eq. (1) for the case when $A=0$ and $V=Ze/r$ have been given by Darwin.¹⁴ For given l and $u(=m-\frac{1}{2})$ there are two sets of solutions. We label these by introducing the quantum number j , which takes on the values $j=l\pm\frac{1}{2}$ to agree with spectroscopic notation. The two sets are:¹⁵

$$\begin{aligned} j &= l + \frac{1}{2} & j &= l - \frac{1}{2} \\ \psi_1 &= -iM_\theta F_l P_{l+1}^u & \psi_1 &= -i(l+u)M_\theta F_{-l-1} P_{l-1}^u \\ \psi_2 &= -iM_\theta F_l P_{l+1}^{u+1} & \psi_2 &= i(l-u-1)M_\theta F_{-l-1} P_{l-1}^{u+1} \\ \psi_3 &= (l+u+1)M_\theta G_l P_l^u & \psi_3 &= M_\theta G_{-l-1} P_l^u \\ \psi_4 &= -(l-u)M_\theta G_l P_l^{u+1} & \psi_4 &= M_\theta G_{-l-1} P_l^{u+1}, \end{aligned} \quad (9a) \quad (9b)$$

in which M_θ is the part of the total normalizing factor associated with the angular coordinates. The radial functions F_l and G_l contain their own normalizing factor.

The function $P_l^u(\theta, \phi)$ is a spherical harmonic defined by Darwin as follows:

$$P_l^u = (l-u)! \sin^l \theta \left(\frac{d}{d \cos \theta} \right)^{l+u} \frac{(\cos^2 \theta - 1)^l}{2^l l!} e^{iu\phi}. \quad (10)$$

The radial functions F_l and G_l satisfy the equations

$$\begin{aligned} \frac{2\pi}{h} \left(\frac{W+eV}{c} + mc \right) F_l + \frac{dG_l}{dr} - \frac{l}{r} G_l &= 0 \\ -\frac{2\pi}{h} \left(\frac{W+eV}{c} - mc \right) G_l + \frac{dF_l}{dr} + \frac{l+2}{r} F_l &= 0. \end{aligned} \quad (11)$$

We shall use the solutions of Eq. (11) given by Gordon.¹⁶ These are:

DISCRETE SPECTRUM: $W/mc^2 < 1$

$$F_l = \left(\frac{N_l - \rho_l - n_r}{N_l + \rho_l + n_r} \right)^{1/2} M_r(\sigma_1 - \sigma_2) \quad (12)$$

$$\begin{aligned} G_l &= M_r(\sigma_1 + \sigma_2) \\ \sigma_1 &= (N_l + l + 1) r^{\rho_l - 1} e^{-k_0 r} {}_1F_1(-n_r; 2\rho_l + 1; 2k_0 r) \\ \sigma_2 &= -n_r r^{\rho_l - 1} e^{-k_0 r} {}_1F_1(-n_r + 1; 2\rho_l + 1; 2k_0 r) \end{aligned} \quad (13)$$

¹⁴ C. G. Darwin, Roy. Soc. Proc. A118, 654 (1928).

¹⁵ In interpreting Eq. (9) it should be noted that in certain cases meaningless spherical harmonics are cancelled by a zero factor. Thus when $l=0$, and $u=-1$, ψ_3 in (9a) is to be taken to be zero.

where

$${}_1F_1(\alpha; \beta; x) = \sum_{n=0}^{\infty} \frac{(\alpha, n)}{(\beta, n)} x^n \quad (14)$$

$$(\alpha, n) = \alpha(\alpha+1) \cdots (\alpha+n-1).$$

M_r = radial normalizing factor.

n_r = radial quantum number.

$$\rho_l = ((l+1)^2 - \alpha^2)^{1/2}. \quad (15)$$

$$k_0 = \frac{2\pi mc}{h} \left(1 - \left(\frac{W}{mc^2} \right)^2 \right)^{1/2} = \frac{1}{a_z N_l}. \quad (16)$$

$$N_l = (n_r^2 + (l+1)^2 + 2\rho_l n_r)^{1/2} \quad (17)$$

$$W = mc^2 \frac{n_r + \rho_l}{N_l} = mc^2 \left\{ 1 + \frac{\alpha^2}{(n_r + (j + \frac{1}{2})^2 - \alpha^2)^{1/2}} \right\}^{-1/2}. \quad (18)$$

$$a_z = \frac{h^2}{4\pi^2 m e^2 Z}; \quad \alpha = \frac{2\pi e^2 Z}{hc}. \quad (19)$$

CONTINUOUS SPECTRUM: $W/mc^2 > 1$

$$F_l = -i \frac{\left(\frac{W}{mc^2} - 1 \right)^{1/2}}{\left(\frac{W}{mc^2} + 1 \right)^{1/2}} M_r (\sigma_1 - \sigma_2) \quad (20)$$

$$G_l = M_r (\sigma_1 + \sigma_2)$$

$$\sigma_1 = A r^{\rho_l - 1} e^{-ik'_0 r_1} F_1(\rho_l + iq + 1; 2\rho_l + 1; 2ik'_0 r)$$

$$\sigma_2 = B r^{\rho_l - 1} e^{-ik'_0 r_1} F_1(\rho_l + iq; 2\rho_l + 1; 2ik'_0 r) \quad (21)$$

$$\frac{A}{B} = \frac{l+1+iQ}{\rho_l - iq} = \frac{\rho_l + iq}{l+1-iQ} \quad (22)$$

$$q = \frac{\frac{\alpha W}{mc^2}}{\left(\left(\frac{W}{mc^2} \right)^2 - 1 \right)^{1/2}} = (Q^2 + \alpha^2)^{1/2} \quad (23)$$

$$k'_0 = \frac{2\pi mc}{h} \left(\left(\frac{W}{mc^2} \right)^2 - 1 \right)^{1/2}. \quad (24)$$

The discrete states of the Dirac electron are specified by the quantum numbers n_r , l , j , and u . These may have the following values:

$$n_r = 0, 1, 2, \dots$$

$$l = 0, 1, 2, \dots$$

$$j = l \pm \frac{1}{2}, \geq 0$$

(When $n_r = 0$ the state $j = l - \frac{1}{2}$ is to be excluded.)

$$[-j] \leq u \leq [j],$$

where $[j]$ is the greatest integer contained in j .

The states of the continuous spectrum are specified by W , l , j , and u , with W arbitrary but $\geq mc^2$ and l , j , and u the same as for the discrete spectrum.

NORMALIZATION OF THE WAVE FUNCTIONS DISCRETE SPECTRUM

We require to normalize our solutions in such a way that

$$\int_0^\infty \int_0^\pi \int_0^{2\pi} \psi \psi^* r^2 dr \cdot \sin \theta d\theta d\varphi = 1,$$

where

$$\psi \psi^* = \psi_1 \psi_1^* + \psi_2 \psi_2^* + \psi_3 \psi_3^* + \psi_4 \psi_4^*.$$

Suppose first that $j = l + \frac{1}{2}$. Then we find from Eq. (9a) that

$$\begin{aligned} \psi \psi^* = M_\theta^2 [F_l F_l^* \{ P_{l+1}^u P_{l+1}^{*u} + P_{l+1}^{u+1} P_{l+1}^{*u+1} \} + G_l G_l^* \{ (l+u+1)^2 P_l^u P_l^{*u} \\ + (l-u)^2 P_l^{u+1} P_l^{*u+1} \}] \end{aligned} \quad (25)$$

or

$$\psi \psi^* = M_\theta^2 [F_l F_l^* + G_l G_l^*] [P_{l+1}^u P_{l+1}^{*u} + P_{l+1}^{u+1} P_{l+1}^{*u+1}],$$

as may be readily demonstrated.¹⁷

From the known relation

$$\int_0^\pi \int_0^{2\pi} P_l^u P_l^{*u} \sin \theta d\theta d\varphi = \frac{4\pi}{2l+1} (l+u)!(l-u)! \quad (26)$$

we find

$$M_\theta^2 \left(l, l + \frac{1}{2}, u \right) = \frac{1}{4\pi(l+u+1)!(l-u)!}. \quad (27)$$

The integral

$$I = \int_0^\infty [F_l F_l^* + G_l G_l^*] r^2 dr$$

can be evaluated as follows: one can easily show, by use of the generating function for the Laguerre polynomials,¹⁸ that

$$\sum_{s=0}^\infty \binom{s+l}{s} {}_1F_1(-s; l+1; x) t^s = \frac{e^{-\frac{xt}{1-t}}}{(1-t)^{l+1}}; l \text{ arbitrary.} \quad (28)$$

¹⁷ Cf. e.g., D. R. Hartree, Proc. Camb. Phil. Soc. 25, 225 (1929).

¹⁸ Courant and Hilbert, "Methoden der math. Physik," p. 78.

Hence

$$\begin{aligned} \sum_{r,s=0}^{\infty} \binom{r+2\rho}{r} \binom{s+2\rho}{s} \int_0^{\infty} x^{2\rho} e^{-x} {}_1F_1(-r; 2\rho+1; x) {}_1F_1(-s; 2\rho+1; x) dx \cdot t^s \tau^r \\ = \int_0^{\infty} x^{2\rho} e^{-x} \frac{e^{-xt/(1-t)-x\tau/(1-\tau)}}{(1-t)^{2\rho+1}(1-\tau)^{2\rho+1}} dx \\ = \frac{\Gamma(2\rho+1)}{(1-t\tau)^{2\rho+1}} = \Gamma(2\rho+1) \sum_{s=0}^{\infty} \binom{s+2\rho}{s} (t\tau)^s. \end{aligned}$$

Therefore

$$\int_0^{\infty} x^{2\rho} e^{-x} {}_1F_1(-r; 2\rho+1; x) {}_1F_1(-s; 2\rho+1; x) dx = \frac{\Gamma(2\rho+1)}{\binom{s+2\rho}{s}} \delta_{rs}. \quad (29)$$

Thus from Eq. (13)

$$\begin{aligned} \int_0^{\infty} \sigma_1^2 r^2 dr &= \frac{\Gamma(2\rho_l+1)(N_l+l+1)^2}{(2k_0)^{2\rho_l+1} \binom{n_r+2\rho_l}{n_r}} \\ \int_0^{\infty} \sigma_2^2 r^2 dr &= \frac{\Gamma(2\rho_l+1)n_r^2}{(2k_0)^{2\rho_l+1} \binom{n_r-1+2\rho_l}{n_r-1}} \\ \int_0^{\infty} \sigma_1 \sigma_2 r^2 dr &= 0. \end{aligned}$$

Since from Eq. (12)

$$I = \frac{2M_r^2}{N_l + \rho_l + n_r} \int_0^{\infty} [N_l(\sigma_1^2 + \sigma_2^2) + 2\sigma_1\sigma_2(\rho_l + n_r)] r^2 dr,$$

we obtain

$$M_r^2 \left(n_r, l, l + \frac{1}{2} \right) = \frac{(N_l + \rho_l + n_r)(2k_0)^{2\rho_l+1} \Gamma(2\rho_l + n_r + 1)}{n_r! 2N_l [\Gamma(2\rho_l + 1)]^2 [(N_l + l + 1)^2 + n_r(n_r + 2\rho_l)]}. \quad (30)$$

Now let $j = l - \frac{1}{2}$. Then from (9b) we find

$$\psi\psi^* = M_\theta^2 [F_{-l-1} F_{-l-1}^* + G_{-l-1} G_{-l-1}^*] [P_l^u P_l^{*u} + P_l^{u+1} P_l^{*u+1}], \quad (31)$$

and obtain in an exactly similar manner

$$M_\theta^2 \left(l, l - \frac{1}{2}, u \right) = \frac{1}{4\pi(l+u)!(l-u-1)!} \quad (32)$$

and

$$M_r^2 \left(n_r, l, l - \frac{1}{2} \right) = \frac{(N + \rho + n_r)(2k_0)^{2\rho+1} \Gamma(2\rho + n_r + 1)}{n_r! 2N [\Gamma(2\rho + 1)]^2 [(N - l)^2 + n_r(n_r + 2\rho)]} \quad (33)$$

where in Eq. (33) the argument of N and ρ is not l , but $-l-1$. This change of argument occurs whenever $j = l - \frac{1}{2}$.

CONTINUOUS SPECTRUM

The angular normalizing factors are the same as for the discrete spectrum.

We first obtain an asymptotic expansion for the radial solutions, since we must here use a special normalizing method because the solutions are not quadratically integrable.

The asymptotic expansion of ${}_1F_1(\alpha; \beta; x)$ is given by¹⁹

$${}_1F_1(\alpha; \beta; x) \sim \frac{\Gamma(\beta)}{\Gamma(\alpha)} e^{x\alpha-\beta} + \frac{\Gamma(\beta)}{\Gamma(\beta-\alpha)} (-x)^{-\alpha}. \quad (34)$$

Using Eqs. (34) and (21), we find, omitting the prime on k_0 ,

$$\begin{aligned} \sigma_1 &\sim \frac{A\Gamma(2\rho_l+1)(i)^{iq-\rho_l}}{\Gamma(\rho_l+iq+1)(2k_0)^p} \frac{e^{i(k_0r+q\log 2k_0r)}}{r} \\ \sigma_2 &\sim \frac{B\Gamma(2\rho_l+1)(-i)^{-iq-\rho_l}}{\Gamma(\rho_l-iq+1)(2k_0)^p} \frac{e^{-i(k_0r+q\log 2k_0r)}}{r}. \end{aligned} \quad (35)$$

Therefore, from Eq. (20)

$$\begin{aligned} G_l &\sim M_r C \frac{\cos(k_0r + q\log k_0r - \delta_l)}{r} \\ F_l &\sim M_r C D \frac{\sin(k_0r + q\log k_0r - \delta_l)}{r} \end{aligned} \quad (36)$$

in which

$$\delta_l = \rho_l \frac{\pi}{2} + \arg \Gamma(\rho_l + iq + 1) - \beta_0 - q \log 2. \quad (37)$$

$$e^{2i\beta_0} = A/B \quad (37')$$

$$C = \frac{2\Gamma(2\rho_l+1)e^{-q\pi/2}|A|}{(2k_0)^p|\Gamma(\rho_l+iq+1)|} \cdot \left(\frac{A}{B^*}\right)^{1/2}. \quad (38)$$

$$D = \left[\frac{\frac{W}{mc^2} - 1}{\frac{W}{mc^2} + 1} \right]^{1/2} = \left(\frac{q-Q}{q+Q} \right)^{1/2}. \quad (38')$$

We shall use the Weyl normalization method.²⁰

Call the radial normalization factor $M_r(W, l, j) = M(W)$. Then with proper choice of $M(W)$

$$\begin{aligned} I &= \int_0^\infty M^*(W') r^2 dr \int_{W_1}^{W_2} M(W) [F_l(W)F_l^*(W') + G_l(W)G_l^*(W')] dW \\ &= \begin{cases} 1 & \text{when } W_1 < W' < W_2, \\ 0 & \text{when } W' \text{ lies outside the interval } (W_1, W_2). \end{cases} \end{aligned} \quad (39)$$

¹⁹ E. W. Barnes, Trans. Camb. Phil. Soc. 20, 253 (1906).

²⁰ H. Weyl, Math. Ann. 68, 220 (1910).

If we write down Eqs. (11) for the energy value W , and their complex conjugates for the energy value W' , multiply each of the resulting equations by r^2 , then multiply the first equation for W by $F^*(W')$, the second by $-G^*(W')$, the first for W' by $-F(W)$, and the second by $G(W)$, and finally add, we obtain the equation

$$\frac{2\pi}{hc} \cdot (W - W') r^2 [F(W)F^*(W') + G(W)G^*(W')] = \frac{\partial}{\partial r} r^2 [G^*(W')F(W) - G(W)F^*(W')]. \quad (40)$$

Substituting Eq. (40) in Eq. (39), we get

$$I = \int_0^\infty M^*(W') dr \int_{W_1}^{W_2} \frac{hc}{2\pi} \frac{M(W)}{W' - W} \frac{\partial}{\partial r} [r^2 G(W)F^*(W') - G^*(W')F(W)] dW \\ = \lim_{R \rightarrow \infty} \frac{hc}{2\pi} M^*(W') \int_{W_1}^{W_2} \frac{M(W)}{W' - W} R^2 [G(W, R)F^*(W', R) - G^*(W', R)F(W, R)] dW$$

since $r^2 GF = 0$ when $r = 0$.

We may therefore use our asymptotic expansions for F and G . From Eq. (36) we can write

$$I = \lim_{R \rightarrow \infty} \frac{hc}{2\pi} M^*(W') C^*(W') \int_{W_1}^{W_2} \frac{M(W)}{W' - W} [C(W)D(W') \cos Ru \cdot \sin Ru' - C(W)D(W) \sin Ru \cdot \cos Ru'] dW,$$

where

$$Ru = k_0 R + q \log k_0 R - \delta_l,$$

or

$$u(W) = \frac{2\pi mc}{h} \cdot \left(\left(\frac{W}{mc^2} \right)^2 - 1 \right)^{1/2} + \frac{\alpha}{\left(1 - \left(\frac{mc^2}{W} \right)^2 \right)^{1/2}} \frac{1}{R} \log \frac{2\pi mc}{h} R \left(\left(\frac{W}{mc^2} \right)^2 - 1 \right)^{1/2} - \frac{\delta_l}{R}. \quad (41)$$

We can choose R large enough so that $u(W)$ for $W_1 \leq W \leq W_2$ is an increasing function of W , and so can find the inverse function $W = f(u)$, which is continuous and possesses a continuous derivative for $W > mc^2$. We make a simple rearrangement in I and change variables from W to u , obtaining

$$I = \lim_{R \rightarrow \infty} \frac{hc}{2\pi} M^*(W') C^*(W') \int_{u_1}^{u_2} \frac{M[f(u)] C[f(u)]}{f(u') - f(u)} [D[f(u')] \sin R(u' - u) + \{D[f(u')] - D[f(u)]\} \sin Ru \cdot \cos Ru'] f'(u) du, \\ = \lim_{R \rightarrow \infty} \frac{hc}{2\pi} M^*(W') C^*(W') (I_{R'} + I_{R''}).$$

Consider

$$\lim_{R \rightarrow \infty} I_R'' = \lim_{R \rightarrow \infty} \cos Ru' \int_{u_1}^{u_2} M[f(u)] C[f(u)] f'(u) \frac{D[f(u')] - D[f(u)]}{f(u') - f(u)} \sin Ru \cdot du.$$

Now $D'(W)$ exists for $W > mc^2$, and the remaining functions in the integrand are continuous, so that we can apply the well-known result²¹ that

$$\lim_{n \rightarrow \infty} \int_a^b \psi(t) \sin nt \, dt = 0$$

when $\psi(t)$ is integrable in (a, b) . This gives us

$$\lim_{R \rightarrow \infty} I_R'' = 0.$$

By the same argument we can show that $\lim_{R \rightarrow \infty} I_R' = 0$ when W' is not in the interval (W_1, W_2) . When $W_1 < W' < W_2$, we can write, putting $u' - u = y$,

$$\begin{aligned} I_R' &= D(W') \int_{u'-u_1}^{u'-u_2} M[f(u' - y)] C[f(u' - y)] f'(u' - y) \frac{\sin Ry}{f(u' - y) - f(u')} dy \\ &= D(W') \int_{u'-u_2}^{u'-u_1} M[f(u' - y)] C[f(u' - y)] \frac{\sin Ry}{y} dy \frac{f'(u' - y)}{f'(u')} \\ &+ D(W') \int_{u'-u_1}^{u'-u_2} M[f(u' - y)] C[f(u' - y)] f'(u' - y) \left[\frac{1}{f(u' - y) - f(u')} \right. \\ &\quad \left. - \frac{1}{f'(u')y} \right] \sin Ry \cdot dy = I_R''' + I_R^{IV}. \end{aligned}$$

Since the function in the square brackets in I_R^{IV} is finite at $y = 0$, the same argument as above shows that $\lim_{R \rightarrow \infty} I_R^{IV} = 0$. Further,

$$\lim_{R \rightarrow \infty} I_R''' = D(W') M(W') C(W') \pi$$

by the Dirichlet integral.²²

Finally, therefore,

$$I = \frac{1}{2} hc |M(W')|^2 |C(W')|^2 D(W'),$$

and we must take

$$M_r^2(W, l, l + \frac{1}{2}) = 2/hcD |C|^2. \quad (42)$$

Since the above calculation has not made use of a particular value for j , we have also

$$M_r^2(W, l, l - \frac{1}{2}) = 2/hcD |C|^2, \quad (43)$$

where in Eq. (43) the argument of ρ and A is $-l-1$, not l .

²¹ See K. Knopp, *Unendliche Reihen*, p. 363.

²² Knopp, reference 21, p. 366.

SELECTION RULES

The selection rules for the matrix elements B^s in Eq. (4'), when retardation is neglected, have been shown by Darwin¹⁴ to be

$$\begin{aligned}\Delta l &= 1, \\ \Delta j &= 0, \pm 1, \\ \Delta u &= 0, \pm 1.\end{aligned}\tag{44}$$

The table below gives the possible transitions:

Initial State				Initial State			
n_r	l	$l + \frac{1}{2}$	u	n_r	l	$l - \frac{1}{2}$	u
Final State				Final State			
n_r'	$l + 1$	$l + 3/2$	u'	n_r'	$l + 1$	$l + \frac{1}{2}$	u'
n_r'	$l + 1$	$l + \frac{1}{2}$	u'	n_r'	$l - 1$	$l - \frac{1}{2}$	u'
n_r'	$l - 1$	$l - \frac{1}{2}$	u'	n_r'	$l - 1$	$l - 3/2$	u'

(45)

with $u' = u, u \pm 1$, and arbitrary n_r' . The only degeneracy of the possible final states of the discrete spectrum is that with respect to u' . If n_r' stands for the energy W of a state in the continuous spectrum, all possible final states having this value W fall together.

THE MASS ABSORPTION COEFFICIENT OF THE K SHELL

The atomic absorption coefficient τ_ν for a given energy jump is defined as follows:

$$\tau_\nu I(\nu) d\nu = \text{energy absorbed per second} = h\nu \cdot w' dW' \tag{46}$$

where $w' dW'$ ($= w' d\epsilon''$ of Eq. (8)) is the transition probability for the energy jump under consideration, and $I(\nu) d\nu$ is the intensity of the incident radiation in the range $d\nu$. Thus

$$(\tau_\nu)_K I(\nu) d\nu = h\nu \cdot w'(W; 0, 0, \frac{1}{2}) dW',$$

since in the K shell $n_r = l = 0$, and $j = \frac{1}{2}$.

The formula for the mass absorption coefficient $(\tau_\nu/\rho)_K$ ²³ becomes, since $dW = h \cdot d\nu$,

$$\left(\frac{\tau_\nu}{\rho}\right)_K = \frac{N h^2 \nu}{A I(\nu)} w' \left(W; 0, 0, \frac{1}{2}\right) = \frac{N h^2 \nu}{A 8 \pi c \rho(\nu)} w' \left(W; 0, 0, \frac{1}{2}\right), \tag{47}$$

where N is Avogadro's number, A is the atomic weight, and $\rho(\nu)$ is defined in connection with Eq. (5).

²³ The ρ in τ_ν/ρ is not to be confused with $\rho(\nu)$. The former is the mass of an atom, while the latter is energy density.

Consulting the table (45) of possible transitions, we see that the sum over the degenerate states in Eq. (8) extends over the initial values of u , the final values u' , and $j = \frac{1}{2}, 3/2$, the only possible final l being 1. We thus obtain

$$\left(\frac{\tau_\nu}{\rho}\right)_K = \frac{2\pi e^2 c N}{3A\nu} \left[\sum_{u,u'} \left| P\left(W, 1, \frac{3}{2}, u'; 0, 0, \frac{1}{2}, u\right) \right|^2 + \sum_{u,u'} \left| P\left(W, 1, \frac{1}{2}, u'; 0, 0, \frac{1}{2}, u\right) \right|^2 \right]. \quad (48)$$

Carrying out the angular integrations indicated by the definitions (8') and (4') of the P 's, and using the angular normalizing factors given by Eqs. (27) and (32), and finally summing over u and u' , we easily obtain

$$\left(\frac{\tau_\nu}{\rho}\right)_K = \frac{4\pi e^2 c N}{3A\nu} \left[\frac{8}{3} \left| \int_0^\infty F_0 G_1 r^2 dr \right|^2 + 3 \left| \int_0^\infty F_{-2} G_0 r^2 dr + \frac{1}{3} \int_0^\infty F_0 G_{-2} r^2 dr \right|^2 \right]. \quad (49)$$

Writing $\rho = (1 - \alpha^2)^{1/2}$, $\rho' = (4 - \alpha^2)^{1/2}$, $a = k_0'/k_0$, and taking

$$A = \frac{((l+1)^2 + Q^2)^{1/2}}{Q} e^{i \tan^{-1} Q/(l+1)}$$

$$B = \frac{((l+1)^2 + Q^2)^{1/2}}{Q} e^{-i \tan^{-1} Q/\rho'}$$
(50)

we find for the functions F_0 , G_0 , G_1 , G_{-2} , and F_{-2} , using Eqs. (12), (13), (20), (21), (30), (42), (43), (38), and (38'),

$$F_0 = (2k_0)^\rho \left(\frac{(1-\rho)k_0}{\Gamma(2\rho+1)} \right)^{1/2} r^{\rho-1} e^{-k_0 r}. \quad (51)$$

$$G_0 = (2k_0)^\rho \left(\frac{(1+\rho)k_0}{\Gamma(2\rho+1)} \right)^{1/2} r^{\rho-1} e^{-k_0 r} \quad (52)$$

$$G_1 = \frac{(2ak_0)^\rho |\Gamma(\rho' + iq + 1)| e^{q\pi/2}}{2\Gamma(2\rho' + 1)} \left(\frac{2}{hc}\right)^{1/2} \left(\frac{q-Q}{q+Q}\right)^{-1/4} \cdot [e^{i[\tan^{-1} Q/2 - ak_0 r]} r^{\rho'-1} {}_1F_1(\rho' + iq + 1; 2\rho' + 1; 2iak_0 r) + e^{-i[\tan^{-1} Q/\rho' + ak_0 r]} r^{\rho'-1} {}_1F_1(\rho' + iq; 2\rho' + 1; 2iak_0 r)]. \quad (53)$$

$$G_{-2} = \frac{(2ak_0)^\rho |\Gamma(\rho + iq + 1)| e^{q\pi/2}}{2\Gamma(2\rho + 1)} \left(\frac{2}{hc}\right)^{1/2} \left(\frac{q-Q}{q+Q}\right)^{-1/4} \cdot [e^{i[\tan^{-1} Q/\rho - ak_0 r]} r^{\rho-1} {}_1F_1(\rho + iq + 1; 2\rho + 1; 2iak_0 r) + e^{-i[\tan^{-1} Q/\rho' + ak_0 r]} r^{\rho-1} {}_1F_1(\rho + iq; 2\rho + 1; 2iak_0 r)]. \quad (54)$$

$$F_{-2} = \frac{(2ak_0)^\rho |\Gamma(\rho + iq + 1)| e^{q\pi/2}}{i2\Gamma(2\rho + 1)} \left(\frac{2}{hc}\right)^{1/2} \left(\frac{q-Q}{q+Q}\right)^{1/4}.$$

$$\cdot [e^{i[\tan^{-1}Q/-1-ak_0r]}r^{\rho-1}{}_1F_1(\rho + iq + 1; 2\rho + 1; 2iak_0r) \quad (55)$$

$$- e^{-i[\tan^{-1}q/\rho+ak_0r]}r^{\rho-1}{}_1F_1(\rho + iq; 2\rho + 1; 2iak_0r)].$$

Integrating and rearranging, we obtain

$$\int_0^\infty F_0 G_1 r^2 dr = 2^{\rho'+\rho} a^{\rho'} \cdot \left(\frac{1-\rho}{2hck_0\Gamma(2\rho+1)} \right)^{1/2} \frac{|\Gamma(\rho'+iq+1)| e^{q\pi/2}}{(1-ia)^{\rho'+\rho+1}} \left(\frac{q-Q}{q+Q} \right)^{-1/4} \cdot$$

$$\frac{\Gamma(\rho'+\rho+1)}{\Gamma(2\rho'+1)} \cdot \left[e^{-i\tan^{-1}Q/2} {}_2F_1 \left(\rho'+\rho+1, \rho'-iq+1; 2\rho'+1; -\frac{2ia}{1-ia} \right) \quad (56)$$

$$+ e^{i\tan^{-1}q/\rho'} {}_2F_1 \left(\rho'+\rho+1, \rho'-iq; 2\rho'+1; -\frac{2ia}{1-ia} \right) \right].$$

$$\int_0^\infty F_0 G_{-2} r^2 dr = 2^{2\rho} a^\rho \cdot \left(\frac{1-\rho}{2hck_0\Gamma(2\rho+1)} \right)^{1/2} \frac{|\Gamma(\rho+iq+1)| e^{q\pi/2}}{(1-ia)^{2\rho+1}} \left(\frac{q-Q}{q+Q} \right)^{-1/4} \cdot$$

$$\cdot \left[e^{i\tan^{-1}Q/-1} {}_2F_1 \left(2\rho+1, \rho-iq+1; 2\rho+1; -\frac{2ia}{1-ia} \right) \quad (57)$$

$$+ e^{i\tan^{-1}q/\rho} {}_2F_1 \left(2\rho+1, \rho-iq; 2\rho+1; -\frac{2ia}{1-ia} \right) \right].$$

$$\int_0^\infty F_{-2} G_0 r^2 dr = i2^{2\rho} a^\rho \cdot \left(\frac{1+\rho}{2hck_0\Gamma(2\rho+1)} \right)^{1/2} \frac{|\Gamma(\rho+iq+1)| e^{q\pi/2}}{(1-ia)^{2\rho+1}} \left(\frac{q-Q}{q+Q} \right)^{1/4} \cdot$$

$$\cdot \left[e^{-i\tan^{-1}Q/-1} {}_2F_1 \left(2\rho+1, \rho-iq+1; 2\rho+1; -\frac{2ia}{1-ia} \right) \quad (58)$$

$$- e^{i\tan^{-1}q/\rho} {}_2F_1 \left(2\rho+1, \rho-iq; 2\rho+1; -\frac{2ia}{1-ia} \right) \right].$$

The two hypergeometric functions in (56) cannot be readily evaluated in their present form because of very slow convergence or non-convergence of the usual series. There are two possible methods of evaluating them numerically. One method is to express them as definite integrals and then to integrate numerically. Because $\rho'-\rho-1$ is so small, the numerical integration will be inaccurate or laborious if no further transformation of the resulting integrals is made. A convenient transformation which is satisfactory over the range of values of a and q which corresponds to $\frac{1}{2}\lambda_k \leq \lambda \leq \lambda_k$, is that which results in the integral J defined by Eq. (62) below.

Using the relationship

$${}_2F_1(\alpha, \beta; \gamma; x) = \frac{\Gamma(\gamma)}{\Gamma(\alpha)\Gamma(\gamma-\alpha)} \int_0^1 u^{\alpha-1} (1-u)^{\gamma-\alpha-1} (1-ux)^{-\beta} du, \quad (59)$$

and making some simple transformations, we can write

$$\begin{aligned}
 {}_2F_1\left(\rho' + \rho + 1, \rho' - iq + 1; 2\rho' + 1; -\frac{2ia}{1 - ia}\right) \\
 = \left(\frac{1 + ia}{1 - ia}\right)^{iq - \rho - 1} \left\{1 + \frac{J^*}{B(\rho' - \rho, \rho' + \rho + 1)}\right\} \quad (60)
 \end{aligned}$$

$$\begin{aligned}
 {}_2F_1\left(\rho' + \rho + 1, \rho' - iq; 2\rho' + 1; -\frac{2ia}{1 - ia}\right) \\
 = \left(\frac{1 + ia}{1 - ia}\right)^{iq - \rho'} \left\{1 + \frac{J}{B(\rho' - \rho, \rho' + \rho + 1)}\right\} \quad (61)
 \end{aligned}$$

where

$$J = \int_{-1/2}^{+1/2} \left(\frac{1}{2} - t\right)^{\rho' + \rho} \left(\frac{1}{2} + t\right)^{\rho' - \rho - 1} dt \left[\left(\frac{1 + ia}{1 - 2iat}\right)^{\rho' - iq} - 1 \right] \quad (62)$$

and

$$B(\alpha, \beta) = \frac{\Gamma(\alpha)\Gamma(\beta)}{\Gamma(\alpha + \beta)} \quad (63)$$

The other method of evaluating the hypergeometric functions in Eq. (56) is to transform them to another combination of hypergeometric functions which do converge fairly rapidly. By use of the transformation²⁴ connecting Y_1 with Y_3 and Y_4 one finds readily from Eq. (60) that

$$\begin{aligned}
 B(\rho' - \rho, \rho' + \rho + 1) + J &= \frac{(1 + a^2)^{\rho'}}{(2a)^{2\rho'}} e^{i\rho'\pi} \left[B(\rho - iq, \rho' - \rho) \left(\frac{1 - ia}{1 + ia}\right)^\rho \right. \\
 &\quad \cdot {}_2F_1\left(-\rho' - \rho, 1 + iq - \rho'; 1 + iq - \rho; \frac{1 + ia}{1 - ia}\right) \\
 &\quad + B(-\rho + iq, \rho' + \rho + 1) \left(\frac{1 - ia}{1 + ia}\right)^{iq} \\
 &\quad \cdot {}_2F_1\left(1 + \rho - \rho', -\rho' - iq; \rho - iq + 1; \frac{1 + ia}{1 - ia}\right) \left. \right] \quad (64)
 \end{aligned}$$

The series for the hypergeometric functions in Eq. (64) converge fairly rapidly for any range of wave-length. The chief difficulty in the use of this formula is the calculation of the gamma functions. High accuracy can be obtained from this formula with less work than from numerical integration, but for three-figure accuracy the latter is much quicker. All the calculations in this paper were performed by numerical integration.

The hypergeometric functions occurring in Eqs. (57) and (58) can be reduced to elementary functions by the use of the relation

$${}_2F_1(\alpha, \beta; \alpha; x) = (1 - x)^{-\beta} \quad (65)$$

²⁴ E. W. Barnes, Proc. Lond. Math. Soc. (2), 6, 141 (1908).

Making these transformations and noting that $Q=1/a$, we obtain for the three integrals

$$\int_0^\infty F_0 G_1 r^2 dr = 2^{\rho'+\rho} a^{\rho'} \left(\frac{1-\rho}{2hc k_0 \Gamma(2\rho+1)} \right)^{1/2} \frac{|\Gamma(\rho'+iq+1)| e^{q(\pi/2-2\tan^{-1}a)}}{\Gamma(\rho'-\rho)(1+a^2)^{(\rho'+\rho+1)/2}} \left(\frac{q-Q}{q+Q} \right)^{-1/4} \cdot [e^{-i[\tan^{-1}Q/2-(\rho'-\rho-1)\tan^{-1}a]} \cdot \{B(\rho'-\rho, \rho'+\rho+1) + J^*\} + e^{i[\tan^{-1}q/\rho'-(\rho'-\rho-1)\tan^{-1}a]} \cdot \{B(\rho'-\rho, \rho'+\rho+1) + J\}]. \quad (66)$$

$$\int_0^\infty F_0 G_{-2} r^2 dr = 2^{2\rho} a^\rho \cdot \left(\frac{1-\rho}{2hc k_0 \Gamma(2\rho+1)} \right)^{1/2} \frac{|\Gamma(\rho+iq+1)| e^{q(\pi/2-2\tan^{-1}a)}}{(1+a^2)^{\rho+1/2}} \left(\frac{q-Q}{q+Q} \right)^{-1/4} \cdot [ie^{-2i\tan^{-1}a} + e^{i[\tan^{-1}q/\rho+\tan^{-1}a]}] \quad (67)$$

$$\int_0^\infty F_{-2} G_0 r^2 dr = 2^{2\rho} a^\rho \cdot \left(\frac{1+\rho}{2hc k_0 \Gamma(2\rho+1)} \right)^{1/2} \frac{|\Gamma(\rho+iq+1)| e^{q(\pi/2-2\tan^{-1}a)}}{(1+a^2)^{\rho+1/2}} \left(\frac{q-Q}{q+Q} \right)^{1/4} \cdot [e^{-2i\tan^{-1}a} - ie^{i[\tan^{-1}q/\rho+\tan^{-1}a]}]. \quad (68)$$

Substituting in Eq. (49) we obtain finally for the mass absorption coefficient for the K shell

$$\left(\frac{\tau_\nu}{\rho} \right)_K = \frac{\dot{N}}{AZ} \frac{h\lambda}{3\pi m c} \frac{2^{2\rho} e^{q(\pi-4\tan^{-1}a)}}{\Gamma(2\rho+1)(1+a^2)^{\rho+1}} \left[\frac{8}{3} \frac{(2a)^{2\rho'}(1-\rho)}{(1+a^2)^{\rho'}} \cdot \frac{|\Gamma(\rho'+iq+1)|^2}{[\Gamma(\rho'-\rho)]^2} \left(\frac{q-Q}{q+Q} \right)^{-1/2} |B(\rho'-\rho, \rho'+\rho+1) + J|^2 (1+\cos\phi) + 3 \frac{(2a)^{2\rho}}{(1+a^2)^\rho} \left\{ (1+\rho) \left(\frac{q-Q}{q+Q} \right)^{1/2} (1+\sin\delta) + \frac{1-\rho}{9} \left(\frac{q-Q}{q+Q} \right)^{-1/2} (1-\sin\delta) + \frac{2}{3} (1-\rho^2)^{1/2} \cdot \cos\delta \right\} \right]. \quad (69)$$

in which

$$\phi = \tan^{-1} \frac{1}{2}Q + \tan^{-1}q/\rho' - 2(\rho'-\rho-1)\tan^{-1}a + 2\tan^{-1}\chi.$$

$$\chi = \arg [B(\rho'-\rho, \rho'+\rho+1) + J]$$

$$\delta = 3\tan^{-1}a + \tan^{-1}q/\rho$$

$$a^2 = x \frac{2+xy}{2-y}; \quad Q = \frac{1}{a}; \quad q^2 = Q^2 + \alpha^2; \quad \alpha^2 = y(2-y);$$

$$x = \lambda_k/\lambda - 1; \text{ and } y = h/mc\lambda_k.$$

The two expressions in Eq. (69) which are most difficult to calculate are the absolute value of the gamma function of complex argument, and the

integral J . The gamma function can be most conveniently calculated from the asymptotic expansion

$$\log |\Gamma(x + iy)| \sim \frac{1}{2}(x - \frac{1}{2}) \log(x^2 + y^2) - y \tan^{-1} y/x - x + \frac{1}{2} \log 2\pi + \sum_{n=1}^{\infty} \frac{B_{2n}}{2n(2n-1)} \frac{\cos[(2n-1) \tan^{-1} y/x]}{(x^2 + y^2)^{n-1/2}}. \quad (70)$$

where the B_{2n} are the well-known Bernoulli numbers. By taking x large and using the difference equation satisfied by the gamma function, Eq. (70) forms a relatively easy method of calculation.

Under adverse circumstances, the calculation of the integral J could be very laborious. Fortunately, when the wave-length is confined to the range $\frac{1}{2}\lambda_k$ to λ_k , the integrand of Eq. (62) does not change rapidly and has no important oscillations, so that an approximate formula of integration may be expected to give sufficient accuracy. The formula used is one given by Woolhouse,²⁵ namely,

$$\int_0^1 f(x) dx = \frac{7}{390}[f(0) + f(1)] + \frac{16,807}{133,380}[f(1/14) + f(13/14)] + \frac{128}{570}[f(1/4) + f(3/4)] + \frac{71}{270}f(\frac{1}{2}). \quad (71)$$

It would be very difficult to obtain a numerical value for the error involved in using this formula when evaluating an integral as complicated as J . However, the writer has tried the formula in evaluating known integrals of functions which have closely the same shape as the actual integrand in J , and from these trials he is convinced that in the wave-length range mentioned above at least three- and very probably four-figure accuracy can be expected. This is further supported by the close agreement of the results for Al ($Z=13$) with those calculated from the Nishina-Rabi formula, an entirely independent procedure. The effect on the absorption coefficient of an error in calculating J depends of course upon the relative magnitude of the two parts of Eq. (69). In the range under consideration the term containing J is from 2 to 3 times as large as the other term.

MASS ABSORPTION COEFFICIENT AT THE ABSORPTION EDGE

At the absorption edge, where $\lambda = \lambda_k$, Eq. (69) cannot be used to calculate the absorption coefficient because there $a=0$ and $q=Q=\infty$. A limiting process is necessary, and it is most convenient to pass to the limit for the individual proper functions and then to integrate, instead of passing to the limit directly in Eq. (69). Another more simple method if only the form of the proper functions is necessary, is to solve the radial differential Eqs. (11) when $W=mc^2$, but this has the disadvantage for our purpose of requiring another normalization using Weyl's method.

²⁵ Woolhouse, Journ. Inst. Act. 27, 122, (1888). Cf. Whittaker and Robinson, "Calculus of Observations," p. 158.

We want to find $\lim_{a \rightarrow 0} F_l$ and $\lim_{a \rightarrow 0} G_l$. To do this we consider separately the radial normalizing factor and the functions σ_1 and σ_2 (see Eq. 21)). From the well-known Stirling formula, we can write²⁶

$$|\Gamma(\rho' + iq + 1)| \sim (2\pi)^{1/2} a^{-\rho'-1/2} e^{-q\pi/2},$$

also

$$|A| \sim 1, \quad \text{and} \quad (2k_0')^{\rho'} = (2k_0)^{\rho'} a^{\rho'},$$

so that from Eq. (38)

$$|C| \sim 2\Gamma(2\rho' + 1)(2k_0)^{-\rho'} (a/2\pi)^{1/2} \quad (72)$$

Also, from Eq. (38'),

$$D = \left(\frac{q - Q}{q + Q} \right)^{1/2} = \left(\frac{(1 + a^2\alpha^2)^{1/2} - 1}{(1 + a^2\alpha^2)^{1/2} + 1} \right)^{1/2} \sim \frac{1}{2} a\alpha \quad (73)$$

since $q^2 = Q^2 + \alpha^2 = 1/a^2 + \alpha^2$. Therefore, from Eq. (42),

$$M_r = \frac{1}{|C|} \left(\frac{2}{hcD} \right)^{1/2} \sim \left(\frac{2\pi}{hc\alpha} \right)^{1/2} \frac{(2k_0)^{\rho'}}{\Gamma(2\rho' + 1)} \frac{1}{a} = \frac{(2k_0)^{\rho'}}{e(Z)^{1/2} \Gamma(2\rho' + 1)} \frac{1}{a}, \quad (74)$$

using Eq. (19).

It is a known property²⁷ of the degenerate hypergeometric function that

$$\lim_{\epsilon \rightarrow \infty} \frac{(\frac{1}{2}z)^\alpha}{\Gamma(\alpha + 1)} {}_1F_1 \left(\frac{1}{\epsilon}; \alpha + 1; -\epsilon z^2/4 \right) = J_\alpha(z), \quad (75)$$

where $J_\alpha(z)$ is the ordinary Bessel function. It is evident, therefore, that

$$\begin{aligned} \lim_{a \rightarrow 0} \sigma_2 &= \lim_{a \rightarrow 0} B r^{\rho'-1} e^{-ia k_0 r} {}_1F_1(\rho' + iq; 2\rho' + 1; 2iak_0 r) \\ &= -i\Gamma(2\rho' + 1)(2k_0)^{-\rho'} r^{-1} J_{2\rho'}((8k_0 r)^{1/2}). \end{aligned} \quad (76)$$

It can easily be shown that

$$\begin{aligned} {}_1F_1(\rho' + iq + 1; 2\rho' + 1; 2ik_0' r) &= \frac{2\rho'}{\rho' + iq} {}_1F_1(\rho' + iq; 2\rho'; 2ik_0' r) \\ &\quad - \frac{\rho' - iq}{\rho' + iq} {}_1F_1(\rho' + iq; 2\rho' + 1; 2ik_0' r). \end{aligned} \quad (77)$$

With Eqs. (77) and (21), we find

$$\begin{aligned} \sigma_1 \pm \sigma_2 &= r^{\rho'-1} e^{-ik_0' r} \left[A \frac{2\rho'}{\rho' + iq} {}_1F_1(\rho' + iq; 2\rho'; 2ik_0' r) \right. \\ &\quad \left. + \left[\pm B - A \frac{\rho' - iq}{\rho' + iq} \right] {}_1F_1(\rho' + iq; 2\rho' + 1; 2ik_0' r) \right]. \end{aligned} \quad (78)$$

²⁶ The symbol \sim , as used in this section, has the following significance. if $f(a) \sim g(a)$ then $\lim_{a \rightarrow 0} f(a)/g(a) = 1$.

²⁷ G. N. Watson, "Bessel Functions," p. 154.

From Eqs. (78), (76), and (50), we find after some calculation

$$(\sigma_1 + \sigma_2) \sim a \cdot r^{-1} \Gamma(2\rho' + 1) (2k_0)^{-\rho'} [J_{2\rho'-1}((8k_0r)^{1/2}) \cdot (2k_0r)^{1/2} + (l + 1 - \rho') J_{2\rho'}((8k_0r)^{1/2})],$$

$$\lim_{a \rightarrow 0} (\sigma_1 - \sigma_2) = 2ir^{-1} \Gamma(2\rho' + 1) (2k_0)^{-\rho'} J_{2\rho'}((8k_0r)^{1/2}),$$

so that finally, with Eqs. (20) and (74),

$$\lim_{a \rightarrow 0} F_l = \alpha / e(Z)^{1/2} r \cdot J_{2\rho'}((8k_0r)^{1/2}) \quad (79)$$

$$\lim_{a \rightarrow 0} G_l = 1/e(Z)^{1/2} r \cdot [(2k_0r)^{1/2} J_{2\rho'-1}((8k_0r)^{1/2}) + (l+1 - \rho') J_{2\rho'}((8k_0r)^{1/2})]. \quad (80)$$

After some simple calculations, using the formula²⁸

$$\begin{aligned} & \int_0^\infty J_\nu(at) \exp(-p^2 t^2) t^{\mu-1} dt \\ &= \frac{\Gamma\left(\frac{\nu + \mu}{2}\right) \left(\frac{a}{2p}\right)^\nu}{2p^\mu \Gamma(\nu + 1)} \exp(-a^2/4p^2) {}_1F_1\left(\frac{\nu - \mu}{2} + 1; \nu + 1; a^2/4p^2\right), \end{aligned}$$

we find for the mass absorption coefficient at the absorption edge

$$\begin{aligned} \left(\frac{\tau_\nu}{\rho}\right)_{K' \text{ edge}} &= \frac{h^2 N \lambda_k}{3\pi m e^2 \cdot 1} \frac{2^{2\rho} \exp(-4)}{Z^2 \Gamma(2\rho + 1)} \left[\frac{8}{3} 2^{2\rho'} (1 - \rho) \left[\frac{\Gamma(\rho' + \rho + 1)}{\Gamma(2\rho' + 1)} \right]^2 \right. \\ &\quad \cdot [2\rho' {}_1F_1(\rho' - \rho - 1; 2\rho'; 2) + (2 - \rho') {}_1F_1(\rho' - \rho; 2\rho' + 1; 2)]^2 \\ &\quad \left. + 3 \cdot 2^{2\rho} \left[\alpha(1 + \rho)^{1/2} - \frac{3 - \rho}{3} (1 - \rho)^{1/2} \right]^2 \right]. \quad (81) \end{aligned}$$

Eqs. (69) and (81) for the mass absorption coefficient have been derived for a one-electron atom. Actually, of course, the *K* shell contains two electrons, so that one might expect, in the absence of interaction between the electrons, merely to multiply the values for the one-electron atom by two. This is incorrect. In the one-electron atom the lowest energy level is doubly degenerate since there are two possible directions for the "spin" magnetic moment of the electron, represented analytically by $u=0$ or -1 . In the two-electron atom, however, the lowest state is non-degenerate. If the Pauli exclusion principle were not in force, the degeneracy of the lowest state would be four, since in the absence of interaction each electron may have the values $u=0$ or -1 . Since, however, no two electrons may have the same quantum numbers, and because of the identity of the electrons,²⁹ three of the degener-

²⁸ Watson, reference 27, p. 394.

²⁹ W. Heisenberg, *Zeits. f. Physik* 38, 411 (1926).

ate states are ruled out, so that multiplying by two for the two K electrons and dividing by two because there is no degeneracy leaves Eqs. (69) and (81) unchanged.

Since the completion of this paper an article by Stobbe³⁰ has appeared in which the mass absorption coefficient is calculated by means of the non-relativistic quantum mechanics. Stobbe uses a screening constant for the K electrons which is considerably smaller than that necessary to make the energy of the model agree with that experimentally determined from the K edge. He justifies this procedure by pointing out that in the final state with one K electron ejected, the energy of the remaining electrons is different from that in the initial state, so that the absorbed frequency does not correspond exactly to the change in energy of the ejected K electron alone.

The present calculations can easily be adapted to a model with a smaller screening constant by lowering Z to compensate for the decrease in s ; the results then apply to different atoms, for instance to gold (79) instead of lead (82) if s is changed from 4.512 to 1.512. With the smaller screening constant, however, the λ_k' of the model will no longer agree with the experimental value. We want the abscissas of the computed and observed curves to coincide at the experimental λ_k . Now the absorption coefficient depends on a matrix element which is a function of λ_k' and W , the energy of the ejected electron. In the present calculations W was connected with a wave-length λ' of the incident x-rays given by $W = mc^2 + h(\nu' - \nu_k') = mc^2 + hc(1/\lambda' - 1/\lambda_k')$. In the adapted calculations ν_k' is replaced by ν_k corresponding to the actual absorption edge and so W must be connected with a wave-length λ given by $W = mc^2 + hc(1/\lambda - 1/\lambda_k)$. We must now use λ and not λ' in Eq. (47) since the factor multiplying the matrix element in this equation arose originally from the change in energy of the atom as a whole. The new absorption coefficient is therefore

$$\frac{\tau}{\rho}(\lambda) = \frac{\lambda}{\lambda'} \cdot \frac{\tau}{\rho}(\lambda'),$$

where

$$\frac{1}{\lambda} - \frac{1}{\lambda_k} = \frac{1}{\lambda'} - \frac{1}{\lambda_k'}.$$

When one calculates this new absorption it turns out, however, that the agreement with experiment is worse. This does not mean that if one calculated the absorption coefficient for gold using a larger screening constant that one would find better agreement with experiment, but merely that the use of a large screening constant for lead agrees better with experiment than the use of a small one with gold, and is probably to be attributed to the rapid loss of accuracy of the model as Z is decreased.

That the agreement with experiment is worse can be seen roughly from the following considerations. At the absorption edge $\lambda/\lambda' = (Z'/Z)^2$ by Moseley's law, where Z' is the atomic number used in the calculation and Z

³⁰ M. Stobbe, Ann. d. Physik (5), 7, 661 (1930).

that of the atom to which it is now applied. But the observed absorption coefficients are closely in the ratio $(Z'/Z)^3$ at the edge; and the theoretical values are already too low. It is therefore not thought worth while to publish the modified values.

The writer wishes to thank Dr. I. I. Rabi for suggesting this problem, and also to express his appreciation to Professor E. H. Kennard for his constant interest and for the many stimulating discussions throughout the writer's graduate study.

INTERCHANGE OF TRANSLATIONAL, ROTATIONAL
AND VIBRATIONAL ENERGY IN MOLECULAR
COLLISIONS

BY CLARENCE ZENER*

JEFFERSON PHYSICAL LABORATORY

HARVARD UNIVERSITY

(Received January 5, 1931)

ABSTRACT

The change in internal energy of molecules upon collisions has been analysed. Formulae, (26) to (27-C), for the effective cross section of inelastic collisions have been obtained as functions of known properties of the molecules, subject to certain conditions. These conditions are: the atoms which come into contact during collision must belong to the first row of the periodic table; the vibrational quantum numbers which suffer a change must be small.

Vibrational quantum numbers have a marked reluctance to change during collisions at room temperature. The probability that a N_2 molecule in its first excited vibrational state transfer its energy to He in a head on collision is 0.076. The probability that another N_2 molecule absorb this energy is 0.04. A lack of resonance of 0.01 volt can decrease the effective cross section by a factor of 0.02.

Rotational quantum numbers change readily except in unusual cases.

I. INTRODUCTION

IN A gaseous system we often wish to know the effective cross section of a collision between two systems in which one or both suffer a change of quantum numbers. If this change involves electron jumps, as in the quenching of resonance radiation, it is not limited to collisions in which the systems would be said classically to come into contact. Such transitions have been observed to take place when the closest distance of approach is many times the classical diameter of the systems.¹ In this type of collision the changes in the motion of the two systems as a whole may be relatively unimportant in comparison to the change of quantum numbers.

In another interesting type of collision the electronic states remain unaltered, and the vibrational and rotational states are changed. The experimental data have been discussed by Oldenberg.² In many cases the probability of a transfer is very small even in head-on collisions. In such collisions changes in the internal molecular quantum numbers are unimportant in comparison to changes in the motion of the two systems as a whole. A study of the latter change must thus precede a study of the former. Such a procedure is adopted in this paper. The exact motion of the centers of gravity of the two colliding systems is found when the internal coordinates are replaced

by their averaged values. This motion corresponds to an elastic collision. The internal motions of the systems are then treated as perturbations that give rise to changes in the internal quantum numbers during collision.

The discussion of collision phenomena is preceded by an examination of inter-molecular forces (II). The principles of energy interchange may be most clearly analyzed in systems so idealized that all irrelevant difficulties are absent. Thus the interchange of vibrational and translational energy is investigated in the simplified collision of an atom and a diatomic molecule where all motion is confined to a line (III). Similarly the interchange of rotational and translational energy is examined first for the collision of an atom with a rigid symmetrical molecule, all motion being limited to a plane (IV). The results of the investigation of these idealized collisions are then combined in such a way as to give definite numerical information about collisions in an actual gaseous system (V).

II. INTER-MOLECULAR FORCES

In ordinary collisions the inter-molecular forces need be known only for those inter-molecular distances in which the overlapping of electrons is slight. At these collision distances the mutual energy may be split to a good approximation into three parts: that due to van der Waal's attraction, the negative coulomb energy arising from interpenetration of electrons, and the repulsive resonance energy. The mutual energy between two molecules is approximately the sum of the mutual energies between the constituent atoms, provided the resonance forces are taken to be repulsive.

London and Eisenschitz³ have shown that the repulsive resonance energy between two H atoms dominates the attractive energies. This may safely be considered to be true for all atoms in the first row of the periodic table. However, this resonance energy becomes smaller both with an increase of the total quantum number n^4 and of the azimuthal quantum number l^5 . Hence the following considerations will be confined to atoms in the first row.

In the outer region of an atom, i.e., the region that overlaps in ordinary thermal collisions, the electronic density varies approximately⁶ as $r^{n*} \exp(-2\alpha s)$. Here s is the distance from the nucleus, and α is the square root of the ionization potential.⁷ The asymptotic expansion of the resonance energy⁸ between two atoms will contain the factor $\exp(-(\alpha_1 + \alpha_2)R)$, where α_1 and α_2 refer

⁶ D. R. Hartree, *Proc. Camb. Phil. Soc.* **24**, 89 (1928).

⁷ Energy, length, mass will in this paper be expressed in the atomic units 13.53 volts, 0.528×10^{-8} cm, m_e , unless otherwise specified.

⁸ This may be verified by examining the general type of integral that arises in calculating the resonance energy. See Zener and Guillemin, *Phys.* **34**, 999 (1929), Eqs. (28) and (29). When the integral logarithms are replaced by their asymptotic expansions all terms will have the factor $\exp(-(\alpha_1 + \alpha_2)r)$. This opportunity is taken for pointing out that $m - v + 1$ should replace $m - v$ in Eq. (25), and $m!/(m - v)! \cdot v + 1$ should replace $e^{-\alpha} A_v(1, \alpha)$ in (26) and (30) of this reference.

to the two atoms, and R is their nuclear separation. The mutual potential between atoms or symmetrical diatomic molecules, averaged over all internal molecular coordinates, will contain the factor $\exp(-(\alpha_1 + \alpha_2)r)$, where r is the distance between the centers of gravity of the two systems. An approximation to the actual potential may thus be written as

$$V(r) = E'' e^{(\alpha_1 + \alpha_2)(r_{E''} - r)}. \quad (1)$$

The constants E'' , $r_{E''}$ are to be experimentally determined. They have the relation $V(r_{E''}) = E''$. If $E'' = E_{300}$ denotes the average energy of a gas molecule at room temperature, then r_{300} will be the classical average closest distance of approach.

It is desirable to compare the theoretical formula (1) with experimental data. The data on inter-molecular forces have been thoroughly reviewed by Lennard-Jones.⁹ If the constants c , α are determined to make $c \exp(-\alpha r)$ join smoothly to the repulsive energy formulae of Lennard-Jones at r_{300} , then α should be considered as the experimental value of $\alpha_1 + \alpha_2$. A comparison of these constants is given in Table I.

III. VIBRATION-TRANSLATION

The interchange of vibrational and translational energy will be investigated in the collision of atom A with the molecule $B-C$, the atoms A , B , C being confined to a line.

This interchange will be a function of the various physical parameters, such as the force binding B and C , the repulsive force between A and B , the initial translational and vibrational energies, and the relative masses.

If the atoms were sufficiently massive, and if the translational and vibrational energies were sufficiently great, only an investigation by classical mechanics would be necessary. But these conditions are not satisfied in the interesting cases where only the first vibrational states are excited. Nevertheless, it is profitable to consider the classical picture, as in general the same qualitative dependence upon the physical parameters will be present in the mechanics of the classical and quantum theory.

The classical picture will now be used in finding the conditions of maximum transfer of energy from vibration to translation with the optimum phase relation between the vibrational and translational motion. The system is first simplified by assuming the impact between A and B to be instantaneous.

⁹ R. H. Fowler, *Statistical Mechanics*, Chap. X (1929).

ous. Then if the mean vibration velocity of B is comparable to the relative velocity of A and the molecule $B-C$, with an optimum phase relation, the impact between A and B will occur when the molecule has all its internal energy in the form of kinetic energy. The energy transfer will then be a maximum when the masses of A and B are nearly equal. However, the vibrational energy of light molecules is much larger than the mean translational energy at room temperatures. Hence in order that A strike B while the latter has a maximum velocity, A must be lighter than B .

The effect of the finite time of impact between A and B is now examined. If this time is small in comparison to the period of oscillation of the molecule $B-C$, the impact may be regarded as instantaneous. As it becomes large in comparison to the period of oscillation, the atom will tend to act only upon the center of gravity of the molecule. The interchange of vibrational and translational energy then becomes small. With a fixed initial translational energy, a decrease in the mass of A will lessen this time of impact, and thus increase this interchange irrespective of the mass of B .

It is of interest to compare this time of impact with the period of oscillation in collisions between actual molecules. If r is the distance between A and B , their mutual energy may be taken to be

$$V(r) = E''e^{-\alpha(r-r_E'')} \quad (1')$$

as was seen in II. If E'' is set equal to the mutual energy E , then a reasonable value for the time of impact is the time τ_i during which $r < r_0$. Here, r_0 , together with F , is determined to make the parabola

$$U(r) = F(r - r_0)^2 \quad (2)$$

join smoothly to $V(r)$ at $r = r_E$. Thus (1') has been replaced by the potential

$$W(r) = \begin{cases} F(r - r_0)^2, & r < r_0. \\ 0, & r > r_0. \end{cases} \quad (3)$$

The ratio of τ_i to the period of vibration of $B-C$, τ_v , is one half the ratio of the frequency of vibration of the molecule to the frequency of vibration of a particle of mass

$$\mu = \frac{M_A(M_B + M_C)}{M_A + M_B + M_C} \quad (4)$$

in the potential (2). This ratio is

$$\beta = \frac{40}{\alpha} \frac{\omega_0}{8106} \left(\frac{\mu}{E} \right)^{1/2}$$

where ω_0 is the wave number of the molecule, μ is expressed in units of atomic hydrogen, and E is in units of the mean energy of a gas molecule at room temperature, E_{300} . A numerical example shows this ratio to be relatively large. For instance, in the collision of He with N_2 at room temperature, $\alpha = 2.4$, $\omega_0 = 2345$, $\mu = 3.5 E \approx 1$, giving $\beta = 9$.

The above considerations lead to the following classical conclusions for light molecules. Since the intra-molecular binding forces are large in comparison to the inter-molecular repulsive forces at collision distances, and since the internal energy of these molecules is large in comparison to their temperature equilibrium translational energy, the interchange of vibrational and translational energy will be small. H_2 will absorb more readily than any other molecule translational energy not only from a C-H bond but from any light molecule.

A precise quantitative theory for the one dimensional collision is developed by the following quantum mechanical analysis.

The coordinates will be taken to be: the center of gravity of the complete system, X ; the nuclear separation of molecule $B-C$, x ; and the distance between the atom A and the center of gravity of the molecule, r . This choice has been made in order that the kinetic energy may be written as

$$T = T_x + T_r + T_r.$$

The wave equation, after eliminating the center of gravity of the complete system, then becomes⁷

$$\left\{ \frac{1}{\mu_m} \frac{d^2}{dx^2} + \frac{1}{\mu} \frac{d^2}{dr^2} - V(x) - V(x, r) + E \right\} \Psi = 0 \quad (5)$$

Here

$$\mu_m = \frac{M_B M_C}{M_B + M_C}$$

and μ is given by (4). The energy $V(x)$ is the potential energy of the isolated molecule $B-C$, and $V(x, r)$ is the mutual energy of atom A and the molecule. The energy E has a continuous range of values. If E_i is the energy of the isolated molecule, then $p_i = \mu^{1/2}(E - E_i)^{1/2}$ is proportional to the momentum associated with the translational motion.

Let the normalized function $\psi_i(x)$ be a solution of the wave equation for the isolated molecule, namely

$$\left\{ \frac{1}{\mu_m} \frac{d^2}{dx^2} - V(x) + E_i \right\} \psi_i(x) = 0.$$

Corresponding to the physical requirement that before collision the molecule be in the vibrational state v_0 , a solution of (5) is to be found of the form

$$\Psi = \frac{e^{ip_{v_0}r} + e^{-ip_{v_0}r}}{(p_{v_0})^{1/2}} + \sum_v \gamma_{v,v_0} \frac{e^{-ip_v r}}{(p_v)^{1/2}} \psi_v(x) \quad (6)$$

The summation is over all indices for which p_v is real. The probability that the molecule has changed its vibrational quantum number from v_0 to v will be $|\gamma_{v,v_0}|^2$.

In order to obtain the coefficients γ_{v,v_0} , Ψ is expanded as follows:

$$\Psi = \sum_v Q_v(r) \psi_v(x). \quad (7)$$

The Q_v 's are undetermined functions. Substitution of this expansion into (5) gives

$$\sum_v \left\{ \frac{d^2}{dr^2} - \mu V(x, r) + p_v^2 \right\} Q_v(r) \Psi_v(x) = 0.$$

Multiply by $\Psi_v(x)$ and integrate with respect to x .

$$\left\{ \frac{d^2}{dr^2} - \mu V_v^v(r) + p_v^2 \right\} Q_v(r) = \mu \sum_{v' \neq v} Q_{v'}(r) V_v^{v'}(r) \quad (8)$$

where

$$V_v^{v'}(r) = \int \Psi_v(x) V(x, r) \Psi_{v'}(x) dx.$$

By neglecting the right member an equation for the zeroth approximation, $Q_v^0(r)$, is obtained.

$$\left\{ \frac{d^2}{dr^2} - \mu V_v^v(r) + p_v^2 \right\} Q_v^0(r) = 0.$$

Since $V_v^v(\infty) \rightarrow 0$, $Q_v^0(r)$ becomes sinusoidal for large r . Denote that particular solution that vanishes at $r=0$ by $U(p_v/r)$. Let this solution be so normalised that

$$U(p_v/r) \stackrel{r \rightarrow \infty}{=} \frac{\sin(p_v r + \theta_v)}{p_v^{1/2}}. \quad (9)$$

Choose another particular solution by its asymptotic behavior

$$X(p_v/r) \stackrel{r \rightarrow \infty}{=} \frac{e^{-i(p_v r + \theta_v)}}{p_v^{1/2}}. \quad (9')$$

The zeroth approximation to $Q_v(r)$ corresponds to an elastic collision in which the molecule has the quantum number v . Hence

$$Q_v^0(r) = \begin{cases} U(p_v/r), & v = v_0. \\ 0, & v \neq v_0. \end{cases} \quad (10)$$

The first approximation to $Q_v(r)$ is obtained by substituting this zeroth approximation into the right member of (8).

$$\left\{ \frac{d^2}{dr^2} - \mu V_v^v(r) + p_v^2 \right\} Q_v^1(r) = \begin{cases} \mu U(p_{v_0}/r) V_{v_0}^v, & v \neq v_0 \\ 0, & v = v_0. \end{cases} \quad (11)$$

The solution of these equations that satisfies the boundary condition (6) is

$$-Q_v^1(r) = \mu X(p_v/r) \int_0^r U(p_v/r') V_{v_0}^v(r') U(p_{v_0}/r') dr' \quad (12)$$

$$+ \mu U(p_v/r) \int_r^\infty X(p_v/r') V_{v_0}^v(r') U(p_{v_0}/r') dr'$$

$$Q_{v_0}^1(r) = C_1 X(p_{v_0}/r). \quad (12')$$

The validity of (12) may be verified by direct substitution into (11). The left member vanishes identically except for the term

$$-\mu U(p_{v0}/r) V_{v0}^v \{ X'(p_v/r) U(p_v/r) - X(p_v/r) U'(p_v/r) \}.$$

Now the subtraction of

$$X \left(\frac{d^2}{dr^2} - \mu V_v^v + p_v^2 \right) U = 0$$

from

$$U \left(\frac{d^2}{dr^2} - \mu V_v^v + p_v^2 \right) X = 0$$

gives

$$\frac{d}{dr} (X'U - XU') = 0.$$

Hence

$$X'U - XU' = C.$$

But from (9), (9'), $C = -1$. Hence (12) satisfies (11) identically.

C_1 is to be determined from the equation of continuity,—

$$\int \left(\Psi \frac{d}{dr} \Psi^* - \Psi^* \frac{d}{dr} \Psi \right) dx = 0.$$

Since the second integral in (12) vanishes as r becomes infinitely large, the first two approximations to the coefficients in the expansion (7) gives a ψ of the form (6) with

$$\begin{aligned} \gamma_{v0}^v &= \mu \int_0^\infty dr \int_{-\infty}^\infty dx U(p_v/r) \Psi_v(x) V(x, r) \\ &\quad \cdot U(p_{v0}/r) \Psi_{v0}(x), \quad v \neq v_0. \\ \gamma_{v0}^{v_0} &= C_1. \end{aligned} \tag{13}$$

The conditions under which this first approximation is valid will now be investigated. In general the successive approximations of the Born collision method do not converge. However, if the first terms become smaller, they may form a semi-convergent series that has a physical meaning. The relative magnitude of successive approximations will depend upon the physical parameters of the system. The application of (13) is thus limited to those systems with parameters such that the first successive approximations to the solutions of (8) which vanish at $r=0$ become smaller. It will be found that all systems examined in this study satisfy this condition.

An approximation to the probability is obtained by assuming a simplified potential of the form

$$V(x, r) = E'' e^{-\alpha(r-r'')}(1 + qz)$$

where z is the displacement of x from its equilibrium value. A reasonable value for q is the coefficient in the first term of the expansion of $e^{-\lambda \alpha z}$, where

$$\lambda = \frac{M_C}{M_B + M_C} \quad (14)$$

Neglecting the higher powers of z limits this analysis to molecules in which the amplitudes of vibration are relatively small. With this potential $\gamma_{v_0}^p$ may be factored as

$$\gamma_{v_0}^p = \xi_{v_0}^p \eta_{pv_0}^{pv}$$

where

$$\xi_{v_0}^p = q \int_{-\infty}^{\infty} \Psi_v(z) z \Psi_{v_0}(z) dz \quad (15)$$

and

$$\eta_{pv_0}^{pv} = \mu E'' \int_0^{\infty} U(p_v/r) e^{-\alpha(r-\tau E'')} U(p_{v_0}/r) dr. \quad (15')$$

The U 's are solutions of

$$\left(\frac{d^2}{dr^2} - \mu E'' e^{-\alpha(r-\tau E'')} + p^2 \right) U(p/r) = 0 \quad (16)$$

and are normalised to satisfy (9).

Fig. 1.

Since only a very rough approximation to $\eta_{p,p}$ can be obtained without great analytical difficulties, it is profitable to consider first the qualitative dependence of $\eta_{p,p}$ upon the physical parameters.

In Fig. 1 are drawn the potentials and pertinent wave functions. The energy levels to $V(r)$ are drawn for energy values whose $U(p/r)$ have nodes at

$r=r_0$, where r_0 is chosen arbitrarily at a point where $V(r)$ first becomes appreciable. Here E, E' refer to the initial and final translational energies, with $E < E'$, and p, p' to the corresponding momenta.

An increase of the molecular binding force $-dV(z)/dz$ relative to the repulsive force $-dV(r)/dr$ will increase the number of energy levels between E' and E , thus increasing the fluctuations in sign of the integrand of (17), and thus decreasing $\eta_{p,p'}$. An increase in the reduced mass μ will have a similar effect.

An increase of E and E' by similar amounts will increase $\eta_{p,p'}$ by lessening the number of energy levels between E and E' .

An examination shows that in ordinary thermal collisions between molecules whose atoms belong to the first row of the periodic table, the first maximum of $g(p/r)$ lies in the region $r < r_0$, and that several "energy levels" always lie between E and E' . The qualitative results of the classical and the quantum mechanical treatment are thus similar in such collisions. In the language of the former a decrease in the slope of $V(r)$ or an increase of the reduced mass μ results in an increase of the time of collision. In the language of the latter, similar changes result in an increased fluctuation of sign in the integrand of (17).

An analytical approximation to $\eta_{p,p'}$ is obtained by replacing the exponential potential by a potential which renders Eq. (16) soluble in known functions. Such a potential is

$$V_a = \frac{A}{(r-B)^2}, \quad r > B$$

$$V_a = \infty, \quad r < B.$$

The constants A, B are adjusted to make V_a as similar as possible to the potential (1') in the important range of r . With the choice

$$V_a = \frac{4E''/\alpha^2}{(r-r_{E''}+2/\alpha)^2} \quad (17)$$

the two potentials join smoothly at $r=r_{E''}$. A reasonable value of E'' is $(EE')^{1/2}$.

The differential equation (16) now becomes

$$\left\{ \frac{d^2}{dx^2} - \frac{4\mu E''/\alpha^2}{x^2} + p^2 \right\} U(p/x) = 0$$

where $x = r - r_{E''} + 2/\alpha$. Its solution is the Bessel function

$$U(p/x) = \left(\frac{\pi}{2} \right)^{1/2} x^{1/2} J_v(px) \quad (18)$$

with

$$v = (4\mu E''/\alpha^2 + 1/4)^{1/2} \simeq 2(\mu E'')^{1/2}/\alpha.$$

This solution is normalized to satisfy (9).

The expression (15') for $\eta_{p,p'}$ now becomes

$$\eta_{p,p'} = 2\pi \frac{\mu E''}{\alpha^2} \int_0^\infty \frac{J_v(px) J_v(p'x) dx}{x}.$$

The substitution of

$$\int_0^\infty \frac{J_v(px) J_v(p'x)}{x} dx = (p/p')^v / 2v, \quad p < p'$$

(Watson, Theory of Bessel Functions, p. 401) reduces this to

$$\eta_{p,p'} = \frac{\pi(\mu E'')^{1/2}}{2\alpha} (E/E')^{(\mu E'')^{1/2}/\alpha}. \quad (19)$$

If the molecule is assumed to be vibrating as a linear oscillator, then (15) reduces to

$$\xi_{v-1}^v = \frac{\alpha}{2} \left(\frac{v}{\mu_m(E_v - E_{v-1})} \right)^{1/2}, \quad (20)$$

all the other integrals vanishing.

As a numerical example, consider the one dimensional collision at room temperature of He with N₂, in which N₂ is deactivated from the first excited vibrational state to the normal state. Here $\alpha = 2.14$, $E/E' = 1/8$, $\mu E'' = 58$, $\mu_m(E_1 - E_0) = 274$. The probability for this deactivation is thus given by

$$(\gamma_0^1)^2 = (\xi_0^1)^2 (\eta_{p,p'})^2 = 0.004 \times 0.0415 = 0.076. \quad (21)$$

IV. ROTATION-TRANSLATION

The principles involved in the interchange of rotational and translational energy are most readily studied in the collision of a rigid diatomic molecule and an atom, all motion being confined to a plane. This collision will first be discussed from the classical standpoint.

The symmetry of the molecule limits the energy transfer in a single impact. If an electron is excited to such a state that its time average distribution is nearly spherical, then the energy interchange in a collision will become small. Hence the energy transferred during a collision will be very dependent upon the electronic state of the molecule. This has been empirically observed.¹³ Comparison of the time of collision with periods of rotation is not important, since the latter is usually the larger.

In order to treat this collision problem by quantum mechanics, a suitable mutual potential must be found. If the analysis is limited to symmetrical diatomic molecules, a simple potential having the necessary properties is

$$V(r, \epsilon) = V(r) \left\{ 1 + h(\cos^2 \epsilon - \frac{1}{2}) \right\}. \quad (22)$$

Here r has the same meaning as in the previous section, and ϵ is the angle between the molecular axis and the line joining the atom with the center of the molecule. The potential $V(r)$ is taken to be (1'). A reasonable value for h

¹³ R. Rompe, Zeit. f. Physik 65, 428 (1930).

is obtained by requiring that the ratio $V(r, 0)/V(r, \pi/2)$ equal the ratio $V(r+x_0/2)+V(r-x_0/2)/2V([r^2+x_0^2/4]^{1/2})$, where x_0 is the nuclear separation in the molecule, and where r is set equal to r_{300} . This condition gives

$$h = \frac{2[e^{\alpha x_0/2} + e^{-\alpha x_0/2} - 2e^{-\alpha([r_{300}^2 + x_0^2/4]^{1/2} - r_{300})}]}{[e^{\alpha x_0/2} + e^{-\alpha x_0/2} + 2e^{-\alpha([r_{300}^2 + x_0^2/4]^{1/2} - r_{300})}]} \quad (23)$$

By considerations similar to those leading to (5), the following wave equation of our two dimension system of a rotator and an atom may be obtained:

$$\left\{ \frac{1}{I} \frac{d^2}{d\phi_1^2} + \frac{1}{\mu} \frac{1}{r} \frac{d}{dr} r \frac{d}{dr} + \frac{1}{\mu} \frac{1}{r^2} \frac{d^2}{d\phi^2} - V(r, \epsilon) + E \right\} \Psi = 0.$$

Here ϕ_1, ϕ are the azimuthal angles associated with the molecule and the line joining the atom to the center of the molecule.

A solution of this equation corresponding to the molecule being in a definite rotational state before collision, and having a probability of being in several after the collision, is obtained by a method closely analogous to that of the previous section. The zeroth approximation is of the form

$$\Psi = e^{im_1\phi_1} \sum_{m=-\infty}^{\infty} e^{i\delta_m} e^{im\phi} U_m(p_{m1}/r).$$

The phase factor δ_{m1} is arbitrary. The function $U_m(p_{m1}/r)$ is the solution of

$$\left\{ \frac{1}{\mu} \frac{1}{r} \frac{d}{dr} r \frac{d}{dr} - \frac{1}{\mu} \frac{m^2}{r^2} - V(r) + E - \frac{m_1^2}{I} \right\} U_m(p_{m1}/r) = 0$$

that vanishes¹² at $r=0$ and is normalised to satisfy

$$U_m(p_{m1}/r)^{r \rightarrow \infty} = \frac{\sin(p_{m1}r + \beta_{m1})}{(p_{m1}r)^{1/2}}.$$

The only allowable transitions are $m = \pm 2$. The probability that the quantum numbers change from m_1, m to $m_1-2, m+2$ is

$$\begin{aligned} \left(\gamma \begin{matrix} m_1-2, & m+2 \\ m_1, & m \end{matrix} \right)^2 &= \frac{h^2}{16} \left\{ \int_0^\infty U_m(p_{m1}/r) V(r) U_{m+2}(p_{m1-2}/r) r dr \right\}^2 \\ \text{or} \quad \left(\gamma \begin{matrix} m_1-2, & m+2 \\ m_1, & m \end{matrix} \right)^2 &\leq \frac{h^2}{16} \left\{ \int_0^\infty U_0(p_{m1}/r) V(r) U_0(p_{m1-2}/r) r dr \right\}^2. \end{aligned} \quad (24)$$

However, these individual probabilities are not of primary interest, but only the effective cross section of such a collision. If

$$\gamma \begin{matrix} m_1-2 & m+2 \\ m_1 & m \end{matrix} = \begin{matrix} 1, & m < m_0 \\ 0, & m > m_0 \end{matrix}$$

¹¹ W. Pauli, *Probleme der Modernen Physik* p. 42. (Hirzel, Leipzig, 1928.)

¹² The formulation of this boundary condition is rather arbitrary, as an equally justifiable condition would be to require that $U(p/r)$ have a zero slope at $r=0$. However, as long as the probability remains negligibly small that the atom pass through the molecule, both boundary conditions will give the same result.

this effective cross section would be equal to the kinetic theory cross section, σ_{KT} . Here, m_0 is the largest m for which the molecule and atom would classically come into contact. An upper limit to the effective cross section σ_{eff} is obtained by using the equality sign in (24) when $m < m_0$, and setting the left member equal to zero when $m > m_0$. This gives

$$\sigma_{eff} < \frac{h^2}{16} \left\{ \int U_0(p/r) V(r) U_0(p'/r) r dr \right\}^2 \sigma_{KT},$$

in which p_m, p_{m-2} have been replaced by p, p' .

An approximation to this integral is obtained in a manner identical to that used in the previous section. The only difference is that here the relation $v = 2(\mu E'')^{1/2}/\alpha$ is exact. An upper limit to the cross section is then

$$\sigma_{eff} < \frac{h^2}{16} (\eta_p^n)^2 \sigma_{KT}$$

in which η_p^n is given by (19).

As a numerical example, consider the probability that a N_2 molecule, considered as non-vibrating, give two quanta of rotational energy to a He atom in a two dimensional collision at room temperature. In this example $h = 1.3$, $(\eta_p^n)^2 = 11$, resulting in

$$\sigma_{eff} < 1.2 \sigma_{KT}.$$

V. GENERAL COLLISIONS

In the previous sections discussion has been restricted to a one-dimensional collision of an atom and a vibrating molecule, and to a two-dimensional collision of an atom and a rotating molecule. The analysis is now extended to three-dimensional collisions between two molecules both of which vibrate and rotate.

The quantum mechanical treatment of such a collision in three dimensions is difficult, since the equation whose solution corresponds to an elastic collision is not in general separable in the mutual coordinates. However, in the classical theory collisions of the second kind are most probable between an atom and vibrator when all motion is confined to a line, and between an atom and rotator when all motion is confined to a plane. We may expect a similar relation in quantum mechanics, so the previous inequalities obtained for one and two dimensional collisions may be taken to be valid for three-dimensional collisions.

Provided the amplitude of vibrations are relatively small, the mutual potential may be approximated by the product of functions of individual coordinates. Thus when both molecules are diatomic, a simple potential is

$$V = V(r)(1 + a_1 z_1)(1 + a_2 z_2)(1 + f_1(\epsilon_1)(1 + f_2(\epsilon_2)) \quad (25)$$

where $V(r)$ is taken to be (1'); z_1 and z_2 are the displacements of the internuclear separations of the two molecules from their equilibrium values; ϵ_1 and ϵ_2 are the mutual angles between the line joining the centers of gravity of the

two molecules and the axes of the two molecules; and f_1, f_2 are arbitrary functions.

When the mutual potential is so factorable, the probability of an inelastic collision will also be expressible as a product. One factor of this product will be a function of the constants of translational motion. Denote this factor by $P_{E,E'}$. Each of the other factors will be associated with a change of one quantum number. These factors will be independent of one another. For example, in a collision in which the vibrational quantum number v changes to $v-1$, the associated probability factor $P_{v,v-1}$ will not be influenced by changes of other quantum numbers.

Hence if σ_{KT} is the kinetic theory cross section of a collision, the effective cross section of a collision in which the quantum numbers v_1, l_1, \dots change to v_1', l_1', \dots will be

$$\sigma_{\text{eff}} < \sigma_{KT} P_{E,E'} P_{v_1,v_1'} P_{l_1,l_1'} \dots \quad (26)$$

In the following description of these factors, atomic units⁷ are used.

When μ refers to the reduced mass of the two systems, α to the sum of the square roots of the ionization energies (in units of 13.53 volts) of the two atoms which become adjacent during collision, $E(E')$ to the smaller (greater) of the initial and final mutual energies of translation, and $E'' = (E E')^{1/2}$, reference to (19) shows that for sub-elastic collisions

$$P_{E,E'} = \frac{\mu E'' \pi^2}{4\alpha^2} \cdot (E/E')^{2(\mu E'')^{1/2}/\alpha} \quad (27a)$$

In super-elastic collisions¹³ $P_{E,E'}$ is to be multiplied by the factor $(E/E')^{1/2}$.

When the mutual potential contains only the first power of the displacement of a vibrator from its equilibrium position, the vibrational quantum number can change only by unity. Reference to (20) shows that the factor $P_{v,v-1}$ associated with a change of vibrational quantum number $v \rightarrow v-1$ or $v-1 \rightarrow v$ is

$$P_{v,v-1} = \frac{\lambda^2 \alpha^2 v}{4\mu_m(E_v - E_{v-1})} \quad (27-b)$$

where the difference in energy between the two states is $E_v - E_{v-1}$, where λ is given by (14), and μ_m is the reduced mass of the vibrator.

If one of the colliding systems is a symmetrical diatomic molecule, the dependence of the interaction energy upon the mutual angle ϵ is approximately expressed by the factor $1 + h(\cos^2 \epsilon - \frac{1}{2})$, corresponding to (22). The constant h , determined from (23), varies from 1 to 1.5 for diatomic symmetrical molecules whose electronic states are normal. If the electronic states are highly excited, h may approach zero. Insofar as this approximation is valid, the molecule can change its rotational quantum number l by only ± 2 . The corresponding probability factor is

$$P_{l,l\pm 2} = h^2/16. \quad (27-c)$$

The statistical factor¹³ relating the probability of the transition $l \rightarrow l+2$ to that of $l+2 \rightarrow l$ is neglected.

A few general observations will be drawn from the above formulae.

The molecules to which this analysis applies change a few rotational quantum numbers freely.

The transfer of vibrational energy may be difficult even in cases of exact resonance,¹⁴ e.g. the cross section for the transfer of vibrational energy from a N_2 molecule in its first excited state to a normal N_2 at room temperature is $0.044 \times$ kinetic theory cross section. This resonance cross section increases both with the reduced mass of the two molecules, and with temperature. However, the effects of a lack of resonance are most marked in heavy molecules. If the reduced mass is $30 m_H$, the effective cross section is reduced by a factor of 0.025 if the translational energy must change by 0.01 volt at room temperature.

The efficiency of H_2 as contrasted to He in deactivating molecules¹⁵ cannot be explained as due to their difference in mass. It is to be ascribed to the much greater facility with which H_2 can absorb a considerable amount of energy by a change of a few rotational quantum numbers, than by a change of translational energy.

The writer wishes to express his gratitude to Professor Kemble for frequent discussions, and to Harvard University for enabling him to commence this study in Bristol, England.

THE ABSORPTION COEFFICIENT FOR SLOW
ELECTRONS IN THALLIUM VAPOR

BY ROBERT B. BRODE

DEPARTMENT OF PHYSICS, UNIVERSITY OF CALIFORNIA

(Received January 19, 1931)

ABSTRACT

The absorption coefficient α has been observed by sending a beam of electrons through thallium vapor and measuring the decrease in intensity of the beam as a function of the pressure of the vapor. α , plotted as a function of the velocity of the electrons, decreases rapidly to a minimum of 15 at 1.4 volts, rises less rapidly to a maximum of 51 at 4.5 volts, and then slopes off gradually to 20 at 100 volts.

IN THE study of the absorption coefficients of the monatomic elements of the periodic system, all of the noble gases,^{1,2} four of the alkali metals³ and three of the elements of the second column, i.e., Hg,⁴ Cd and Zn,⁵ have been investigated. Thallium has been chosen for the extension of these observations to the third column of the periodic table. In the vapor state thallium is monatomic but it differs from all of the elements previously investigated in the nature of its normal spectroscopic state. The thallium normal state is of a *P* type while all of the other elements mentioned above have normal states of the *S* type.

For the range of pressure (5×10^{-3} to 5×10^{-2} mm of Hg) necessary for satisfactory measurements, thallium requires temperatures from 550 to 630° C. The apparatus was therefore enclosed in a quartz tube. The electric connections to the apparatus were made by fusing molybdenum wires into quartz capillaries. This was not a vacuum tight seal but it was sufficient to prevent the rapid diffusion of the metal vapor out of the quartz tube. The molybdenum wires were continued in quartz tubes to the outside of the furnace. Quartz to Pyrex graded seals enabled vacuum tight connections to be made by tungsten seals through the Pyrex.

The metal parts of the apparatus were made of tantalum as shown in the cross-sectional view of the apparatus in Fig. 1. The tungsten filament, *F*, was the source of electrons which were bent in a circle through the slit *S* and into the collecting box *B* at the end of the path. The mean radius of the path was 7.0 mm and the widths of the slits at *F*, *S*, and *B* were 0.5, 1.0, and 0.5 mm respectively.

In the preparation of the tube the spaces on both sides of the quartz capillaries were connected to the vacuum pumps. The apparatus was baked

out to 800°C and the metal parts glowed to a bright yellow by an induction furnace. A small amount of thallium metal was then slowly distilled into the lower end of the apparatus. The vacuum connections to the quartz tube and to the Pyrex seals were sealed off.

The main portion of the tube was enclosed in a non-inductively wound electric furnace. The small tube containing the metal was enclosed in a heavy copper tube in a separate furnace directly below the main furnace. The temperatures in the two furnaces were measured by chromel-alumel thermocouples. From the vapor pressure equation and the temperature of the lower furnace the pressure of the thallium vapor could be calculated. This pressure was corrected for the difference in pressure caused by the difference in temperatures of the upper and lower furnaces.

Fig. 1. Diagram of apparatus and furnaces.

The measurements of the absorption coefficient were made in the same way as those previously described for mercury.⁴ The total emission from the filament was assumed to be proportional to the initial current I_0 that would have reached the end of the path if there had been no collisions. The current I at the end of the path was measured by a galvanometer connected to the box B . The currents I and I_0 are related by the equation, $I = I_0 e^{-\alpha x p}$, where α is the absorption coefficient, x the path length and p the pressure of the absorbing vapor. From this equation the logarithm of the ratio of I/I_0 should be a linear function of the pressure. Measurements were made at from 3 to 5 pressures for every velocity studied and the value of α computed from this linear relation.

The results of the measurements are shown in Fig. 2, where the absorption coefficients in cm^2 per cm^3 of the thallium vapor at 1 mm pressure at 0°C are plotted as a function of the velocity of the electrons which is expressed in square root of volts. The first two resonance potentials, 3.3 and 4.5 volts, and

the ionization potential, 6.1 volts, are indicated by the letters *R*, *R*, and *I*. The curve is characterized by a sharp minimum at 1.4 volts and a maximum at 4.5 volts.

The magnitude of the absorption coefficient depends on the constants chosen for the equation relating the vapor pressure and the temperature. Measurements of the vapor pressure of thallium have been made by Gibson⁶ and von Wartenberg.⁷ Professor Gibson has advised me to use the data of von Wartenberg instead of his own. He suggested that his own data for thallium vapor pressures might be somewhat uncertain because of the effect of the high temperatures, 1000 to 1600°C, on the elastic properties of the quartz of which his manometer was constructed. The vapor pressure of thallium measured by Gibson at 970°C, his lowest temperature, agrees well with the value from von Wartenberg's data for the same temperature. For the vapor pressure equation, $\log p_{\text{mm}} = B - A/T$, the International Critical Tables⁸ give the values $A = 6,280$, and $B = 6.14$, based on Gibson's high temperature data.

Fig. 2. The absorption coefficient α for electrons in thallium vapor as a function of the velocity of the electrons.

The data of von Wartenberg give for the constants the values $A = 8,890$, and $B = 8.55$, which are the values used in this experiment to calculate the vapor pressure. At the temperatures used in this experiment, the I. C. T. values of the pressure are about five times those of von Wartenberg for the same temperature. If the I. C. T. values of the constants were used, the values of α shown in Fig. 2 should be reduced to about 1/5 of their value or at 4.5 volts, the maximum, $\alpha = 10$ and at 100 volts $\alpha = 4$. These values seem improbably small as helium has a value of $\alpha = 15$ at 4.5 volts and $\alpha = 3.5$ at 100 volts.

In the curves for thallium vapor, the alkali metal vapors and the heavier noble gases, the maximums are at about the resonance potentials while the minimums are at definitely lower velocities. This means that the probability of an elastic collision between an electron and an atom increases as the energy of the electron approaches the critical potential of the atom.

⁸ International Critical Tables, Vol III, 205.

Because of the maxima and minima in the absorption coefficient curves, the relative magnitude of the curves of different elements is somewhat uncertain. By taking the value of the absorption coefficient for a velocity well beyond the region of maxima and minima, a definite order of arrangement for the elements can be obtained. Choosing arbitrarily 100 volts as the velocity for comparison of the curves, the order of arrangement of the absorption coefficients for the 13 monatomic elements that have been measured is, with the exception of thallium, inversely proportional to the ionization potential. To fit into this arrangement, thallium with an ionization potential of 6.1 volts should have an absorption coefficient at 100 volts of about 100 instead of 20. Further experimental observations will be necessary to determine whether this deviation of thallium from the general order is really a property of the thallium atom or is due to the inaccuracies in the vapor pressure. Since the normal state of the thallium atom is a *P* state as compared with *S* states for the other atoms, it would not be unexpected to find a real difference.

OSCILLATIONS AND TRAVELLING STRIATIONS IN AN ARGON DISCHARGE TUBE

BY T. C. CHOW

PALMER PHYSICAL LABORATORY, PRINCETON UNIVERSITY

(Received January 15, 1931)

ABSTRACT

The effects of current and external circuit conditions on the frequency of travelling striations were observed. Some information concerning the voltage fluctuations at different parts of the tube was obtained. Electron temperatures in the positive column were determined at different pressures. A set of wave-lengths bearing simple relations with the length of the tube were calculated by means of Tonks' and Langmuir's theory of electric sound waves and the experimental values of the flash frequency.

INTRODUCTION

IN THE course of an experiment to determine certain quantities in the positive column of a discharge tube, the author encountered the difficulty that the voltage across the tube was not constant. After an unsuccessful attempt to eliminate this fluctuation, it was thought desirable to investigate the phenomenon in more detail.

Oscillations in a discharge tube were observed and studied quite long ago. Recent work has been done by Penning,¹ Tonks, and Langmuir,² Webb and Pardue,³ Fox⁴ and others. Webb, Pardue, and Fox found that the phenomenon of travelling striations studied by Aston and Kikuchi,⁵ Whiddington,⁶ and others was accompanied by oscillations. In this paper a few more points are reported concerning travelling striations and oscillations in an argon discharge tube with a positive column.

APPARATUS AND METHOD

The discharge tube is shown in Fig. 1. The length of the tube was 72.5 cm. The inner diameter was 7.2 cm. An oxide coated cylindrical nickel cathode *C* and a hollow cylindrical nickel anode *A* were used. The shortest distance between cathode and anode was 60 cm. The tube was baked out at about 350°C for several hours. The cathode and anode were degassed by means of an induction coil. Between the tube and the pumping system there were two liquid air traps with a stopcock between them. During a run this stopcock was closed. Liquid air was continually kept on the trap which was on the tube side of the stopcock. For the study of voltage fluctuation a cath-

ode-ray oscillograph was used. For the observation of instantaneous pictures of the discharge tube and the measurement of flash frequency, a stroboscope, which is essentially a rotating toothed-wheel together with a fixed slit put right behind it, was used.

RESULTS

1. *An instantaneous picture of the discharge.* (Fig. 1). The negative glow and the head of positive column remain stationary. Flashes travelling from anode to cathode run into the head of the positive column but do not run across the Faraday dark space. There are cases in which the Faraday dark space is not present. In these cases, it is observed that the flashes run into the negative glow which is stationary. The distance between successive flashes is of the order of 10 cm.

2. *Fluctuation of space potential in the tube.* In a non-oscillating tube we know that there is a definite potential distribution. When oscillations are present and the potential difference between cathode and anode fluctuates it is quite natural to expect that the space potential distribution should fluctuate too.

Fig. 1. Diagram of tube. The shaded regions are luminous parts. The numbers represent the distances in cm between the different probe wires.

In order to get exact information one has to take Langmuir probe wire measurements at particular phases of the cycle of voltage fluctuation at different parts in the tube. Wishing to continue with his original problem, the author has not gone into this work. He reports here such information as he has been able to obtain otherwise. There are a number of probe wires situated at different parts of the tube. When they are left floating in the tube each of them charges up to a certain potential negative with respect to the surrounding space such that electrons and positive ions reach the wire at equal rates. If the surrounding space potential is fluctuating the potential of the floating wire must also fluctuate. The fluctuation of the probe wire potential would be just equal to that of the space potential provided the ratio of the concentration of positive ions and that of electrons and the ratio of the velocities remain unchanged. What was done, therefore, was to connect anode or cathode and each one of the probe wires successively to a pair of deflecting plates of the cathode ray oscillograph. The amplitudes of voltage fluctuation at different parts with respect to cathode and anode were observed. The results are shown in Table I. Each vertical line shows the position of a probe wire and the numbers in the column under it give the corresponding voltage fluctuations. The pressures are given in the first column. The upper row corresponding to a particular pressure gives the amplitudes of the voltage fluctuation in volts between the probe wires and the anode. The lower row gives the amplitudes with respect to the cathode.

TABLE I. *Amplitudes of the voltage fluctuations in different parts of the tube with respect to the anode and cathode. Pressures are all measured when the gas is at room temperature. After two hours of running the pressure does not change very much.*

Travelling striations do not appear distinctly until the gas pressure is reduced to about 0.775 mm. However, fluctuations of luminosity are still present at high pressures. The frequency of luminosity fluctuation can still be measured. The probe wire nearest the cathode is on the cathode side of the negative glow, except in a few cases at high pressures when the positive column extends very close to the cathode. The position of the second probe wire with respect to the positive column goes from inside the head to just outside in the pressure range from 0.775 mm to 0.071 mm. Very little can be concluded from these values because we do not know the phase differences between the voltage fluctuations at different parts. However, we can say that the disturbance is very small in the cathode region compared with that in the anode region. This seems to agree with the fact that the travelling striations are present in the positive column. It has also been observed that when the second probe wire is situated in a rather distinct Faraday dark space, there is no voltage fluctuation between this probe wire and the cathode and also no voltage fluctuation between the first probe wire and cathode.

3. *Variation of flash frequency with current through the tube.* Whiddington observed that this phenomenon of travelling striations covers quite a large range of current. He divided the moving striations into five types according to their velocities as the current is increased. Since it is observed that the distance between successive striations does not change appreciably with current the relation between flash frequency and current is therefore similar to that between velocity and current. By flash frequency we mean the number of striations moving across a certain cross-section of the tube per second. The result is summarized in Table II. There are two modes of frequency change,

TABLE II. *Variation of flash frequency with current through the tube. Battery voltage $E=62$ volts.*

Current (amp.)	Flash frequency	Voltage across tube (volts)	Remarks
0.27	1.71×10^3	53.0	Current unsteady light fluctuation visually observed.
0.6	1.89 "	47.9	
1.0		44.0	
2.6	0.97×10^3	37.3	Steady, instantaneous picture clear.
3.0	1.14 "	34.5	"
3.4	1.19 "	33.5	"
3.8	1.21 "	33.0	"
4.4	1.23 "	32.3	"
5.0	1.26 "	32.0	"
5.4	1.26 "	32.0	"
6.0	4.71 "	31.5	"
3.5	1.18 "	34.0	"

one is a continuous variation and the other is a discontinuous jump. In the continuous region the frequency increases with the current. The relation is indeed not simple. One would suspect that the current is not the only thing responsible for the change of frequency because in order to change the current other quantities in the circuit have been changed too; for instance, the external resistance in the circuit. Other observations are therefore made to test the effect of the external circuit.

4. For a given current the frequency changes with the external resistance (non-inductive). An interesting fact was observed. When a large battery voltage (E) is used, thus with large external resistance, the Faraday dark space ex-

TABLE III. Variation of flash frequency with external resistance.

Current	Battery voltage	Voltage across tube	Flash frequency	External series resistance
0.4 amp.	60 volts	53.1	9.88×10^2	18 ohms approx.,
0.4 "	118 "	51.7	1.92×10^3	166 " "
0.4 "	345 "	51.7	2.09×10^3	733 " "

ists. When E is small the Faraday dark space disappears. On one occasion I was able to observe a Faraday dark space, although not so distinct, by using E equal to about 60 volts. The frequency measured was 1.61×10^3 . Suddenly the Faraday dark space disappeared and the frequency became 9.8×10^2 . This change seems to correspond to a change-over from a "fast-type" to a "slow-type" in the previous current-frequency relation.

5. Inductance increases the frequency, capacity decreases it. The frequency decreases rapidly with increase in the capacity put in parallel with the tube.

TABLE IV. Variation of flash frequency with inductance and capacity.

Flash frequency	Condition in external circuit
2.22×10^3	Only noninductive resistance about 300 ohms
1.92×10^3	With a condenser of 2 mf connected parallel to tube
2.40×10^3	An inductance in series with series resistance
E equal about 120 volts $V=58.8$ volts $i=0.2$ amp. kept same in three cases	

When the capacity in parallel with the tube was large, the Faraday dark space disappeared. Under this condition, although no distinct striation can be seen, there are bright and less bright regions. These regions fluctuate violently in position.

6. The filament current has an effect on the frequency. An increase in the filament current decreases the frequency.

TABLE V. Variation of flash frequency with filament current.

Filament current	Current in tube	Voltage across tube	Flash frequency	External resistance
6.2 amp.	0.3 amp.	87.5 volts	2.21×10^2	842 ohms
8.7 "	0.3 "	51.7 "	2.08×10^2	961 "
$E=340$ volts				

7. A search for electric sound waves: variation of flash frequency with pressure. That the flash frequency is the same as the sound frequency heard in a telephone receiver connected to the circuit suggests that there might be present a kind of electric sound wave such as Tonks and Langmuir derived in

their theory of plasma ion oscillation. Their expression for the velocity of electric sound waves is this

$$v = 3.9 \times 10^5 \left(\frac{T_e m_e}{m} \right)^{1/2}$$

where T_e is the electron temperature in degrees m_e and m are the masses of the electron and the argon atom, respectively. The frequency of the electric sound wave is indeterminate from their theory. The only condition is that λ is very much greater than $(\pi k T_e / ne^2)^{1/2}$. Experimental values of T_e and calculated values of v at different pressures are given in Table VI. They are not in agreement with the flash velocities. If the flash frequency were the

(iii) Distance between successive striations = 10.5 cm. approx.

same as that of electric sound waves, the wave-length would be very long compared with the distance between flashes. However, there is a very peculiar relation between all these calculated λ 's. Most of them are integral or half-integral multiples of a certain length which is rather closely the length of the whole tube. (A few deviate from integers or half-integers but most of them are within experimental errors. Flash frequency is subject to 1 percent error. Electron temperature may have a maximum deviation of 5 percent.) This would mean that if we take the frequency of electric sound waves (suppose there is such a kind of wave in the tube) equal to some higher harmonics

of the flash frequency the wave-length of the electric sound waves turns out to be a fraction of the tube length like a standing wave in that distance. The author does not attempt to interpret this phenomenon but believes that the fact is a real one, and may be very significant. The relation between flash frequency and pressure is plotted in Fig. 2.

Fig. 2. The relation between flash frequency and pressure.

8. *Miscellaneous note.* There is often found a ring of glow light surrounding the anode. As the pressure is reduced this ring of velvet glow moves down towards the end of the anode. Sometimes the discharge is so unsteady that the needles of the voltmeter and the ammeter vibrate. In the range of pressure in which travelling striations are observed it is often possible to restore the discharge to steady condition by putting a magnet somewhere near the tube. Then distinct travelling striation patterns can be seen. There are a certain number of definite regions in which the magnet must be put in order to be effective. Right above the head of the positive column, and above the negative glow are favorable places but by no means the only places. Once the magnet had to be put a little behind the cathode. In some previous observations, some places near the anode are also effective.

In this laboratory, Dr. Cravath found oscillations too in his mercury discharge tube. His tube had about the same length as mine; the diameter was even larger. It was suggested that the large diameter of the tube is responsible for oscillations because the larger the diameter the smaller will be the area of the wall surface per unit volume of the tube. Loss of ions and electrons

due to recombination at the wall will be less, so that the concentrations of ions and electrons in the tube are large. Therefore the process of cumulative ionization is favorable for the production of ions and electrons. The rate of production of ions and electrons by cumulative ionization processes is proportional to the square of the electron concentration. A small change of electron concentration will cause a large change in the rate of production of ions and electrons. This is a state of instability. A tube of about one inch diameter was built. However, oscillations existed as badly as in the tube with large diameter. This would mean that the above theory is certainly incomplete, if not wrong.

The author wishes to thank Professor K. T. Compton and Professor H. D. Smyth for their deep interest and encouragement.

COLD EMISSION FROM UNCONDITIONED SURFACES

BY WILLARD H. BENNETT*

NORMAN BRIDGE LABORATORY OF PHYSICS, PASADENA, CALIFORNIA

(Received January 26, 1931)

ABSTRACT

The greatest difficulty in obtaining higher potentials in tubes is due to auto-electronic emission from the electrode surfaces. A study of emission from unconditioned metals is described leading to the result that either loose fine particles in a tube, or else the targets of emission will probably have more to do with the quantity of emission than will the kind and "conditioning" of the cathode itself.

NUMEROUS measurements have been made of the emission in high electric fields, from fine wires and fine points of metals, which have been heated nearly to melting, in vacuum, and thus thoroughly conditioned.¹ Since metal parts in high voltage tubes are so restricted in size and shape by the necessity of such heating, it has been considered of importance to investigate cold emission with a view to finding what else can be done to a metal surface to decrease the emission, besides heating to high temperatures. This problem is of particular interest in connection with the development of a design for a tube to give higher order potentials than those now obtainable with unconditioned or partially conditioned electrodes.²

1. APPARATUS

The experimental apparatus was designed by Julius Pearson in accordance with plans outlined by R. A. Millikan, to measure the current passing between electrodes in high vacuum at known fields. Spherical electrodes were used at distances small compared with the radius of either electrode.

The cathode was mounted on a fixed steel post extending down into the evacuated bulb, as shown in Fig. 1. The anode was mounted on a steel post which could either be moved towards or away from the cathode by means of the micrometer screw, and also which could be rotated about the cathode by turning the movable part of the base, as shown in Fig. 2. When the latter rotation was made, the anode retained its orientation so that fresh surfaces both of the anode and of the cathode were brought together at each setting of the base. Several sets of readings were thus possible at each mounting of the electrodes.

The anode post was sealed vacuum-tightly to the fixed part of the base by means of a copper syphon. Both the cathode post and the anode base were sealed to the glass bulb with red sealing wax. The bulb was connected to the pumps at all time. An ionization gauge was used for measuring pressures.

The source of potential was a Thordarson transformer and kenetron rectifier, the potential being smoothed out with a 0.25 microfarad condenser. This generator, which gave up to 20 kv steady potential, was connected through a 10,000,000 ohm xylene-alcohol resistance to the cathode post. The

Fig. 2. Diagram of anode.

potential difference applied between the electrodes was measured by the electrostatic voltmeter which was calibrated with a sphere-gap. The anode base was connected to the current measuring circuit. The entire high-potential generator was enclosed in a grounded screen cage, since it was found that without it, leakage currents in the air would get to the galvanometer giving large deflections.

2. METHOD OF OBSERVATION

Immediately before mounting, the electrodes were polished with 600 mesh carborundum powder held on the heel of the hand. They were washed in alcohol, dried without touching, and mounted.

The field between the electrodes could be varied by varying either the

distance between the electrodes or the applied potential. Numerous measurements showed that the two methods gave the same result.

After the first complete field-current curve had been measured, the potential was cut off and the electrodes touched to measure the setting of the micrometer for zero distance between electrodes. The e.m.f.'s in the rectifying tube (not more than 5 volts) were sufficient to give dependable deflections on the galvanometer upon contact. The largest emission previously drawn was again drawn at the corresponding field, and it was assumed that the intermediate determination of the zero had not effectively changed the surfaces for further study. When mixed electrodes were used (see section 6), zero distance was always measured after all measurements of emission were completed.

The data collected were plotted with the inverse field times 10^6 and the logarithm of the current, as coordinates. The points on the curves represent the lower limits of the current at each sitting. This was done because a study showed that in those comparatively few cases the current varied over a material range, the lowest value was quite near the final value if allowed to become steady. Most of the first emission curves are curled back at currents above 10^{-4} amperes because the drop in applied potential caused by the drop through the external resistance becomes appreciable at this value. No attempt has been made to draw straight lines to represent characteristics because it is believed to be more important to keep clearly in mind the probable uncertainty of the measurements. It is believed that reliable conclusions can be drawn only when the zone on a figure enclosing all of the emission from one kind of electrode surface is entirely separate from the zone enclosing all of the emission from another kind of an electrode surface.

3. GENERAL OBSERVATIONS

The behavior of surfaces which have not been "conditioned" is exceedingly erratic and unsystematic. In spite of this fact, a very considerable amount of data was taken in an attempt to determine statistically what relations (1) degree of polish, (2) purity, (3) electroplating, (4) hardness and (5) work function, have to emission. Measurements were made on cast iron, steel, armco iron, vacuum fused electrolytic iron, magnesium (two grades of purity), aluminum, copper, brass, zinc, gold-plated copper, nickel-plated brass, chromium-plated brass, and "Plymite" (an extremely hard compound of tungsten and carbon). This quite extensive study did not lead to any conclusive results.

It was established, however, that with fair polish and fair purity, or better, the first emission always began at a much higher field, and suffered a sudden spontaneous increase of a large order of magnitude at a still higher field, i.e., a "breakdown," than the fields at which emission was drawn from the same emitting surface subsequently.

4. EFFECT OF SPACE CHARGE DUE TO POSITIVES

The possibility suggested itself that positives liberated from the anode by the electron stream from the cathode, might follow the electron stream,

which is known to be well focussed, and set up a space charge which in turn increased the emission. This possibility was tested by measuring the emission in an apparatus as shown in Fig. 3. *P* is a needle-point of the metal to be studied. It was mounted on a screw-in-vacuum which could be moved by a magnet, in the direction of the point. *A* and *B* are polished copper bars, six inches long, 3/4 inch wide, and 1/8 inch thick, with edges rounded. There was a hole in *A* as shown, through which the point was extended toward *B*. *A* and *P* were at ground potential and *B* was at any desired potential up to 20,000 volts. Currents were measured from *P*. Any desired magnetic field up to 7,000 gauss could be applied perpendicularly to the figure by an electromagnet with pole-pieces as shown. The apparatus was always baked out before

Fig. 3. Diagram of apparatus for measuring emission in magnetic field.

measurements were begun, and the pressure between the bars was, in all experiments, less than 1×10^{-5} mm, as shown by an ionization gauge at the opposite end of the tube from the pumping outlet.

Both a tungsten and a copper needle-point were tried. Emission began from the points at a comparatively low potential, and decreased (fatigued) even with increased potentials. There were times, however, during this fatigue, when the emission would remain steady within five percent for several minutes.

If the tip of the point, *P* is above the plane of the lower face of the upper plate, and a magnetic field of 7,000 gauss is applied to apparatus of the dimensions used in this experiment, it can be shown that electrons emitted from *P* cannot arrive at the plate *B* directly below *P*, but will be displaced along *B* to some place beyond the region of this magnetic field.

The cycloidal path predicted by the theory was actually seen outlined on the glass walls opposite the space between the plates, and displaced down the tube to the edge of the region of high magnetic field.

Emission was drawn from *P* in the above position and the current measured while putting the magnetic field on and off. The magnetic field was

found to have no effect on the magnitude of the current, to within five percent, which was the degree of steadiness of the emission from the points.

The conclusion may be drawn that if the positives which are known to go from the anode to the cathode, produce a space charge near the emitting surface, the effect of this space charge on the field at the surface is *not* of importance in determining the magnitude of emission after breakdown.

5. EFFECT OF DISCHARGES THROUGH HYDROGEN ON EMITTING SURFACES

Four filaments were mounted on the tube shown in Fig. 1 at the four quadrants about the center electrode. They were sealed in glass plugs which could be sealed with wax into the ground glass joints on the tube as shown in Fig. 4. At the side of one of these joints, the pumping tube *V* was attached.

Fig. 4. Diagram of tube showing arrangement of four filaments.

At the side of another, the ionization gauge *G* was attached. At the side of a third, a slow gas inlet *C* consisting of a fine capillary and a stopcock was attached. Glass shields for both steel electrode posts, *A* and *B*, were mounted to eliminate emission from the posts and also to protect them from sputtering.

Copper electrodes were used throughout this work on the effect of discharge through hydrogen.

In order to differentiate sharply between the true effect of discharges upon the emitting surfaces and any auxiliary phenomena in the tube, tests were made of the effect of lighting the filaments introducing hydrogen to atmospheric pressure and pumping out, introducing air similarly, letting stand for up to sixteen hours, and bombarding with electrons (20 m.a., bringing the electrode to about 75°C temperature). The changes due to none of these treatments was materially greater than the changes observed between repeated measurements of the characteristic of a particular surface.

Fig. 5 is submitted as a basis of comparison for the following figures. Curves 1, 2, 3, and 4 are the first emission observed at each of four independent emitting areas. Curves 5, 6, 7 and 8 are the subsequent emissions for the same areas in order.

Each group of three curves in Fig. 6 represents the history of an independent emitting area. In each group, curve 1 represents the first emission, which emission followed bombardment with positives at the current and for

Fig. 5. Emission from untreated copper electrodes.

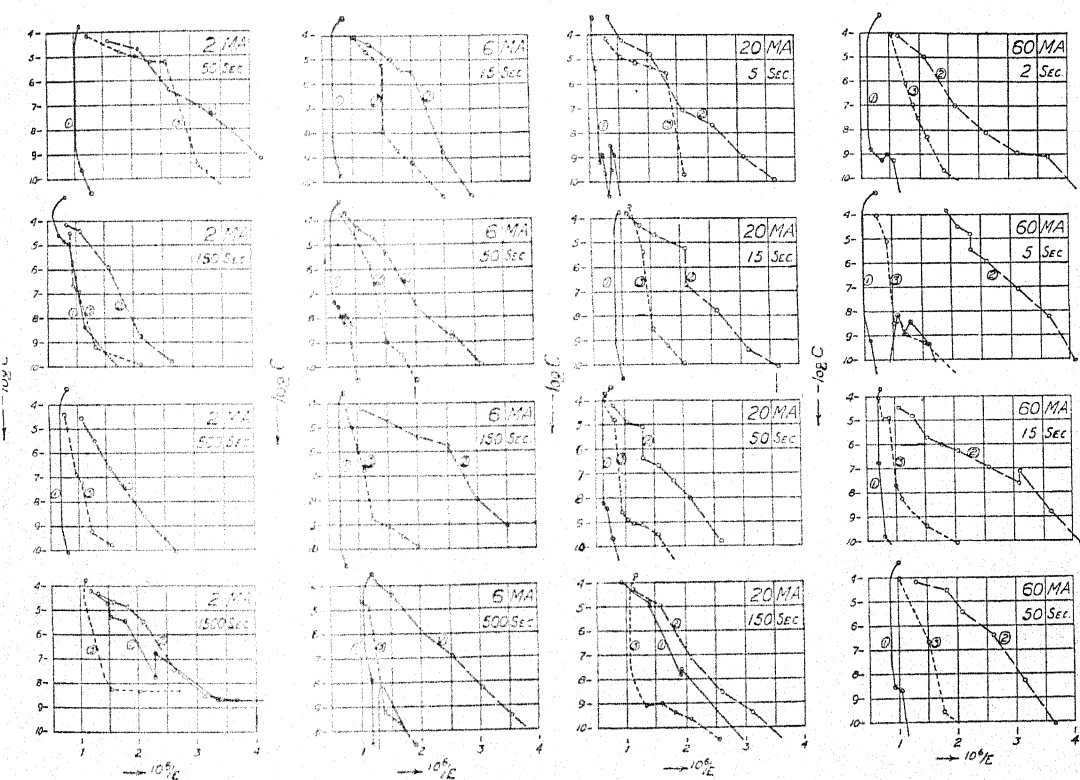

Fig. 6. Effect of discharge through hydrogen.

the time indicated. Curve 2 represents the subsequent emission, which was measured immediately following the first emission. Curve 3 represents the emission which followed another bombardment with positives at the same current and for the same time as before. These bombardments were made through hydrogen at the highest pressure (between 1 mm and 12 mm pressure) which would permit the negative glow completely to surround the bombarded electrode, which was the cathode in both the glow discharge and the measurement of the emission.

A study of the curves will show that up to a certain point, bombardment with positives does not seem to affect the field at which breakdown first occurs, but that there is a current and time for which a bombardment with positives restores the emitting surface after breakdown to the condition it had before breakdown occurred.

6. EFFECT OF THE ANODE

Measurements were made of the emission from a copper cathode but with various anodes. Anodes used were of copper, iron, magnesium, zinc, plymite,

Fig. 7. Plymite anode.

Fig. 8. Copper anode.

aluminum, chromium-plate, and molybdenum. Complete sets of measurements were made for at least four independent emitting areas for each combination of electrodes, and the set which appeared to be most typical for each kind of anode is shown with the corresponding label in Figs. 7 to 14. The curves are numbered in the order taken.

Repeated attempts to fatigue the emitting surfaces on copper cathodes, using copper, plymite, or iron anodes, giving emission like that shown in curve 2 of Figs. 7, 8 or 10, respectively, failed to give any significant change in slope. The change was uncertain with a zinc anode.

On the other hand, using either a molybdenum, aluminum, chromium, or magnesium anode, the emitting surface quickly fatigued to a new group of curves occupying a zone on the figure definitely removed from that occupied by subsequent emission curves for copper anodes, and corresponding to much lower currents from the same fields.

7. TEMPORARY BREAKDOWN

Frequently, with various electrodes, throughout the entire investigation, there have occurred very sudden large order increases in current (up to 10^6)

which behaved like premature breakdowns. These presently just as suddenly completely disappeared, accompanied by a distinct click of the glass, sounding as though a metal particle had hit the glass. On pushing the field up, the breakdown occurred at the usual field and all subsequent currents behaved the same as though the premature breakdown had not occurred.

Fig. 9. Iron anode.

Fig. 10. Zinc anode.

Fig. 11. Magnesium anode.

Fig. 12. Aluminum anode.

Fig. 13. Chromium plate anode.

Fig. 14. Molybdenum anode.

8. DISCUSSION

The idea that the first breakdown is simply due to a rupturing of the surface of the cathode and that the emission is determined by the composition and conditioning of the cathode, has appeared to be open to question from early in this investigation.

The phenomenon of premature breakdown seems to leave no doubt that foreign particles either from the anode or from parts of the tube other than the cathode, *can* fly through the tube to the cathode, adhere, give emission, and be torn from the cathode leaving no scar on the cathode of sufficient irregularity to give measurable emission.

Following excessive discharge through hydrogen (which was observed to give sputtering), the first emission was seen to behave either as though a complete breakdown has been produced during the discharge through hydrogen, or else as though no sensible effect had been produced on the cathode surface at all (see curves 1, each of the lower four groups in Fig. 6). It was never observed after sputtering had been produced in the tube either during these measurements or with any other electrodes under different conditions, that immediately subsequent field-current curves lay in the region between the two zones belonging to emission leading up to the usual breakdown, or the emission following the usual breakdown, respectively. This fact would seem to indicate that the adhesion of a loose particle to the cathode gives emission indistinguishable from that following the usual breakdown.

Following breakdown, when molybdenum, aluminum, chromium, or magnesium were used as anode, the lowest subsequent currents measurable occurred at fields much higher than those at which the lowest currents occurred when copper was used as the anode. The most plausible explanation of this seems to be that auto-electronic emission is from a particle torn from the anode and which is adhering to the cathode.

If, on the other hand, the breakdown is due to a rupturing of the copper cathode surface, it would be necessary to suppose that the steeper slopes, when one of the above four metals was used as anode, are due to beating down the ragged edges by positives coming from the anode at emission currents of less than 10^{-10} amperes, and that the emitting point is bombarded with positives of the same order of density as occur in a discharge through hydrogen of several milliamperes spread over the entire cathode surface. In view of the small size of the emitting points, this is a possible supposition. It is further supported by the fact that after prolonged auto-electronic discharge, the white color of the anode metal becomes distinguishable as a small spot at the emitting point on the copper cathode. This explanation, however, forces us to the conclusion that the emission measured is from a surface of metal originally composing the anode, and hence the emission is determined by the metal used as anode, anyhow.

In conclusion, the author wishes to thank Drs. Millikan, MacKeown, and Lauritsen for advice borne of their longer experience in this field, and also Dr. Millikan for making available the necessary facilities for this investigation.

SCATTERING OF HIGH VELOCITY ELECTRONS IN HYDROGEN AS A TEST OF THE INTERACTION ENERGY OF TWO ELECTRONS

By HUGH C. WOLFE*

CALIFORNIA INSTITUTE OF TECHNOLOGY, PASADENA

(Received January 26, 1931)

ABSTRACT

1. The electronic scattering of high velocity electrons is considered as a test of the formulas for the interaction energy of two electrons. Three formulas for the interaction energy of two Dirac electrons are considered: I, the simple electrostatic interaction, II, the Gaunt formula, III, the Breit formula.

2. The Dirac transition probability method is reviewed briefly.

3. The cross-section of free electrons at rest for scattering high velocity electrons is calculated by the Dirac transition probability method, using each of the three formulas for interaction energy. Random distribution of spins is assumed. Relativistic variation of mass with velocity is taken into account, removing the symmetry about 45° of the classical scattering formula. Expanded to terms in β^2 the formulas obtained are compared with the classical Darwin formula and the recent formula of Mott. They differ from Mott's formula and from each other by terms of order β^2 .

4. For high-velocity electrons, the scattering by hydrogen may be considered as the sum of nuclear and electronic scattering. A criterion for the validity of this procedure is obtained. The advantage of using hydrogen as the scatterer in experiments to test these formulas is discussed.

I. THE scattering of electrons by hydrogen may be considered as the sum of the scattering by free protons and the scattering by free electrons, provided the incident velocity is high and the scattering angle is not too near 0 or $\pi/2$. A criterion for the validity of this approximation is developed in section 4.

The cross-section for scattering depends upon the energy of interaction of the scatterer and the scattered particle and there is no completely justified theoretical formula for the interaction of two electrons or of an electron and a proton. Three formulas have been used,

$$\begin{aligned} \text{I} \quad V &= e^I e^{II} / r \\ \text{II} \quad V &= e^I e^{II} / r [1 - (\alpha^I \cdot \alpha^{II})] \\ \text{III} \quad V &= e^I e^{II} / r \left[1 - \frac{(\alpha^I \cdot \alpha^{II})}{2} - \frac{(\alpha^I \cdot r)(\alpha^{II} \cdot r)}{2r^2} \right]. \end{aligned} \quad (1)$$

The α 's, written here as vectors, have components which are the matrices of four rows and columns appearing as coefficients in the Dirac linear Hamiltonian for one particle. r is the distance between the particles. I is just the electrostatic interaction. II includes "spin" terms. III includes also the effect of

* National Research Fellow.

retardation of the potentials. III, which was first derived by Breit,¹ on the analogy $v/c \rightarrow \alpha$, and which is obtained in first approximation from the Heisenberg-Pauli field theory by systematic neglect of the infinite proper energy terms, has the most theoretical justification. However, Breit² has calculated the fine structure of helium with it and his results are no better than those of Gaunt,³ who derived and used II. This failure may be due to the inadequacy of the approximate wave functions used. It is, therefore, of interest to find another place to use these formulas, where it may be possible to determine which gives results in better agreement with experiment.

For scattering of electrons by protons, a calculation similar to that given here for scattering by electrons has been carried out. The result is that the extra terms in II or III have a negligible influence. Massey⁴ concurs in this result. Thus Mott's calculation using I, gives the best formula for nuclear (proton) scattering.⁵

2. The cross-section of an electron for scattering electrons is calculated here in first approximation by the transition probability method of Dirac.⁶ The Hamiltonian for the system, incident electron plus scatterer, is to be written in the form $H = H^0 + V$, where H^0 represents the system as it is observed experimentally. The eigenstates $\Psi(\alpha')$ of the unperturbed system whose Hamiltonian is H^0 , are known and are specified by giving the values, here assumed continuous in range, of a set of observables, $\alpha_1 \cdots \alpha_n$, which are constants of the motion. We shall frequently use α to represent $\alpha_1 \cdots \alpha_n$. The state Ψ of the system whose Hamiltonian is H is to be expanded in the eigen Ψ 's of the unperturbed system,

$$\Psi = \int \Psi(\alpha') d\alpha' a(\alpha'),$$

where $a(\alpha')$ is a function of the time, i.e., the method of variation of constants. Substituting in the equation

$$H\Psi = \frac{i\hbar}{2\pi} \frac{\partial}{\partial t} \Psi,$$

we obtain an integral equation for the time variation of $a(\alpha')$. Assuming that at some initial time our system would certainly be observed in the state α^0 , i.e., initially $a(\alpha') = \alpha^0 \delta(\alpha' - \alpha^0)$, this equation reduces to a simple differential equation which can be integrated. The normalization of the $a(\alpha')$ is such that we are concerned not with one system but with an ensemble of similar

⁴ Massey, Proc. Roy. Soc. **A127**, 666 (1930).

⁵ Mott, Proc. Roy. Soc. **A124**, 425 (1929). He formulates the problem rigorously, using Gordon's solutions of the Dirac equation, and approximates by expanding in powers of $\alpha = Z(2\pi e^2/\hbar c)$, neglecting terms in α^2 .

⁶ Dirac, Proc. Roy. Soc. **A114**, 243 (1927) or Dirac, Principles of Quantum Mechanics, Oxford, 1930, section 54.

systems. The number of systems in our ensemble is $|a^0|^2 \int dx |\psi_{\alpha 0}(x)|^2$, where x stands for the whole set of coordinates and $\psi_{\alpha 0}(x)$ is a solution of the wave-equation for the unperturbed system in the initial state. Then $|a(\alpha')|^2 d\alpha'$ is the number of systems at time t such that α lies between α' and $\alpha' + d\alpha'$. The expression for $|a(\alpha')|^2$ shows that essentially only those transitions occur in which energy is conserved. If we transform to a new set of parameters, $W, \gamma_1 \cdots \gamma_{u-1}$, which are arbitrary independent functions of the α 's, the number of transitions per second from the initial state to states in which the γ 's have values between γ' and $\gamma' + d\gamma'$ is found, by integration with respect to W' , to be

$$4\pi^2/h^2 |a^0|^2 |(W^0, \gamma' | V | W^0, \gamma^0)|^2 J(W^0, \gamma') d\gamma_1' \cdots d\gamma_{u-1}'. \quad (2)$$

$J(W^0, \gamma')$ is the Jacobian, $\partial(\alpha_1' \cdots \alpha_u')/\partial(W', \gamma_1' \cdots \gamma_{u-1}')$, with the values $W^0, \gamma_1' \cdots \gamma_{u-1}'$ for the variables. $(W^0, \gamma' | V | W^0, \gamma^0)$ is the matrix element $(\alpha' | V | \alpha^0)$, where the α 's are so determined that the parameters, $W, \gamma_1 \cdots \gamma_{u-1}$, have the values $W^0, \gamma_1^0 \cdots \gamma_{u-1}^0$ in the initial state and $W^0, \gamma_1' \cdots \gamma_{u-1}'$ in the final state. If $V = V(x, p)$ is a function of the coordinates and conjugate momenta, then

$$(\alpha' | V | \alpha^0) = \int N_{\alpha'} \psi_{\alpha'}(x) dx V \left(x, \frac{h}{2\pi i} \frac{\partial}{\partial x} \right) \psi_{\alpha 0}(x). \quad (3)$$

All of our expressions assume that the wave functions have the continuous spectrum normalization, equivalent to the Dirac δ normalization. $N_{\alpha'}$ is the normalizing factor for the final state wave functions and is given⁷ by

$$N_{\alpha'}^2 \int dx \tilde{\psi}_{\alpha'}(x) \int_{\alpha' - \Delta\alpha'}^{\alpha' + \Delta\alpha'} d\alpha'' \psi_{\alpha''}(x) = 1. \quad (4)$$

For our purposes, the normalization of the initial state wave functions is quite arbitrary. This is because we are interested in the cross-section for scattering, σ_s , which is defined from the classical treatment of collision scattering by

$$\sigma_s = \frac{\text{Number of transitions per sec. of the specified type, i.e. (2)}}{(\text{Flux of incident particles}) \cdot (\text{number of scatterers})}. \quad (5)$$

Both $|a^0|^2$ and the initial state normalizing factors occur in both numerator and denominator and cancel out.

3. In our problem the Hamiltonian H^0 is the sum of the Dirac linear Hamiltonians for two free electrons. The wave equation for the unperturbed system is

$$\left[W - \frac{hc}{2\pi i} \{ (\alpha^I \cdot \text{grad}^I) + (\alpha^{II} \cdot \text{grad}^{II}) \} - mc^2(\alpha_0^I + \alpha_0^{II}) \right] \psi = 0.$$

This equation has solutions of the form $\psi = \psi^I \psi^{II}$ with $W = W_1 + W_2$, where ψ^I is a solution of

⁷ Oppenheimer, Phys. Rev. 31, 66 (1928).

$$\left[W_1 - \frac{\hbar c}{2\pi i} (\alpha^I \cdot \text{grad}^I) - mc^2 \alpha_0^I \right] \psi^I = 0$$

and similarly ψ^{II} . The solution in the form of plane waves has been given by Darwin.⁸ The four components of ψ^I are

$$\begin{aligned} \psi_3 &= AS_1^I & \psi_1 &= \frac{-Ap_{1z} - B(p_{1x} - ip_{1y})}{mc + W_1/c} S_1^I, \\ \psi_4 &= BS_1^I & \psi_2 &= \frac{-A(p_{1x} + ip_{1y}) + Bp_{1z}}{mc + W_1/c} S_1^I \end{aligned} \quad (6)$$

where

$$\begin{aligned} W_1 &= c(m^2c^2 + p_{1x}^2 + p_{1y}^2 + p_{1z}^2)^{1/2} \\ S_1^I &= \exp \left[\frac{2\pi i}{h} (p_{1x}x_1 + p_{1y}y_1 + p_{1z}z_1 - W_1t) \right]. \end{aligned}$$

Darwin shows that the orientation of the spin axis, as given by its colatitude f , measured from the z axis, and longitude ω , is given by the relation $-B/A = \cot f/2e^{i\omega}$. Accordingly, $A=0, B=1$, means that the spin is "parallel" to the z axis, and the corresponding four components of the wave function may be represented by the one symbol Ψ_α . Likewise, $B=0, A=1$, means that the spin is "antiparallel" to the z axis and for this case we may write ψ_β . The constants of the motion, whose values designate the eigenstates of the unperturbed system (the α 's of section 2), are the components of momentum of the two particles $p_{1x}, p_{1y}, p_{1z}, p_{2x}, p_{2y}, p_{2z}$. We shall use a lower index 1 or 2 to indicate that the corresponding momentum is (p_{1x}, p_{1y}, p_{1z}) or (p_{2x}, p_{2y}, p_{2z}) . Thus the symbol $\psi_{2\alpha}^I$ means the four component wave function in the coordinates (x_1, y_1, z_1) for momentum (p_{2x}, p_{2y}, p_{2z}) with $A=0, B=1$.

To take account of the random distribution of spins of the two electrons before the collision, we use wave functions for the initial state which represent equal probabilities for each electron to have its spin parallel or antiparallel to the z axis. As pointed out by Oppenheimer,⁹ our wave functions must be antisymmetric to conform to the Pauli principle, since we are dealing with identical particles with spin. Accordingly, our initial state wave functions may have the form

$$\begin{aligned} \psi_a &= 1/(2)^{1/2} (\psi_{1\alpha}^I \psi_{2\alpha}^{II} - \psi_{2\alpha}^I \psi_{1\alpha}^{II}) \\ \psi_b &= 1/(2)^{1/2} (\psi_{1\beta}^I \psi_{2\beta}^{II} - \psi_{2\beta}^I \psi_{1\beta}^{II}) \\ \psi_c &= \frac{1}{2} (\psi_{1\alpha}^I \psi_{2\beta}^{II} - \psi_{2\beta}^I \psi_{1\alpha}^{II} + \psi_{1\beta}^I \psi_{2\alpha}^{II} - \psi_{2\alpha}^I \psi_{1\beta}^{II}) \\ \psi_d &= \frac{1}{2} (\psi_{1\alpha}^I \psi_{2\beta}^{II} - \psi_{2\beta}^I \psi_{1\alpha}^{II} - \psi_{1\beta}^I \psi_{2\alpha}^{II} + \psi_{2\alpha}^I \psi_{1\beta}^{II}). \end{aligned} \quad (7)$$

where the first three of these are symmetric in the spins and the fourth is antisymmetric in the spins.

The spin distribution in the final state is not to be measured and is deter-

⁸ Darwin, Proc. Roy. Soc. A120, 621 (1928).

⁹ Oppenheimer, Phys. Rev. 32, 361 (1928).

mined only by the transition probabilities. Wave functions representing any spin orientations can be built up by superposition of four wave functions of the type (7). We shall use a ϕ to represent the complex conjugate of a final state wave function, only the complex conjugates occurring in our formulas. The final state momenta will be designated by $p_{1x}', p_{1y}', p_{1z}', p_{2x}', p_{2y}', p_{2z}'$. The total transition probability out of any one of the four initial spin states is the sum of the transition probabilities to four final spin states of type (7). We shall have taken account of the initial random spin orientations if we take the unweighted average of the total probabilities of transition out of the four initial spin states. Specifically, this means to calculate sixteen cross-sections for scattering, using the matrix elements obtained from all combinations of $\phi_a, \phi_b, \phi_c, \phi_d$ with $\psi_a, \psi_b, \psi_c, \psi_d$, and to take one fourth of the sum.

We shall transform from $p_{1x}, p_{1y}, p_{1z}, p_{2x}, p_{2y}, p_{2z}$ to a new set of parameters $W, P_x, P_y, P_z, \theta, \phi$ (the $W, \gamma_1 \cdots \gamma_{u-1}$ of section 2), where (P_x, P_y, P_z) is the momentum of the center of gravity and θ, ϕ are the polar angles of the momentum (p_{1x}, p_{1y}, p_{1z}) , the z axis being taken as pole. The equations of transformation are

$$\begin{aligned} W &= c(m^2c^2 + p_1^2)^{1/2} + c(m^2c^2 + p_2^2)^{1/2} & P_x &= p_{1x} + p_{2x} \\ \cos \theta &= p_{1z}/p_1 & P_y &= p_{1y} + p_{2y} \\ \tan \phi &= p_{1y}/p_{1x} & P_z &= p_{1z} + p_{2z} \end{aligned}$$

It is convenient also to use center of gravity coordinates X, Y, Z , relative coordinates x, y, z and relative momenta p_x, p_y, p_z , the equations of transformation being

$$\begin{aligned} X &= \frac{1}{2}(x_1 + x_2) & x &= x_1 - x_2 & p_x &= \frac{1}{2}(p_{1x} - p_{2x}) \\ Y &= \frac{1}{2}(y_1 + y_2) & y &= y_1 - y_2 & p_y &= \frac{1}{2}(p_{1y} - p_{2y}) \\ Z &= \frac{1}{2}(z_1 + z_2) & z &= z_1 - z_2 & p_z &= \frac{1}{2}(p_{1z} - p_{2z}). \end{aligned}$$

Note that

$$\frac{\partial(x_1, y_1, z_1, x_2, y_2, z_2)}{\partial(X, Y, Z, x, y, z)} = 1.$$

Let us now consider the matrix elements $(\alpha' | V | \alpha'')$. They are of the form

$$\int \cdots \int dx_1 \cdots dz_2 \phi_i V \psi_j$$

where i and j take on the values a, b, c, d . V is considered as an operator on ψ_j . The integrand will consist of a sum of terms of the form

$$\phi_{l'n'}^I \phi_{n't'}^{II} V \psi_{ls}^I \psi_{nt}^{II}$$

where l, n , may be 1, 2 or 2, 1; l', n' may be 1, 2 or 2, 1; s, t, s', t' may be α or β . The only operators contained in V are the Dirac α 's and the result of their operation is just to permute the four components of a ψ function and to introduce some factors -1 or i . Also α^I operates¹⁰ only on ψ^I and α^{II} on ψ^{II} so that, for example,

¹⁰ The two electrons are independent in the unperturbed system and all matrices associated with one commute with all matrices associated with the other.

$$\phi^I \phi^{II} \alpha_1^I \alpha_3^{II} \psi^I \psi^{II} = (\phi^I \alpha_1^I \psi^I) (\phi^{II} \alpha_3^{II} \psi^{II}).$$

We write the expressions (6) for the four components of $\phi_{\nu'}^I$ in the form $(\phi_{\nu'}^I)_\lambda = a_\lambda' S_{\nu'}^I$, and for the four components of ψ_i^I in the form $(\psi_i^I)_\lambda = a_\lambda S_i^I$, where $\lambda = 1, 2, 3, 4$, and define

$$\begin{aligned}\Omega_4 &= a_1' a_1 + a_2' a_2 + a_3' a_3 + a_4' a_4 \\ \Omega_1 &= a_1' a_4 + a_2' a_3 + a_3' a_2 + a_4' a_1 \\ \Omega_2 &= a_1' a_4 - a_2' a_3 + a_3' a_2 - a_4' a_1 \\ \Omega_3 &= a_1' a_3 - a_2' a_4 + a_3' a_1 - a_4' a_2.\end{aligned}\tag{8}$$

We define Ω' 's similarly in terms of the components of $\phi_{\nu'}^{II}$ and ψ_n^{II} . Further we write

$$S = \exp [2\pi i/h \{ (p_1^0 \cdot r_1) + (p_n^0 \cdot r_2) - (p_{\nu'}^I \cdot r_1) - (p_n^{II} \cdot r_2) \}].$$

Then with our three V 's of (1), we have for our typical term in the integrand

$$\begin{aligned}& \phi_{\nu'}^{I*} \phi_{\nu'}^{II} V \psi_{is}^I \psi_{nt}^{II} = \\ & \text{I} \quad e^2/r [\Omega_4 \Omega_4'] S \\ & \text{II} \quad e^2/r [\Omega_4 \Omega_4' - \Omega_1 \Omega_1' + \Omega_2 \Omega_2' - \Omega_3 \Omega_3'] S \\ & \text{III} \quad e^2/r [\Omega_4 \Omega_4' - \frac{1}{2} \{ \Omega_1 \Omega_1' - \Omega_2 \Omega_2' + \Omega_3 \Omega_3' \} \\ & \quad - 1/2r^2 \{ x\Omega_1 - iy\Omega_2 + z\Omega_3 \} \{ x\Omega_1' - iy\Omega_2' + z\Omega_3' \}] S.\end{aligned}\tag{9}$$

Since

$$\begin{aligned}(p_1 \cdot r_1) + (p_2 \cdot r_2) &= (P \cdot R) + (p \cdot r) \\ (p_1 \cdot r_2) + (p_2 \cdot r_1) &= (P \cdot R) - (p \cdot r),\end{aligned}\tag{10}$$

it follows that in every case our integrand contains a factor

$$\exp \left[\frac{2\pi i}{h} \{ (P^0 \cdot R) - (P' \cdot R) \} \right].$$

Consequently, if we carry out the integration in the variables X, Y, Z, x, y, z instead of $x_1, y_1, z_1, x_2, y_2, z_2$, every matrix element has the factor

$$\int \int \int dX dY dZ \exp \left[\frac{2\pi i}{h} \{ (P^0 \cdot R) - (P' \cdot R) \} \right].$$

This integral is of the nature of a δ function of $(P^0 - P')$ so that we have a transition probability only between initial and final states such that the momentum of the system is conserved, as well as the energy. Consequently, we shall be interested only in the number of transitions from the initial state to final states in which θ lies between θ and $\theta + d\theta$ and ϕ lies between ϕ and $\phi + d\phi$. This means going back to (2), the γ 's being $P_x', P_y', P_z', \theta, \phi$, and integrating with respect to P_x', P_y', P_z' as we had previously integrated with respect to W' . Although P' occurs in other factors, e.g., in J , besides

$$\left| \int \int \int dX dY dZ \exp \left[\frac{2\pi i}{h} \{ (P^0 \cdot R) - (P' \cdot R) \} \right] \right|^2,$$

this factor predominates and assures us that we shall have contributions to the integral only for $P' = P^0$. Accordingly, we insert $P' = P^0$ in all other factors and take them outside the integration. We note that the remaining integral is just the cube of

$$\int_{-\infty}^{\infty} dP_x' \left| \int_{-\infty}^{\infty} dX \exp \left[\frac{2\pi i}{h} (P_x^0 - P_x') X \right] \right|^2.$$

We replace $\int_{-\infty}^{\infty} dX$ by $\lim_{X=\infty} \int_X^X dX$ and carry out the limiting process after integrating with respect to P_x' , obtaining $\lim_{X=\infty} 2hX$. Thus the factor obtained from integration over P_x', P_y', P_z' is just $h^3 V$, where V is the infinite volume of space.

For the remainder of our considerations, we may note that instead of using the parameters $W, P_x, P_y, P_z, \theta, \phi$ and inserting $W' = W^0$ and $P' = P^0$, it is more convenient to use $p_{1x}, p_{1y}, p_{1z}, p_{2x}, p_{2y}, p_{2z}$, where the values assigned are to be determined by the principles of conservation of energy and momentum, together with the requirement that p_1' shall have the direction $\theta\phi$. For the initial state, we shall take

$$p_{1z}^0 = p_1^0 = \frac{mv}{(1 - \beta^2)^{1/2}}; p_{1x}^0 = p_{1y}^0 = p_{2x}^0 = p_{2y}^0 = p_{2z}^0 = 0 \quad (11)$$

which means that we consider a plane wave of electrons of velocity $v = \beta c$, incident in the z direction on electrons at rest. For the final state, since we have symmetry about the z axis, we are independent of ϕ and may most conveniently use $\phi = 0$. We shall also introduce the notation

$$\gamma = 1/(1 - \beta^2)^{1/2}, \quad \sigma = \sin \theta, \quad \rho = \cos \theta.$$

Then we have

$$\begin{aligned} p_{1x}' &= p_1^0 \frac{2\sigma\rho}{2 + (\gamma - 1)\sigma^2} & p_{2z}' &= -p_1^0 \frac{2\sigma\rho}{2 + (\gamma - 1)\sigma^2} \\ p_{1y}' &= 0 & p_{2y}' &= 0 \\ p_{1z}' &= p_1^0 \frac{2\rho^2}{2 + (\gamma - 1)\sigma^2} & p_{2x}' &= p_1^0 \frac{(\gamma + 1)\sigma^2}{2 + (\gamma - 1)\sigma^2}. \end{aligned} \quad (12)$$

The density of particles being $\sum_{\lambda=1}^4 |\psi_{\lambda}|^2$, we have by (6) a density $2\gamma/(\gamma + 1)$ electrons per cc in our incident beam and a density of one electron per cc of scatterers. Accordingly, the incident flux is $2\gamma v/(\gamma + 1)$ and the number of scatterers is V , the infinite volume of space. The Jacobian, J , of (2) has the value

$$J = \frac{4m^2 v \gamma \rho \sigma [2\gamma - (\gamma - 1)\sigma^2] [\gamma(\gamma + 1)\sigma^2 + 2\rho^2]}{[2 + (\gamma - 1)\sigma^2]^4}.$$

From the normalization of the final state wave functions by (4), we find for the factor $N_{\alpha'}$.

$$N^2 = \frac{(\gamma + 1)[(\gamma + 1)^2\sigma^2 + 4\rho^2]}{2h^6[2\gamma - (\gamma - 1)\sigma^2][\gamma(\gamma + 1)\sigma^2 + 2\rho^2]}.$$

With this value of J in (2) and of N in (3), we insert in (5) and obtain

$$\sigma_s = \frac{4\pi^2 m^2 \rho \sigma (\gamma + 1)^2 [(\gamma + 1)^2 \sigma^2 + 4\rho^2] d\theta d\phi}{h^4 [2 + (\gamma - 1)\sigma^2]^4} F^2,$$

where F^2 is one fourth of the sum of the squares of the factors obtained by integration over the relative coordinates in the sixteen matrix elements of the interaction energy, V .

To evaluate F^2 , we must go back to (9), which is the typical term of our integrand if we write S_r instead of S and understand by S_r the remainder of the exponential factor, S , after taking out

$$\exp \left[\frac{2\pi i}{h} \{ (P^0 \cdot R) - (P' \cdot R) \} \right].$$

As a consequence of (10) and using the values of p^0 and p' given by (11) and (12), this remaining factor has the following form, determined by values of l and l' ,

$$\begin{aligned} l = 1, \quad l' = 1 \quad S_r &= \exp \left[\frac{2\pi i}{h} (p_2' \cdot r) \right] \\ l = 2, \quad l' = 2 \quad S_r &= \exp \left[-\frac{2\pi i}{h} (p_2' \cdot r) \right] \\ l = 2, \quad l' = 1 \quad S_r &= \exp \left[\frac{2\pi i}{h} (p_1' \cdot r) \right] \\ l = 1, \quad l' = 2 \quad S_r &= \exp \left[-\frac{2\pi i}{h} (p_1' \cdot r) \right]. \end{aligned} \quad (14)$$

The integration of (9) with respect to the relative coordinates x, y, z , may be carried out in cylindrical coordinates¹¹ or in polar coordinates, the pole being taken in the direction of the momentum p_k' which occurs in S_r . In the latter case, convergence is obtained by taking account of screening at infinite distance. The integrals occurring are

$$\begin{aligned} \int \int \int dx dy dz \, 1/r \exp [2\pi i/h p_k' z] &= h^2/(\pi p_k'^2) \\ \int \int \int dx dy dz \, z^2/r^3 \exp [2\pi i/h p_k' z] &= -h^2/(\pi p_k'^2). \end{aligned} \quad (15)$$

¹¹ Oppenheimer, Zeits. f. Physik 43, 413 (1927).

Then the integration of (9) over the relative coordinates gives

$$\begin{aligned}
 \text{I} \quad & \frac{e^2 \hbar^2}{\pi p_k'^2} [\Omega_4 \Omega_4'] \\
 \text{II} \quad & \frac{e^2 \hbar^2}{\pi p_k'^2} [\Omega_4 \Omega_4' - \Omega_1 \Omega_1' + \Omega_2 \Omega_2' - \Omega_3 \Omega_3'] \\
 \text{III} \quad & \frac{e^2 \hbar^2}{\pi p_k'^2} [\Omega_4 \Omega_4' + \Omega_2 \Omega_2' - (\Omega_1 \rho_k - \Omega_3 \sigma_k)(\Omega_1' \rho_k - \Omega_3' \sigma_k)].
 \end{aligned} \tag{16}$$

Here ρ_k and σ_k are the cosine and sine of the angle between $+p_k'$ and the z axis.

The remainder of the task is the evaluation of the Ω 's and Ω' 's, the summing of the various terms of the type (16) that occur in each matrix element, the squaring of the resulting expressions and taking one fourth of their sum. Only the results are given here.

For purposes of comparison with previous formulas, it is useful to expand all our expressions in powers of β^2 , neglecting higher powers than β^2 . The resulting formulas for the cross-section of a free electron at rest for scattering electrons into a solid angle $\sin\theta d\theta d\phi$ are

$$\sigma_s = \frac{e^4}{m^2 v^4} \sin 2\theta \, 2d\theta \, d\phi \left[\frac{1}{\sigma^4} + \frac{1}{\rho^4} - \frac{1}{\sigma^2 \rho^2} - \frac{\beta^2}{4} f(\theta) \right] \tag{17}$$

where $f(\theta)$ is given by

$$\begin{aligned}
 \text{I} \quad f(\theta) &= \frac{4}{\sigma^4} + \frac{2}{\rho^4} - \frac{1}{\sigma^2 \rho^2} \\
 \text{II} \quad f(\theta) &= \frac{4}{\sigma^4} + \frac{2}{\rho^4} - \frac{2}{\sigma^2 \rho^2} \\
 \text{III} \quad f(\theta) &= \frac{4}{\sigma^4} + \frac{2}{\rho^4} - \frac{3}{\sigma^3 \rho^2}.
 \end{aligned} \tag{18}$$

The purely classical formula of Darwin¹² gives the first two terms in the bracket,

$$\frac{1}{\sigma^4} + \frac{1}{\rho^4} = \operatorname{cosec}^4 \theta + \operatorname{cosec}^4 (\pi/2 - \theta).$$

Mott¹³ has calculated the scattering of electrons by electrons, using interaction formula I, rigorously on the wave mechanics, taking account of interchange phenomena but not of the relativistic variation of mass with velocity. For low velocities, his formula is better than ours. In the region in which our formulas apply, we may neglect the square and higher powers of $1/137\beta$, in

¹² Darwin, Phil. Mag. 27, 499 (1914).

¹³ Mott, Proc. Roy. Soc. A126, 259 (1930).

which case Mott's formulas gives just the first three terms in the bracket of (17). It may be noted that $f(\theta)$ is not symmetric about the angle $\theta = \pi/4$, whereas the classical formulas had this symmetry. This was to be expected because, when we take account of the relativistic variation of mass with velocity in setting up the equations for the conservation of energy and momentum, the angle between the two scattered electrons is not $\pi/2$ but is $\arccos \{(\gamma-1)\sigma\rho/(\gamma+1)^2\sigma^2+4\rho^2\}^{1/2}$ or, in the same approximation as the above, $\arccos \{\beta^2/8[1+\beta^2/4(2+\rho^2)]\sin 2\theta\}$.

For comparison with experimental data, we should use the complete formula, rather than the expansion in powers of β^2 . Our F^2 can be written in the form

$$F^2 = \frac{e^4 h^4 [2 + (\gamma - 1)\sigma^2]^4}{\pi^2 m^4 c^4 (\gamma^2 - 1)^2 [4 + (\gamma - 1)(\gamma + 3)\sigma^2]^2} F(\theta). \quad (19)$$

Substituting (19) in (13), we have

$$\sigma_s = \frac{e^4 (\gamma + 1)^2 \sin 2\theta \, 2d\theta \, d\phi}{m^2 v^4 \gamma^4 [4 + (\gamma - 1)(\gamma + 3)\sigma^2]} F(\theta) \quad (20)$$

where the complete expression for $F(\theta)$ is

$$\begin{aligned} \text{II } F(\theta) = & \frac{1}{\sigma^4} + \frac{1}{\rho^4} - \frac{1}{\sigma^2 \rho^2} + \frac{(\gamma - 1)}{\sigma^4 \rho^4} \left[3\sigma^6 + \sigma^4 \rho^6 - \sigma^6 \rho^2 + \frac{2\rho^6(1 + \sigma^2 \rho^2)}{\gamma + 1} \right. \\ & \left. - \frac{2(\gamma + 1)\sigma^2 \rho^4}{4 + (\gamma - 1)(\gamma + 3)\sigma^2} \right] \\ & + \frac{(\gamma - 1)^2}{8\sigma^4 \rho^4} \left[\sigma^6 \{ 12 - (\gamma + 1)(\gamma - 3)\sigma^2 + 2\gamma(\gamma + 2)\sigma^4 \} \right. \\ & + \frac{8\sigma^4 \rho^4 (3 + \sigma^2)}{\gamma + 1} + \frac{24\sigma^4 \rho^4}{4 + (\gamma - 1)(\gamma + 3)\sigma^2} - \frac{16(\gamma - 1)\sigma^2 \rho^6}{(\gamma + 1)[4 + (\gamma - 1)(\gamma + 3)\sigma^2]} \\ & \left. + \frac{8\rho^6(1 + 3\sigma^2 + 3\sigma^4)}{(\gamma + 1)^2} - \frac{32\gamma\sigma^2 \rho^6}{[4 + (\gamma - 1)(\gamma + 3)\sigma^2]^2} \right]. \\ \text{III } F(\theta) = & \frac{1}{\sigma^4} + \frac{1}{\rho^4} - \frac{1}{\sigma^2 \rho^2} + \frac{(\gamma - 1)}{2\sigma^4 \rho^4} \left[5\sigma^6 + \sigma^8 + \frac{4\rho^6}{\gamma + 1} + \frac{4\sigma^2 \rho^6}{(\gamma + 1)^2} \right] \\ & + \frac{(\gamma - 1)^2}{4\sigma^4 \rho^4} \left[\sigma^4 \{ -4 + 23\sigma^2 + (\gamma^2 + 6\gamma - 13)\sigma^4 + (\gamma^2 - 2\gamma - 3)\sigma^6 - (\gamma^2 - 5)\sigma^8 \} \right. \\ & + \frac{2\sigma^4 \rho^4 (5 - 4\sigma^4)}{\gamma + 1} + \frac{8\sigma^2 \rho^4 (2 + 2\sigma^2 + (2\gamma - 3)\sigma^4 - (\gamma - 1)\sigma^6)}{4 + (\gamma - 1)(\gamma + 3)\sigma^2} \\ & \left. + \frac{4\rho^6(1 + 3\sigma^2 + 2\sigma^4)}{(\gamma + 1)^2} - \frac{16(\gamma^2 - 1)\sigma^4 \rho^4}{[4 + (\gamma - 1)(\gamma + 3)\sigma^2]^2} \right]. \end{aligned} \quad (21)$$

4. *Criterion for neglect of orbital motion of electron in hydrogen.* The scattering of electrons in hydrogen may be considered as the sum of the scattering by free protons and the scattering by free electrons, both at rest, provided the error in the scattering by the electrons, due to their orbital motion, is negligible. This error is of the order

$$\epsilon = \Delta\sigma_s/\sigma_s$$

where $\Delta\sigma_s$ is the change in σ_s if the square of the momentum of the incident electron is changed by the square of the orbital momentum of the electron in the atom or molecule. Using our formulas for σ_s , we obtain a value for ϵ which, for fast electrons and small angles may be written

$$\epsilon \sim \frac{1 - 3/2\beta^2}{10^4\beta^2 \sin \theta}$$

and for angles near $\pi/2$ may be written

$$\epsilon \sim \frac{1 - \frac{1}{2}\beta^2}{10^4\beta^2 \cos^2 \theta}$$

This is just equivalent to considering the error in the nuclear scattering formula of Wentzel when we drop the $1/k^2a^2$ term¹⁴ and obtain $1/\sin^4\theta/2$ instead of $1/[\sin^2\theta/2 + (1/ka)^2]^2$. For a 140,000 volt electron, the error is 1 per cent at 7° angle of scattering.

5. Since scattering at angles greater than $\pi/2$ is purely nuclear and should be given by Mott's formula,¹⁵ while scattering at angles less than $\pi/2$ is both nuclear and electronic, it is hoped that the part of the scattering due to the electrons may be separated off experimentally and compared with the formulas derived here. Hydrogen is suggested as the scatterer for this test, in spite of the experimental difficulties of working with gases, first because there, only, is the electronic scattering, which increases with the atomic number Z , comparable with the nuclear scattering, which increases with Z^2 , and second because the separation of nuclear and electronic scattering is possible at lower voltages with hydrogen than with any other element, the necessary voltage going up roughly with Z . Mr. H. V. Neher, at this institute, is hoping to carry out experiments in the scattering of high velocity electrons in hydrogen in the near future.

The writer wishes to thank Professor J. R. Oppenheimer for many helpful suggestions.

ON THE GRAVITATIONAL FIELD PRODUCED BY LIGHT

BY RICHARD C. TOLMAN, PAUL EHRENFEST AND BORIS PODOLSKY
NORMAN BRIDGE LABORATORY OF PHYSICS, PASADENA, CALIFORNIA

(Received January 19, 1931)

ABSTRACT

Expressions are obtained, in accordance with Einstein's approximate solution of the equations of general relativity valid in weak fields, for the effect of steady pencils and passing pulses of light on the line element in their neighborhood. The gravitational fields implied by these line elements are then studied by examining the velocity of test rays of light and the acceleration of test particles in such fields. Test rays moving parallel to the pencil or pulse do so with uniform unit velocity the same as that in the pencil or pulse itself. Test rays moving in other directions experience a gravitational action. A test particle placed at a point equally distant from the two ends of a pencil experiences no acceleration parallel to the pencil, but is accelerated towards the pencil by *twice* the amount which would be calculated from a simple application of the Newtonian theory. The result is satisfactory from the point of view of the conservation of momentum. A test particle placed at a point equally distant from the two ends of the track of a pulse experiences no net integrated acceleration parallel to the track, but experiences a net acceleration towards the track which is satisfactory from the point of view of the conservation of momentum.

§1. *Introduction.* The purpose of this article is to investigate, from the standpoint of the general theory of relativity, the gravitational field in the neighborhood of steady beams and isolated pulses of light.¹

In Part I of the article we shall obtain a general expression for the line element in the presence of a flow of electromagnetic radiation, which will be taken for simplicity as travelling in the X -direction. The calculation will be made on the assumption that the effect of the radiation is small enough so that Einstein's approximate solution of the gravitational equations valid in weak fields can be employed.

In Part II we shall then examine the special form assumed by the line element in the neighborhood of a thin pencil of radiation travelling along the X -axis. We shall find that the pencil must be taken as having only a finite length in order to keep the field weak enough to justify the use of Einstein's approximate method of solution, and hence shall consider the pencil of radiation as travelling between an emitting and an absorbing body which are a finite distance apart.

Abstracting from the gravitational effect of the absorbing and emitting bodies, we shall then investigate the gravitational action of the radiation by determining the effect of its field on the velocity of test rays of light and on the acceleration of test particles in the neighborhood of the pencil. As to the

¹ An investigation of the gravitational field of radiation has also recently been carried out by Rosenfeld, *Zeits. f. Physik* **65**, 589 (1930). The article deals, however, with questions relating to quantization rather than with the problems which we shall treat in the present paper.

behavior of the test rays, we shall find that a ray of light moving parallel to the pencil and in the same direction would have unit velocity, the same as that in the pencil itself; but in the case of rays moving in other directions we shall find that they would suffer a gravitational disturbance when in the field of the pencil. As to the behavior of test particles, we shall find that a stationary test particle located at a point equally distant from the two ends of the pencil would experience no acceleration parallel to the track of the pencil, but would be accelerated towards the pencil by *twice* the amount, which would be calculated from the Newtonian theory of gravitation by taking the gravitational mass of the radiation as equal to its energy divided by the square of the velocity of light.

The fact that the acceleration of the particle is twice that which would be calculated from a simple application of the Newtonian theory does not seem surprising, when we recall that the bending of a ray of light in passing through a given gravitational field, say that of the sun, is found theoretically and experimentally in the case of weak enough fields to permit the Newtonian approximation, also to be *twice* that which would be calculated from the Newtonian theory taking the gravitational mass of the light as equal to its inertial mass. The occurrence of the factor 2 in both places permits us to retain our familiar ideas as to the conservation of momentum as a first approximation.

In Part III we shall turn to a consideration of the gravitational field in the neighborhood of a passing pulse of radiation, and shall find that this would vary with the time in a manner to be calculated by the method of retarded potentials, the gravitational influence spreading out from the pulse with the velocity of light. As in the case of the pencil of radiation, we shall find also here that we must limit the track of the pulse so as to lie between an emitting and an absorbing body a finite distance apart, since Einstein's approximate method of solving the gravitational equations would fail at the time when the pulse passes abreast of the point of interest, if we should assume an infinite length for the track.

With regard to the behavior of test rays of light in the neighborhood of the track, we shall again find that a ray of light moving parallel and in the same direction as the pulse would have unit velocity, the same as that of the pulse itself, and that rays of light moving in other directions would be subject to a gravitational effect when in the field of the passing pulse. To investigate the behavior of particles in the field of the pulse, we shall consider a stationary test particle, located at a point equally distant from the two ends of the track lying between the source and absorber, and then determine in accordance with the method of retarded potentials what acceleration the particle would receive as a result of the gravitational influences emitted from this portion of the track. Parallel to the track we shall find that the particle would first be accelerated in the direction of motion of the pulse and later in the opposite direction, but that the time integral of this component of the acceleration corresponding to the total influence emitted from the portion of the track considered would be zero. Perpendicular to the motion of the pulse we shall find as a *net* result that the particle would act as though attracted to-

wards the track, and that the time integral of the perpendicular acceleration, corresponding to the total influence emitted from the portion of the track considered, would be just sufficient so that here also as in the case of the pencil of radiation we could maintain in first approximation our older ideas as to the conservation of momentum for the gravitational interaction of a particle with light.

PART I. GENERAL TREATMENT OF THE GRAVITATIONAL FIELD OF RADITION

§2. *Einstein's approximate solution of the field equations.* We may now proceed to a general treatment of the gravitational field due to radiation. We shall assume the total amount, density and distribution of the radiation to be such that the gravitational potentials $g_{\mu\nu}$ occurring in the general theory of relativity will differ but slightly from the values which they have in empty space. Such an assumption would presumably be justified in the case of any ordinary beam or pulse of light that we might encounter in nature or the laboratory, and introduces a great simplification by permitting the use of Einstein's approximate solution of the gravitational equations, valid in the case of weak fields.

In accordance with this approximate treatment we may write the line element in the form

$$ds^2 = g_{\mu\nu} dx_\mu dx_\nu = (\delta_{\mu\nu} + h_{\mu\nu}) dx_\mu dx_\nu \quad (1)$$

where the symbols $\delta_{\mu\nu}$ denote the Galilean values of $g_{\mu\nu}$, namely -1 , $+1$ and 0 , and the $h_{\mu\nu}$ are small quantities of the first order whose square can be neglected. We may also use the symbols $\delta^{\mu\nu}$ and δ^ν_μ to denote the Galilean values of $g^{\mu\nu}$ and g^ν_μ and define the quantities h^ν_μ and h by the equations

$$h^\nu_\mu = \delta^{\nu\alpha} h_{\mu\alpha} \text{ and } h = h_\alpha^\alpha. \quad (2)$$

It can then be shown that an approximate solution of the equations of general relativity which connect the metric with the distribution of matter and energy is given by the equation²

$$\left[h^\nu_\mu - \frac{1}{2} \delta^\nu_\mu h \right] (x, y, z, t) = -4 \iiint \frac{[T_\mu^\nu](\bar{x}, \bar{y}, \bar{z}, t-r)}{r} d\bar{x} d\bar{y} d\bar{z} \quad (3)$$

where the integration is to be taken over all elements of spatial volume $d\bar{x} d\bar{y} d\bar{z}$, the quantity r is the coordinate distance from the element of volume at $\bar{x}, \bar{y}, \bar{z}$ to the point of interest at x, y, z , and $[T_\mu^\nu]$ is the value of the energy-momentum tensor in the element of volume at such a time $t-r$, that an influence travelling from $\bar{x}, \bar{y}, \bar{z}$ with unit velocity would reach the point of interest x, y, z at the time of interest t .

§3. *The energy-momentum tensor for radiation.* To use the above solution in our problem, we must have an expression for the energy-momentum tensor for radiation. In any purely electromagnetic field, however, is it known that

² See Eddington, "The Mathematical Theory of Relativity," Cambridge 1923, Eq. (57.6)

the components of the energy-momentum tensor using natural coordinates have the values illustrated by the following typical examples.³

$$T_1^1 = \frac{1}{2}(X^2 - Y^2 - Z^2) + \frac{1}{2}(\alpha^2 - \beta^2 - \gamma^2) \quad (4)$$

$$T_1^2 = XY + \alpha\beta \quad (5)$$

$$T_1^4 = \beta Z - \gamma Y \quad (6)$$

$$T_4^4 = \frac{1}{2}(X^2 + Y^2 + Z^2) + \frac{1}{2}(\alpha^2 + \beta^2 + \gamma^2) \quad (7)$$

where X, Y, Z are the components of the electric field strength and α, β, γ are the components of the magnetic field strength at the point of interest.

Applying these equations now to the case of radiation which we take for simplicity to be moving parallel to the X -axis in the positive direction, and noting the relations of (4) and (5) to the Maxwellian stresses in the field, of (6) to the Poynting vector, and of (7) to the energy density, it can be shown that the only surviving components of the energy-momentum tensor for the case of polarized or unpolarized incoherent radiation will be

$$T_1^1 = -\rho \quad T_4^4 = \rho \quad T_1^4 = -\rho \quad T_4^1 = \rho \quad (8)$$

where ρ is the density of energy, and, since the velocity of light is unity, also the density of energy flow at the point of interest. The results assume the justifiability of neglecting diffraction phenomena, such as would occur at the boundary of a beam of radiation where the hypothesis of a flow of energy solely in the X -direction could not be strictly valid.

§4. *The general form of line element due to radiation.* The above equations give the components of the energy-momentum tensor in coordinates which are Galilean at the point of measurement, but to the order of approximation of the solution we are to use, they may also be taken as the components of that tensor in our general system of coordinates which differs from the Galilean form only by quantities of the first order, and hence may be substituted into equation (3) to determine the form of the line element.

Doing so we obtain

$$\begin{aligned} h_1^1 - \frac{1}{2}h &= 4 \int \frac{[\rho]dV}{r} \\ h_2^2 - \frac{1}{2}h &= 0 \\ h_3^3 - \frac{1}{2}h &= 0 \\ h_4^4 - \frac{1}{2}h &= -4 \int \frac{[\rho]dV}{r} \\ h_1^4 &= -h_4^1 = 4 \int \frac{[\rho]dV}{r} \end{aligned} \quad (9)$$

with all other components of h_{μ}^{ν} equal to zero. And remembering the value of h and the method of raising suffixes given by equations (2) we can easily solve these equations for the $h_{\mu\nu}$. We then obtain as the only surviving components

³ See Eddington, reference 2, Eqs. (77.41-4).

$$h_{11} = h_{44} = -h_{14} = -h_{41} = -4 \int \frac{[\rho] dV}{r} \quad (10)$$

and these values of the $h_{\mu\nu}$ can be substituted into Eq. (1) to give the general form of the line element due to radiation travelling in the X -direction.

PART II. THE GRAVITATIONAL ACTION OF A PENCIL OF LIGHT

§5. *The line element in the neighborhood of a limited pencil of radiation.* As a first application of the expression for the line element due to radiation travelling in the X -direction, it would be natural to try to treat the gravitational field in the neighborhood of a thin pencil of radiation of uniform density, stretching in the X -direction from minus to plus infinity. But this proves to be impossible by the method adopted, since the values of the $h_{\mu\nu}$ come out infinite when the integration indicated in Eq. (10) is performed, which would invalidate the approximate solution of the gravitational equations that has been used.

If we consider, however, a thin pencil of radiation of limited length l and constant linear density ρ , passing steadily along the X -axis between a source at $x=0$ and an absorber at $x=l$, this difficulty does not arise, since we can then evidently write in accordance with Eq. (10) for the contribution of the radiation to the gravitational field at any point of interest x, y, z in the neighborhood of the pencil,

$$\begin{aligned} 4 \int \frac{[\rho] dV}{r} &= -h_{11} = -h_{44} = h_{14} = h_{41} \\ &= \int_{u=0}^{u=l} \frac{4\rho du}{[(x-u)^2 + y^2 + z^2]^{3/2}} \\ &= 4\rho \log \frac{[(l-x)^2 + y^2 + z^2]^{1/2} + l - x}{[x^2 + y^2 + z^2]^{1/2} - x} \end{aligned} \quad (11)$$

which remains finite for finite values of the density ρ and length of pencil l .

It should be noted that Eq. (11) has been derived on the assumption of a *steady* pencil of radiation between the source and absorber, so that no explicit introduction of retarded potentials into the calculation was necessary. Hence of course the expression obtained would not be applicable in the neighborhood of times when the pencil is being started or stopped. It should also be noted that Eq. (11) gives only the contribution of the radiation in the pencil to the gravitational field and neglects the contribution of the bodies which act as source and absorber. This includes a neglect of any effects resulting from changes in the motion or internal condition of these bodies which might themselves be thought of as connected with the flow of radiation.

With these restrictions, however, the values of the surviving components of $h_{\mu\nu}$ given by Eq. (11) may be substituted into Eq. (1) to give the form of the line element in the neighborhood of the pencil of radiation.

§6. *Velocity of a test ray of light in the neighborhood of the pencil.* Having obtained Eq. (11) which gives the effect of the radiation on the form of the line element, we may now investigate the motion of test rays of light and test particles as affected by the presence of the pencil. In accordance with the theory of general relativity, the velocity of light will be given by setting the expression for the line element ds equal to zero. Substituting the values for the components of $h_{\mu\nu}$ given by (11) into the general expression for the line element (1) setting the result equal to zero, and writing

$$h = 4\rho \log \frac{[(l-x)^2 + y^2 + z^2]^{1/2} + l - x}{[x^2 + y^2 + z^2]^{1/2} - x} \quad (12)$$

as an abbreviation, (not the h of §2) we then easily obtain for the velocity of a test ray in the X -direction parallel to the pencil, the two cases

$$\frac{dx}{dt} = +1 \quad \text{and} \quad -\frac{1-h}{1+h} \quad (13)$$

and for the velocity say in the Y -direction in a plane perpendicular to the pencil, the two cases

$$\frac{dy}{dt} = \pm (1-h)^{1/2}. \quad (14)$$

In accordance with these expressions, we note that a test ray of light moving parallel to the pencil and in the same direction would have unit velocity the same as that in the pencil itself, but that rays moving in other directions would have a variable velocity depending as might be expected on their position in the gravitational field of the pencil. Furthermore, it can easily be shown for the case of a test ray moving parallel to the pencil and in the same direction that we should have, not only $dx/dt=1$, but also $d^2x/dt^2=d^2y/dt^2=d^2z/dt^2=0$, which is a satisfactory result from the point of view of the stability of the light pencil itself.

§7. *Acceleration of a test particle in the neighborhood of the pencil.* We may also use our knowledge of the line element to investigate the gravitational acceleration which would be experienced by a test particle placed in the neighborhood of the pencil.

In accordance with the theory of general relativity, the acceleration of a particle is determined by the equation for a geodesic

$$\frac{d^2x_\alpha}{ds^2} + \{\mu\nu, \alpha\} \frac{dx_\mu}{ds} \frac{dx_\nu}{ds} = 0 \quad (15)$$

and if we apply this equation to a particle which is at rest in our system of coordinates, we can substitute

$$\frac{dx_\mu}{ds} = 0 \quad \text{for the cases } \mu = 1, 2, 3 \quad (16a)$$

and to our order of approximation

$$\frac{dx_\mu}{ds} = \frac{dt}{ds} = 1 \text{ for the case } \mu = 4 \quad (16b)$$

so that equation (15) will then assume the simple form

$$\frac{d^2x}{dt^2} = -\{44, 1\}, \quad \frac{d^2y}{dt^2} = -\{44, 2\}, \quad \frac{d^2z}{dt^2} = -\{44, 3\} \quad (17)$$

for the cases $\alpha = 1, 2, 3$.

To calculate the values of the Christoffel symbols occurring in equations (17), we have the general equation of definition

$$\{\mu\nu, \sigma\} = \frac{1}{2}g^{\sigma\lambda}\left(\frac{\partial g_{\mu\lambda}}{\partial x_\nu} + \frac{\partial g_{\nu\lambda}}{\partial x_\mu} - \frac{\partial g_{\mu\nu}}{\partial x_\lambda}\right) \quad (18)$$

and noting the values of the $g_{\mu\nu}$ which correspond to Eqs. (11), we shall evidently obtain to our order of approximation the simple expressions

$$\frac{d^2x}{dt^2} = -\frac{1}{2} \frac{\partial h_{44}}{\partial x}, \quad \frac{d^2y}{dt^2} = -\frac{1}{2} \frac{\partial h_{44}}{\partial y}, \quad \frac{d^2z}{dt^2} = -\frac{1}{2} \frac{\partial h_{44}}{\partial z}. \quad (19)$$

Substituting then for h_{44} the value given by (11), and performing the indicated differentiations, we can finally obtain, after some simplifications, for the acceleration of a stationary test particle parallel to the line of the pencil the expression

$$\frac{d^2x}{dt^2} = 2\rho \left\{ \frac{1}{[x^2 + y^2 + z^2]^{1/2}} - \frac{1}{[(l-x)^2 + y^2 + z^2]^{1/2}} \right\} \quad (20)$$

and for the acceleration in a plane perpendicular to the pencil expressions of the form

$$\frac{d^2y}{dt^2} = -\frac{2\rho y}{y^2 + z^2} \left\{ \frac{x}{[x^2 + y^2 + z^2]^{1/2}} + \frac{l-x}{[(l-x)^2 + y^2 + z^2]^{1/2}} \right\}. \quad (21)$$

The first thing of importance to be noted from these rather complicated expressions for the acceleration is the fact, in accordance with Eq. (20), that the acceleration parallel to the pencil becomes zero for a particle placed at a point $x=l/2$ midway between the two ends of the pencil. Furthermore for a particle midway between the two ends of the pencil, with $x=l/2$ and $z=0$, Eq. (21) gives for the acceleration towards the pencil the simple result

$$-\frac{d^2y}{dt^2} = \frac{2\rho l}{y[(l/2)^2 + y^2]^{1/2}}. \quad (22)$$

The most important characteristic of these expressions for the acceleration, however, is the fact that they can easily be shown to be exactly *twice* as great as would be calculated from the simple Newtonian theory by taking

the gravitational mass of the radiation equal to its inertial mass. This is due to the fact that the quantity $h_{44}/2$ occurring in Eqs. (19) is twice the simple Newtonian expression for the gravitational potential of the pencil. As noted in the introduction this is a very satisfactory result, since in the case of weak fields we now see that the factor 2 occurs not only as is known in the expression for the action of a particle on light, but also in the expression for the action of light on a particle, and we are hence able to retain in first approximation our familiar ideas as to the conservation of momentum.

PART III. THE GRAVITATIONAL ACTION OF A PULSE OF LIGHT

§8. *The line element in the neighborhood of a pulse of radiation.* As already noted, the considerations of Part II were only applicable to the gravitational field surrounding a steady pencil of light and we shall now turn to a consideration of the gravitational field of a passing pulse of radiation. This will be more complicated to treat since the field will obviously be non-static and we shall have to make specific use of the method of retarded potentials to determine the way in which the gravitational effect spreads out from the moving pulse.

Let us consider a pulse of radiation, of length λ , linear density ρ , and small cross-section, travelling along the X -axis from $x=0$ to $x=l$, which may be taken as the points at which the radiation emerges from the source and enters the absorber, or as giving an arbitrary portion of the track selected for investigation. Furthermore, let us for convenience choose our time scale to make $t=0$ when the front end of the pulse crosses the point $x=0$, so that at any later time t the front end of the pulse will be located at $x=t$ and the rear end at $x=t-\lambda$.

Let us now take some point of interest x, y, z in the neighborhood of the track, and calculate with the help of Eq. (10) the gravitational field produced by the pulse at this point at the time t . Since Eq. (10) has to be applied in accordance with the method of retarded potentials, let us denote by $x=a$ the position of the front end of the pulse and by $x=b$ the position of the rear end of the pulse when they "emit" the gravitational influence which is received at the point x, y, z at the time t . Then we may evidently write in accordance with Eq. (10) for the gravitational potentials at x, y, z and t

$$\begin{aligned} 4 \int \frac{[\rho] dV}{r} &= -h_{11} = -h_{44} = h_{14} = h_{41} \\ &= \int_{u=b}^{u=a} \frac{4\rho du}{[(x-u)^2 + y^2 + z^2]^{3/2}} \\ &= 4\rho \log \frac{[(x-a)^2 + y^2 + z^2]^{1/2} - x + a}{[(x-b)^2 + y^2 + z^2]^{1/2} - x + b} \end{aligned} \quad (23)$$

provided we take the YZ -dimensions of the pulse as small compared with $(y^2 + z^2)^{1/2}$.

To evaluate this result, however, we must determine a and b as functions of the time. To do this we note that $t-a$ is the distance through which the

gravitational influence "travels" in going from the front end of the pulse to reach the point x, y, z at the time t , and hence we can evidently write

$$(t - a)^2 = (x - a)^2 + y^2 + z^2 \quad (24)$$

and solving obtain for a the expression

$$a = \frac{t^2 - x^2 - y^2 - z^2}{2(t - x)} \quad (25)$$

Similarly we obtain for b the expression

$$b = \frac{(t - \lambda)^2 - x^2 - y^2 - z^2}{2(t - \lambda - x)} \quad (26)$$

In using these expressions in connection with Eq. (23), however, we shall take the position of the rear end of the pulse to be $b=0$ until the pulse has completely emerged from the source at $x=0$, and take the position of the front end as $a=l$ after the pulse has started to enter the absorber at $x=l$. We do this since our interest lies in the gravitational influences correlated with the track of the pulse between $x=0$ and $x=l$.

Substituting the above values of a and b into Eq. (23), we then easily obtain the three following cases for the time intervals indicated

$$\begin{aligned} 4 \int \frac{[\rho]dV}{r} &= -h_{11} = -h_{44} = h_{14} = h_{41} \\ &= 4\rho \log \frac{t - x}{[x^2 + y^2 + z^2]^{1/2} - x} \quad \left\{ \begin{array}{l} \text{from } t = [x^2 + y^2 + z^2]^{1/2} \\ \text{to } t = [x^2 + y^2 + z^2]^{1/2} + \lambda \end{array} \right. \\ &= 4\rho \log \frac{t - x}{t - \lambda - x} \quad \left\{ \begin{array}{l} \text{from } t = [x^2 + y^2 + z^2]^{1/2} + \lambda \\ \text{to } t = l + [(l - x)^2 + y^2 + z^2]^{1/2} \end{array} \right. \\ &= 4\rho \log \frac{[(l - x)^2 + y^2 + z^2]^{1/2} - x + l}{t - \lambda - x} \quad \left\{ \begin{array}{l} \text{from } t = l + [(l - x)^2 + y^2 + z^2]^{1/2} \\ \text{to } t = l + [(l - x)^2 + y^2 + z^2]^{1/2} + \lambda \end{array} \right. \end{aligned} \quad (27)$$

and the form of the line element in the different time intervals indicated will be given by substituting these values for the surviving components of $h_{\mu\nu}$ in the general expression for the line element (1). The results show that here also as in the case of the pencil it is necessary to take a limited track for the light pulse, since if the pulse were regarded as coming from an infinitely remote position on the X -axis the field would become infinite at the time $t=x$ when the pulse comes abreast of the point of interest. With our treatment, however, there is no effect from the track of the pulse before the time $t=[x^2 + y^2 + z^2]^{1/2}$, nor after the time $t=l+[(l-x)^2 + y^2 + z^2]^{1/2} + \lambda$.

§9. *Velocity of a test ray of light in the neighborhood of the pulse.* Substituting these values for the components of $h_{\mu\nu}$ into the expression for the line element (1) and setting the result equal to zero, we can now obtain information as to the velocity of test rays as affected by the pulse. Writing for simplicity

$$h = 4 \int \frac{[\rho]dV}{r} \quad (28)$$

as a general abbreviation for the different expressions given by Eqs. (27), we then easily obtain for the velocity of a test ray in the X -direction parallel to the track, the two cases

$$\frac{dx}{dt} = +1 \text{ and } -\frac{1-h}{1+h} \quad (29)$$

and for the velocity in a plane perpendicular to the track, say in the Y -direction, the two cases

$$\frac{dy}{dt} = \pm (1-h)^{1/2}. \quad (30)$$

As in the case of the pencil, we note that a test ray of light moving parallel to the motion of the pulse and in the same direction would have unit velocity the same as that for the pulse itself, but that rays moving in other directions would have a variable velocity depending on time and position. Here too, it can easily be shown for the case of a test ray moving parallel to the motion of the pulse and in the same direction that we should have, not only $dx/dt=1$, but also $d^2x/dt^2=d^2y/dt^2=d^2z/dt^2=0$, which is a satisfactory result from the point of view of the stability of the pulse itself.

§10. *Acceleration of a test particle due to the pulse.* We must now investigate the gravitational acceleration which would be experienced by a test particle as a result of the passage of the pulse of light. If we take the particle as stationary the accelerations will evidently be determined by the same Eqs. (17)

$$\frac{d^2x}{dt^2} = -\{44, 1\}, \quad \frac{d^2y}{dt^2} = -\{44, 2\}, \quad \frac{d^2z}{dt^2} = -\{44, 3\} \quad (31)$$

as were applicable in the case of the pencil, but the values of the Christoffel symbols will of course be different. To calculate these we may again start with the general equation of definition

$$\{\mu\nu, \sigma\} = \frac{1}{2}g^{\sigma\lambda}\left(\frac{\partial g_{\mu\lambda}}{\partial x_\nu} + \frac{\partial g_{\nu\lambda}}{\partial x_\mu} - \frac{\partial g_{\mu\nu}}{\partial x_\lambda}\right) \quad (32)$$

and noting the values of the $g_{\mu\nu}$ which correspond to Eqs. (27), we can evidently write to our order of approximation

$$\begin{aligned} \{44, 1\} &= -\frac{1}{2}\left(\frac{\partial h_{41}}{\partial t} + \frac{\partial h_{41}}{\partial t} - \frac{\partial h_{44}}{\partial x}\right) \\ \{44, 2\} &= \frac{1}{2} \frac{\partial h_{44}}{\partial y} \\ \{44, 3\} &= \frac{1}{2} \frac{\partial h_{44}}{\partial z} \end{aligned} \quad (33)$$

Substituting the values of h_{44} and h_{41} given by Eqs. (27), and for simplicity considering the particle to be placed at point for which $z=0$, we can obtain for the acceleration parallel to the track of the pulse during the time intervals indicated

$$\begin{aligned} \frac{d^2x}{dt^2} &= 2\rho \left(\frac{1}{t-x} + \frac{1}{(x^2+y^2)^{1/2}} \right) && \begin{cases} \text{from } t = (x^2+y^2)^{1/2} \\ \text{to } t = (x^2+y^2)^{1/2} + \lambda \end{cases} \\ &= 2\rho \left(\frac{1}{t-x} - \frac{1}{t-\lambda-x} \right) && \begin{cases} \text{from } t = (x^2+y^2)^{1/2} + \lambda \\ \text{to } t = l + [(l-x)^2+y^2]^{1/2} \end{cases} \quad (34) \\ &= -2\rho \left(\frac{1}{t-\lambda-x} + \frac{1}{[(l-x)^2+y^2]^{1/2}} \right) && \begin{cases} \text{from } t = l + [(l-x)^2+y^2]^{1/2} \\ \text{to } t = l + [(l-x)^2+y^2]^{1/2} + \lambda \end{cases} \end{aligned}$$

And for the acceleration perpendicular to the track we obtain for the same time intervals

$$\begin{aligned} \frac{d^2y}{dt^2} &= \frac{-2\rho y}{(x^2+y^2)^{1/2}[(x^2+y^2)^{1/2}-x]} && \begin{cases} \text{from } t = (x^2+y^2)^{1/2} \\ \text{to } t = (x^2+y^2)^{1/2} + \lambda \end{cases} \\ &= 0 && \begin{cases} \text{from } t = (x^2+y^2)^{1/2} + \lambda \\ \text{to } t = l + [(l-x)^2+y^2]^{1/2} \end{cases} \quad (35) \\ &= \frac{2\rho y}{[(l-x)^2+y^2]^{1/2}} \frac{1}{[(l-x)^2+y^2]^{1/2} + l-x} && \begin{cases} \text{from } t = l + [(l-x)^2+y^2]^{1/2} \\ \text{to } t = l + [(l-x)^2+y^2]^{1/2} + \lambda \end{cases} \end{aligned}$$

In accordance with these expressions, we see that parallel to the track the particle would first be accelerated in the same direction as the motion of the pulse, and then in the opposite direction. On the other hand perpendicular to the motion of the pulse, the particle would first be accelerated towards the track and later away from it. And we must now investigate the total integrated acceleration corresponding to the whole track of the pulse, and compare the results with those which might be expected in first approximation from our older ideas as to the conservation of momentum.

§11. *Time integral of acceleration of test particle due to the pulse.* Making use of the expressions for the acceleration of the test particle parallel to the track of the pulse given by Eqs. (34), we may now obtain the time integral of the acceleration over the three intervals given, and adding together obtain an expression for the total time integral corresponding to the track of the pulse. Doing so and cancelling out a considerable number of balancing terms, it can easily be shown that we finally obtain for the total integral

$$\int \frac{d^2x}{dt^2} dt = 2\rho\lambda \left\{ \frac{1}{(x^2+y^2)^{1/2}} - \frac{1}{[(l-x)^2+y^2]^{1/2}} \right\}. \quad (36)$$

As might be expected the net acceleration of the test particle parallel to the track depends on the relative magnitudes of the total length of the track l and

the distance along the track x at which the particle is placed. When the test particle is midway between the two ends of the track at $x=l/2$, there is no net acceleration parallel to the track. Otherwise the net parallel acceleration is in the direction towards which the longer segment of the track lies.

Turning now to the acceleration perpendicular to the track it can easily be shown from Eqs. (35) that we obtain for the net integrated acceleration

$$\int \frac{d^2y}{dt^2} dt = - \frac{2\rho\lambda}{y} \left\{ \frac{x}{(x^2 + y^2)^{1/2}} + \frac{l-x}{[(l-x)^2 + y^2]^{1/2}} \right\}. \quad (37)$$

And considering the particle to be located midway between the two ends of the track at $x=l/2$ this reduces to

$$\int \frac{d^2y}{dt^2} dt = - \frac{2\rho\lambda l}{y[(l/2)^2 + y^2]^{1/2}}. \quad (38)$$

This result may now be compared with what would be expected from a simple application of ideas as to the conservation of momentum for the combined interaction of particle and light pulse. If we write

$$m = \rho\lambda \quad (39)$$

as an abbreviation for the mass of the light pulse, i.e., its energy divided by the square of the velocity of light, and write M for the mass of the particle, Eq. (38) will then give us for the total momentum acquired by the (stationary) test particle towards the track

$$\int M \frac{d^2y}{dt^2} dt = - \frac{2mMl}{y[(l/2)^2 + y^2]^{1/2}}. \quad (40)$$

On the other hand it is well known that the deflection of light in passing through the gravitational field of a particle can be taken in first approximation as twice that which would be calculated from a simple application of the Newtonian theory of gravitation, so that we can evidently write for the momentum acquired by the light pulse in passing over the track

$$\int_0^l \frac{2mMy}{[(l/2 - t)^2 + y^2]^{3/2}} dt = + \frac{2mMl}{y[(l/2)^2 + y^2]^{1/2}} \quad (41)$$

which is equal and opposite to the expression for the momentum acquired by the particle. And since a similar correspondence can be shown for the more general case when the particle is not located midway between the ends of the track, it is evident that we can retain in considerable measure our simple ideas as to the conservation of momentum as a first approximation even in so complicated a process as that of the interaction between a particle and a pulse of light.

PART IV. CONCLUSION

§12. *Some remarks on the problem.* This completes the material which we desired to present in this article. It is particularly hoped that the treatment

has clarified the problem of the mutual gravitational interaction of radiation and a particle, since we have given special attention to the behavior of a particle in the gravitational field of light, while the treatment of the converse problem of the behavior of light in the gravitational field of a particle is well known.

This converse problem is of course the one of usual importance in connection with astronomical observations when we are interested in the effect of the gravitational fields of stars or other particles on the behavior of a ray of light coming from a distant object. Its treatment can usually be carried through with less difficulty and higher approximation than was feasible for the problems which we have considered in the present paper. This arises partly from the fact that we have the exact Schwarzschild solution for the gravitational field surrounding a stationary point particle, and partly from the fact that disturbances in the motions of neighboring particles which are produced by the passage of a pulse of light cannot in general communicate their effects back in time to affect the gravitational field through which the pulse itself has to pass.

One of the main results of the present article has been to show that in the case of weak fields the gravitational action of light on a particle can in considerable measure be correctly calculated from the Newtonian theory of gravitation provided we take the gravitational mass of the radiation as twice its inertial mass. And since it was already known in the case of weak fields that the gravitational action of a particle on light could in considerable measure also be correctly calculated from the Newtonian theory by taking the gravitational mass of the radiation as twice its inertial mass, we have thus shown the possibility of extending the domain in which we can use our simple ideas as to the conservation of momentum. Of course in general we should expect to be able to use the more complicated ideas as to the conservation of momentum which can be obtained by the device of introducing the *pseudo* energy-momentum tensor $t_{\mu\nu}$, but the extent to which the simple ideas would be applicable does not appear to have been certain prior to this investigation.

§13. *Other examples of the gravitational field due to radiation.* The effects of radiation on the gravitational field, studied in this article, may also be compared with two other cases in which radiation has been found to produce a different (greater) effect than ordinary matter on the gravitational field.

The first example is furnished by the case of the static Einstein universe where it has been found⁴ that the radius R of a universe *filled with stationary incoherent matter* would be connected with the proper density of matter ρ by the expression

$$\frac{1}{R^2} = 4\pi\rho \quad (42)$$

while for a universe *filled solely with radiation* of density ρ the relation would be given by the expression

⁴ See for example, Tolman, Proc. Nat. Acad. 15, 297 (1929), Eqs. (35) and (37).

$$\frac{1}{R^2} = \frac{16}{3}\pi\rho. \quad (43)$$

The second example is furnished by the case of the gravitational field of a sphere of perfect fluid of proper macroscopic density ρ_{00} and pressure p_0 . Writing the line element for such a sphere in the form

$$ds^2 = -e^\mu(dx^2 + dy^2 + dz^2) + e^\nu dt^2 \quad (44)$$

where μ and ν are functions of $r = (x^2 + y^2 + z^2)^{1/2}$, it is found⁵ that the line element degenerates at great distances from the sphere into the approximate Schwarzschild form

$$ds^2 = -\left(1 + \frac{2m}{r}\right)(dx^2 + dy^2 + dz^2) + \left(1 - \frac{2m}{r}\right)dt^2 \quad (45)$$

where the constant m has the value, obtained by integration over the material in the sphere,

$$m = \int (\rho_{00} + 3p_0)e^{\nu/2}dV_0 \quad (46)$$

dV_0 being the element of proper volume. Since for radiation we have $3p_0 = \rho_{00}$ and for incoherent matter at ordinary temperatures have $p_0 \ll \rho_{00}$, it is evident here too that the radiation in the sphere can be regarded as having a greater effect on the gravitational field than matter of the same density.

RAMAN LINES OF CYCLOPROPANE AND VALENCE PROPERTIES OF SOME ORGANIC COMPOUNDS

BY ROBERT C. YATES

MATHEMATICS DEPARTMENT, JOHNS HOPKINS UNIVERSITY

(Received January 19, 1931)

ABSTRACT

Three fundamental wave-numbers for C_3H_6 are calculated from the equations of motion of a system of three particles vibrating in a plane. The character of a single bond acting adjacent to a double bond in CH_3CHO and again to a triple bond in CH_3CN is studied.

INTRODUCTION

IN SEVERAL recent papers appearing in the Physical Review^{1,2,3,4} the dynamic properties of molecules were studied with the purpose of correlating the lines of the Raman spectra with different motions of the system. It was assumed that the restoring force arises from a change in the bond length and from a change in the angle between adjacent bonds. It was further assumed that the non-polar chemical bond exhibits the same characteristics throughout the range of organic compounds. For the single bond structure the force constants, k_1 for linear displacement and k_2 for angular displacement, were found to be 5×10^5 and 0.6×10^5 dynes per cm, respectively. These assumptions are adhered to in the present paper but many of the mathematical steps in the calculations are omitted because of the similarity to previous work.³

CYCLOPROPANE

We consider here the small vibrations in a plane of three particles of the same mass m , lying at the vertices of an equilateral triangle. The unstrained bond is of length $2a$, each bond forming a side of the triangle. Let (x_i, y_i) , θ_i be the components of displacement of the particles and the angular changes, respectively. (NOTE: This problem is particularly interesting from the chemical standpoint because it offers a means of testing the validity of the Bayer strain theory.)

In an inertial system the center of gravity remains at rest and if this point be taken as the origin of coordinates

$$\sum x_i = 0, \quad \sum y_i = 0. \quad (1)$$

¹ C. F. Kettering, L. W. Shutts, and D. H. Andrews, Phys. Rev. **36**, 531 (1930).

² D. H. Andrews, Phys. Rev. **36**, 544 (1930).

³ R. C. Yates, Phys. Rev. **36**, 555 (1930).

⁴ A. B. Lewis, Phys. Rev. **36**, 568 (1930).

Since the sum of the forces is zero angular momentum about the origin is constant. This we assume to be zero, giving

$$y_2 = y_1 + 3^{1/2}(x_1 + x_2). \quad (2)$$

The changes in the bond lengths after displacement are found to be [by Eqs. (1) and (2)]

$$\left. \begin{aligned} \Delta_1 &= x_1 - x_2 \\ \Delta_2 &= -\frac{1}{2}[7x_1 + 8x_2 + 3(3)^{1/2}y_1] \\ \Delta_3 &= -\frac{1}{2}[x_1 + 2x_2 + 3(3)^{1/2}y_1] \end{aligned} \right\} \quad (3)$$

If θ_i be small, we find by taking only two terms in a Taylor expansion

$$\left. \begin{aligned} 4a\theta_1 &= -3y_1 - 3^{1/2}(5x_1 + 4x_2) \\ 4a\theta_2 &= -3y_1 + 3^{1/2}(x_1 + 2x_2) \\ 4a\theta_3 &= 6y_1 + 2(3)^{1/2}(2x_1 + x_2) \end{aligned} \right\} \quad (4)$$

The energy functions are set up in the usual manner³

$$\left. \begin{aligned} T &= (m/2) \sum_1^3 (\dot{x}_i^2 + \dot{y}_i^2) \\ &= m[4\dot{x}_1^2 + 4\dot{x}_2^2 + 3\dot{y}_1^2 + 7\dot{x}_1\dot{x}_2 + 3(3)^{1/2}(\dot{x}_1 + \dot{x}_2)\dot{y}_1] \\ V &= -(k_1/2) \sum_1^3 \Delta_i^2 - 2a^2k_2 \sum_1^3 \theta_i^2 \\ &= -(3k_1/4)[9x_1^2 + 12x_2^2 + 9y_1^2 + 18x_1x_2 + 8(3)^{1/2}x_1y_1 + 10(3)^{1/2}x_2y_1] \\ &\quad - (9k_2/8)[14x_1^2 + 8x_2^2 + 6y_1^2 + 20x_1x_2 + 8(3)^{1/2}x_1y_1 + 4(3)^{1/2}x_2y_1] \end{aligned} \right\} \quad (5)$$

giving the equations of motion

$$\left. \begin{aligned} 2m\ddot{x}_1 &= -(3k_1/2)[x_1 - 2x_2 - (3)^{1/2}y_1] - (9k_2/2)[3x_1 + 2x_2 + (3)^{1/2}y_1] \\ 2m\ddot{x}_2 &= -(3k_1/2)[x_1 + 4x_2 + (3)^{1/2}y_1] + (9k_2/2)[x_1 + (3)^{1/2}y_1] \\ 2m\ddot{y}_1 &= -[(3)^{1/2}k_1/2][x_1 + 2x_2 + 3(3)^{1/2}y_1] + [3(3)^{1/2}k_2/2][x_1 + 2x_2 - (3)^{1/2}y_1] \end{aligned} \right\} \quad (6)$$

These yield frequencies:

$$\begin{aligned} \nu_1 &= (1/2\pi)[3(k_1 + 3k_2)/2m]^{1/2}; \quad \nu_2 = (1/2\pi)[3(k_1 + 3k_2)/2m]^{1/2}; \\ \nu_3 &= (1/2\pi)(3k_1/m)^{1/2}. \end{aligned}$$

The molecule C_3H_6 is analogous to the system studied if we assume the mass of the hydrogens concentrated at the nuclei of the carbon atoms. Using $k_1 = 5 \times 10^5$, $k_2 = 0.6 \times 10^5$, $m = 13/6.06 \times 10^{23}$ we find the wave-numbers

$$\bar{\nu}_1 = \bar{\nu}_2 = 400 \text{ cm}^{-1}; \quad \bar{\nu}_3 = 1350 \text{ cm}^{-1}$$

where $\bar{\nu} = \nu/3 \times 10^{10}$.

CHARACTER OF MULTIPLE BONDS

Two particles of the same mass m are joined to a central particle M by bonds with force constants k_1 and k_2 . Let k_3 be the proportionality constant dependent on the change in the angle between the bonds. The particles lie along a straight line in the position of equilibrium and motion is assumed to be in a given plane. The equations of motion are

$$\left. \begin{aligned} mM\ddot{x}_1 &= -k_2[(m+M)x_1 + mx_2] \\ mM\ddot{x}_2 &= -k_1[mx_1 + (m+M)x_2] \\ mM\ddot{y}_1 &= -2k_3[2m+M]y_1 \end{aligned} \right\} \quad (7)$$

with frequencies given by the characteristic:

$$\begin{vmatrix} mM\mu^2 + k_2(m+M) & k_2m & 0 \\ k_1m & mM\mu^2 + k_1(m+M) & 0 \\ 0 & 0 & mM\mu^2 + 2k_3(2m+M) \end{vmatrix} = 0. \quad (8)$$

We assume that the groups of atoms in acetaldehyde and methylcyanide lie along a line in the state of rest and take the masses of the end groups as 15.5 and 14.5, respectively. In the former molecule k_1 and k_2 are assigned the values 5×10^5 and 10×10^5 (for single and double bond); in the latter 5×10^5 and 15×10^5 (single and triple bond).

We find for CH_3CHO $\bar{\nu}_1 = 1695$, $\bar{\nu}_2 = 844$ as compared with observed Raman data 1716 and 932 which is in good agreement.

The motion of the system that alters the angle between the bonds gives rise to a wave-number in the neighborhood of 440 cm^{-1} . Using this in $mM\mu^2 + 2k_3(2m+M) = 0$ [see Eq. (8)] we evaluate k_3 as 0.26×10^5 dynes per cm.

For CH_3CN we find $\bar{\nu}_1 = 2095$, $\bar{\nu}_2 = 905$ compared with the observed values 2240 and 860. The third Raman line occurs at 350 cm^{-1} . This gives $k_3 = 0.15 \times 10^5$ for the bending constant between the single and triple bond.

In these two molecules the assumption on the position of the groups in equilibrium is somewhat dubious. However, the evidence points strongly to a decided weakening of the bending force when multiple bonds lie adjacent to single bonds.

DUST FIGURE IN LIQUID INSULATOR

BY Y. TORIYAMA

HOKKAIDO IMPERIAL UNIVERSITY, JAPAN

(Received October 9, 1930)

ABSTRACT

A dust figure is obtained on the surface of an ebonite plate immersed in a liquid insulator, by dusting it after the application of voltage with a fine powder containing mixture of red lead and resin.

There is a relation between the size of the dust figure and the break down voltage of the liquid insulator.

I. INTRODUCTION

AS THERE is a certain relation between a sparkover in gases and Lichtenberg's figure or the dust figure in the gases, some connection may exist between the break down phenomena of the liquid insulator and Lichtenberg's figure or the dust figure in the liquid insulator. The dust figure in the liquid insulator, mainly ordinary transformer oil, is here studied to throw light on the break down phenomena of the transformer oil.

II. DUST FIGURE IN TRANSFORMER OIL BY IMPULSE VOLTAGE

In order to dry the transformer oil, it is heated to $105^{\circ}\text{C} - 110^{\circ}\text{C}$ for two or three hours, and then filtrated with a paper filter.

Electrodes and an ebonite plate are then immersed in the oil as shown in Fig. 1. (In Fig. 1, N is a needle electrode, P is a plate electrode, E is the ebonite plate, and $M_1 C C W$ denotes the impulse generator). When an impulse

Fig. 1. Diagram of apparatus.

voltage is applied between N and P , and the ebonite plate is then pulled out of the oil, an electric charge will remain on its surface. By sprinkling a fine powder containing a mixture of red lead and resin on the plate, and then washing it gently in gasoline a clear dust figure is produced.

Since the particles of the powder will become electrified by mixing, the positively electrified red lead will stick to the negatively electrified surface,

and the negatively electrified resin will stick to the positively electrified parts. If the dusted surface is then washed in gasoline, the negatively charged part will look reddish because of red lead, and the positively charged part will look yellowish white because of the resin.

An example of a positive dust figure in the oil is shown in Fig. 2, and that of a negative figure in Fig. 3. The crest value of the applied impulse voltage in both cases is 35 k.v. By applying an impulse voltage of 35 k.v., the mean value of the radii of 15 positive figures was 7.13 mm, and that of the negative figures was 4.62 mm. The ratio $R+/R-$ ($R+$ and $R-$ denoting the radius of positive and negative figure respectively) was 1.54.

As mentioned above, the diameter of the positive figure is larger than that of the negative figure. The reason for this fact may be explained somewhat in the following manner. When the impulse voltage is applied between N and P , the needle being the positive pole, the negative ions (including electrons) produced in the ionization by collision will move towards the needle, while the positive ions move radially outwards. Owing to the fact that the velocity

Fig. 2. Positive dust figure in oil. $M_1=8$ mm. Impulse voltage, maximum value, 35.0 k.v. Magnification 1.5.

Fig. 3. Negative dust figure in oil. $M_1=8$ mm. Impulse voltage, maximum value, 35.0 k.v. Magnification 1.5.

of negative ions is greater than that of positive ions, the positive ions will remain near the needle N , so that the high potential gradient at the end of the needle will be weakened by the positive space charge. And the region of high potential gradient will move in time from the needle outwards, and the front of ionization by collision will proceed radially outwards along the ebonite surface. In other words, the potential gradient at the front of the ionization wave, spreading along the surface, will be much larger at a certain moment than the gradient electrostatically calculated.

In the case of a negative needle, the positive ions will remain at the end of the needle, so the ionization by collision may not proceed as in the former case. Accordingly, the radius of the positive figure is greater than that of the negative figure for the impulse voltage of the same intensity.

The radii of the positive and negative dust figures decrease with increasing temperature of the transformer oil, and the ratio $R+/R-$ also decreases with increasing temperature. But the form of the figure does not change. The experimental result is shown in Fig. 4.

The size of the positive and negative figures increases with decreasing atmospheric pressure. The case of a positive figure is shown in Fig. 5.

Fig. 4.

Fig. 5.

A comparison, between the size of the dust figure in the oil and the break down voltage of the oil is as follows:—

(1). In the range of the temperature from -10°C to 70°C , the break down voltage of the oil increases with increasing temperature.

The size of the dust figure decreases with increasing temperature in the same range of temperature.

(2). The break down voltage of oil decreases with decreasing atmospheric pressure,¹ and the size of the dust figure increases with decreasing atmospheric

Fig. 6. Dust figure by A. C. voltage. Voltage, effective value 20.0 k.v.

pressure. Briefly, in the case of increasing break down voltage of the oil, the size of the dust figure in the oil decreases, and vice versa. Since the dust figure in the oil may be produced by the partial electric break down of the

Fig. 7.

¹ J. Sorge, Archiv f. Elekt. 13, (1924).

oil, the theory that there is a relation between the break down voltage and the dust figure is reasonable.

The conduction through the oil may be ionic or electrolytic. The break down voltage of the oil does not depend on the conductivity of the oil,² and neither does the size of the dust figure. The conductivity of the oil does not depend upon the atmospheric pressure.³ However, the size of the dust figure changes with the atmospheric pressure. From the above two facts, it may be certain that the dust figure is not due to the ionic phenomena, but to the electronic phenomena. From the study of the dust figure it may be concluded that the break down of the transformer oil is a pure electric phenomena.

III. DUST FIGURE IN TRANSFORMER OIL BY A. C. VOLTAGE

The dust figure in the oil, applying A. C. voltage, can be obtained in the same process as in the case of an impulse voltage. An example of the figure when applying 20 k. v. eff. is shown in Fig. 6.

The radius of the dust figure increases almost linearly with the applied A. C. voltage.

The relation between the radius of the figure and the applied voltage is shown in Fig. 7.

The size of the dust figure by A. C. voltage increases with decrease of the atmospheric pressure.

THE RESISTANCE OF BISMUTH IN ALTERNATING
MAGNETIC FIELDS

BY WILLIAM W. MACALPINE

THE MARCELLUS HARTLEY RESEARCH LABORATORY,
COLUMBIA UNIVERSITY, NEW YORK, NEW YORK

(Received January 22, 1931)

ABSTRACT

Apparatus for producing a field of 100 gauss r.m.s. at 10^6 cycles with a 50 watt tube is described. Also a method of measuring the behavior of bismuth wire in such a field at liquid air temperature. For this purpose a potentiometer has been developed for the measurement of the amplitude and phase of voltages at frequencies up to at least 10^6 cycles per second. It was found that the resistance of the bismuth follows the instantaneous values of the field, having a magnitude at any instant equal to what it would have if the field at that instant were maintained constant. The precision of the magnitude calculated from the various factors involved is ± 3.5 percent and the experimental value is normal within this precision. At 55 kilocycles and room temperature the resistance of the bismuth was also found to be normal in magnitude and phase.

I. INTRODUCTION

A GREAT deal of work has been done on the various galvanomagnetic and thermomagnetic effects since the discovery of the Hall effect in 1879 by E. H. Hall. This work is abstracted in L. L. Campbell, "Galvanomagnetic and Thermomagnetic Effects."¹ It is to be noted that these investigations were carried out without the aid of the three electrode tube and auxiliary apparatus and experimental technique developed in conjunction with the tube, the investigations having been made for the most part before the tube came into general use. The results of the experiments on the resistance of bismuth in alternating magnetic fields varied widely and it was that state of affairs which seemed to make it desirable to investigate its behavior with modern equipment.

Most of the earlier experiments were limited to low audio frequencies (25 to 100 cycles usually) or to magnetic fields which were made to change rapidly, as from zero field to some steady value. Results showed that the magnitude of the change in resistance often was not as great with a.c. as with d.c. fields and frequently a lag was found. However, it is evident that some of these results were erroneous because of the inadequacy of the apparatus available.

In the present experiments bismuth wire 0.06 mm diameter was mounted bifilarly and immersed in liquid air in a combined d.c. and a.c. field, the latter having a frequency of about 10^6 cycles per second. A direct current which was maintained constant by a r.f. choke was passed through the wire and so an a.c. voltage proportional to its resistance appeared across the wire. This

¹ Previous work done in connection with the subject of the present paper is summarized on pp. 166, 191-194.

voltage was measured in amplitude and phase by a potentiometer constructed for the purpose. Measurements had been made previously at 55 kilocycles and room temperature.

It has been shown by various investigators that the Ettingshausen and Nernst effects cause the appearance of a voltage opposing that due to the resistance drop in the bismuth. This effect is illustrated by Kapitza² in his work at high magnetic fields. However, with alternating fields this effect would diminish rapidly as the frequency is increased and its voltage would approach a 90° lead with respect to the field. The effect must be entirely negligible at the frequencies used in the present case due to the "thermal inertia" of the metal, which is caused by its heat capacity. Even with constant fields it would be almost zero with a round wire due to the thermal conductivity of the wire.

Fig. 1.

Fig. 2.

Fig. 1. (left) Oscillating circuit, mounting of bismuth wire, etc.

Fig. 2. (right) Location of oscillating circuit within Dewar tube and d.c. field coils.

II. APPARATUS

The mounting of the bismuth wire, the coil for obtaining the a.c. field and various other necessary coils are shown in Fig. 1. Coil *A* and condenser *E* form an oscillating circuit which is driven by a power tube, the coil producing the required a.c. field. This coil is wound on a Pyrex tube $\frac{3}{4}$ in. diameter and has 36 turns No. 17 wire, the length of the coil being about 2 in. The condenser is 0.003 mfd. Inside the Pyrex tube a $\frac{3}{8}$ in. diameter bakelite tube is supported by a bakelite plug. The bismuth wire is wound bifilarly on the bakelite tube, being laid in threads cut in the tube, as it is found that if wound on the surface with even the lightest tension necessary to wind the wire properly, the cooling in liquid air causes it to break. When wound in the threads the tension can be made sufficiently light to prevent breaking, but it is not necessary to have it so light that the wire appears loose. In order to

² P. Kapitza, Roy. Soc., Proc. A119, 402, 430 ff. (1928).

make it a bifilar winding, two screws are cut, the threads of one screw lying midway between adjacent threads of the other. There are twelve double turns and the axial length of the winding on the tube is $1/2$ in. Two thin phosphor bronze strips are used as terminals for the bismuth wire, which is fastened to them with Wood's metal. The strips are secured to the bakelite tube by wrappings of ordinary thread, and a pair of twisted leads of No. 28 wire is connected to their upper ends. Below the bismuth wire is a single turn D of No. 28 wire with twisted leads. This is used to measure the a.c. field and to give its vector as a reference for measurements of phase. Two other coils, H and C , are shown. The first has 5 turns and is used to supply the potentiometer. The other has 19 turns and is used to neutralize undesired voltages

Fig. 3. The oscillator.

appearing in the bismuth wire in a way to be described below. The above apparatus is put in an unsilvered Dewar tube and the whole then placed inside a pair of large coils as shown in Fig. 2. These two coils have an inside diameter of 24 cm outside 38 cm and total height of $24 \frac{1}{2}$ cm. Each coil has 375 turns of coarse litz. When the oscillating circuit is placed at the center of these coils they have no appreciable effect on the efficiency of the circuit. They are energized from the d.c. power supply and give ample field for the experiment without undue heating.

The oscillator is shown in Fig. 3, and is of the Hartley type. With the UV 211, a 50 watt tube, fields of 100 gauss r.m.s. could be obtained without overloading the tube. A small choke is inserted in the grid lead to the oscillating circuit to suppress parasitic oscillations. Grid modulation is used by means of the transformer shown. The particular connection of the modulator with r.f. choke is used to prevent audio frequency from getting into the oscillating coil and thence to the detector of the potentiometer. A slight amount of the modulating frequency getting directly to the detector causes either a poorly defined or a double minimum.

The connections to the bismuth wire are shown in Fig. 4. Direct current from a battery may be passed through the wire in either direction, being held constant by an 85 mh radio frequency choke. A $1/2$ mfd mica condenser isolates the d.c. from the potentiometer. All condensers and batteries are at ground potential for the high frequency. Although the bismuth wire is bifilarly wound there is some net induced e.m.f., principally at the end connections. Also there is some capacity between the oscillating coil and the phosphor bronze strips used as terminals for the wire, and since the voltages obtained in the former may be several hundred volts, the resulting voltages in the bismuth wire are appreciable compared to the voltages in which we are interested, which are only a few millivolts. In order to compensate for these voltages coil C is used. One side of this coil is grounded and the other side is passed through a variable resistance and variable condenser in parallel, to the

ungrounded side of the lead to the bismuth wire, as shown in Fig. 4. The resistance is a non-inductive 25,000 ohm variable unit. The variable condenser is of the midget type with maximum capacity of 50×10^{-12} farads. It may be noted that if the stray voltages induced in the bismuth wire should require it, coil *C* could have a tap and suitable number of turns, the tap being grounded and the variable resistance connected to one side and variable condenser to the other.

Fig. 4. Circuit connections to bismuth wire.

Fig. 5 is a diagram of the potentiometer and its associated circuits. There are two circular slide wires called the *R* dial and the *C* dial through which flow currents approximately equal in amplitude and approximately 90° apart in phase. These currents are supplied by coil *H* of Figs. 1 and 5 through a shielded transformer *Tr* and the resistances *R* and condensers *C*, which latter determine the amplitude and phase of the currents in the slide wires. A center tapped wire in parallel with each slide wire serves to connect them together at their electrical mid-points.

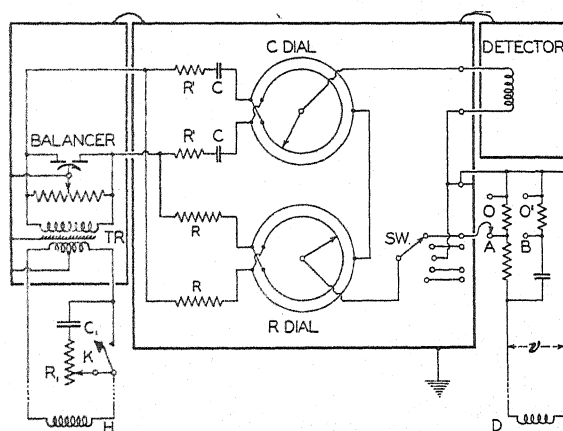

Fig. 5. The potentiometer circuits.

The two sliders are connected in series with the potential to be measured, by a selector switch *Sw*, and a detector. The latter is a grid leak detector with a tuned input transformer whose primary impedance approximately matches that of the potentiometer. Signals are audible because the oscillator, Fig. 3, is modulated.

At the lower right corner of Fig. 5 is shown a calibration circuit which con-

sists of two voltage dividers across the voltage v from a coil such as D of Fig. 1. Voltage v is measured by a thermovoltmeter. The potentiometer dials are calibrated by obtaining the settings for silence in the detector for points O and A , and O' and B' thus determining the number of millivolts per division for each dial. Then the unknown potential, which has been connected to another point of the selector switch, is measured.

Due to distributed inductance and capacity and to skin effect, the constants of the calibration and potentiometer circuits are uncertain, and a more accurate system is desirable. The potentiometer is shielded so the only driving force is through the transformer Tr . A phase shifting circuit C_1R_1 is included in the primary circuit of the transformer, which may rotate the phases of the currents in the two slide wires without altering their relative phase or amplitude. The settings for the calibration circuit are obtained and then the phases of the potentiometer currents rotated through approximately 90° and the new settings for the calibration circuit obtained. A simple calculation then gives the ratios of the currents in the two slide wires and their relative phases. At one million cycles this ratio may be determined to within 1 percent and the phases to $1/2^\circ$.

The details of this system and other features of the potentiometer have been described more fully by the author.³

III. EXPERIMENTAL PROCEDURE

The d.c. field of the large coils was measured by the usual ballistic galvanometer method, using a fixed search coil and obtaining the galvanometer throw when the magnetizing current was switched on or off. Since it was not practical to have coils which would give a uniform field care was taken to have the test coil and later the bismuth wire close to the center of the large coil where the field is fairly uniform. The variation of the resistance of the bismuth wire with d.c. field was determined by ordinary d.c. bridge measurement and gave the usual curve, parabolic at first and then becoming straight. The a.c. measurements should be made with the d.c. field current at such a value that the curve of resistance vs. field strength is practically a straight line.

In taking a set of measurements, the potentiometer is first calibrated. Then setting the selector switch for the bismuth measurements the compensating circuit is adjusted to bring the dial readings to about their midpoint. This should be done with the continuous field at the value to be used in the measurements immediately following, since the setting of the compensator depends on the resistance of the bismuth wire. Then readings may be taken in succession with various values of d.c. flowing through the wire beginning and ending with zero to make sure that no change has occurred in the compensating circuit or any other circuit during the readings. With no continuous field, no change in voltage was observable for various values of d.c. flowing through the bismuth wire. The vector voltage due to the varying resistance of the bismuth wire is then represented by the difference in dial

³ W. W. Macalpine, Proc. I.R.E. 18, 1144 (1930).

readings between those with no d.c. flowing through the wire and those with the value of d.c. in question, the continuous field being the same in both cases. The effect of the leads from the bismuth wire to the potentiometer may be tested by making some measurements with the ordinary leads and then repeating them with considerably longer leads added. The actual leads used were twisted only where they pass up through the 3/8 in. bakelite tube on which the bismuth wire was mounted, a length of 4 in.

In order to measure the field it is necessary to know the diameter of turn D , which may be found at room temperature but not easily in liquid air. For this purpose coil F of 18 turns was wound on the bakelite tube well above the level reached by the liquid air. The voltages induced in D and F were then measured before and after adding the liquid air. The relative voltages induced in F and D were found to be about the same in and out of the liquid air, within experimental error and therefore the area of D changed little in liquid air, due probably to its being on bakelite. The magnetic and electrical properties of the liquid air are of such magnitude that they have little effect on the circuits, and so need not be taken into consideration.

IV. DATA AND RESULTS

Table I gives the arrangement of the various test circuits used to calibrate the potentiometer. These were supplied by coil D of Fig. 1. Circuits a, b, c, d are those illustrated in the lower right hand corner of Fig. 5. Vectors a, b, f, g, p are those with normal phase, switch K in Fig. 5 closed, while c, d, h, k, q are with the phase of the potentiometer currents rotated.

TABLE I. *Test circuits.*

Vectors a, c	$DA = 929$ ohms	$OA = 17.4$ ohms
b, d	$DB = 153 \times 10^{-12}$ farads	$OB = 16.1$ "
f, h	193×10^{-12} "	11.5×10^{-9} farads
g, k	929 ohms	9.9×10^{-9} "
p, q	bismuth vectors	

In Table II each of the values of the coordinates *as read* are the average of several readings made at various times during the experimental run and include both positive and negative readings. The leads to coil D were reversed for the negative readings. In the cases of p and q readings were taken with various values of i , the current in the bismuth wire, but all are reduced to the equivalent readings for $i = 17.8$ ma. The rectangular coordinates are calculated with the use of α and m as determined by Eqs. (1) and (2) of the article on the potentiometer.⁴ v is the voltage induced in turn D and is given in dial divisions, being calculated from the column of *lengths* by the ratios v/length , which are calculated from the above data on the test circuits. It should be noted that the value of v in dial divisions for the $a b f g$ system is not necessarily equal to its value for the $c d h k$ system. The phase angle of each vector with respect to the positive R axis is given under θ_R .

⁴ Reference 3, $(90^\circ - \alpha)$ is the phase angle between the currents in the two slide wires, while m is the ratio of the current in the C dial to that in the R dial.

TABLE II. *Experimental data.*

TABLE IV. *Continued*

Vec- tor	Coordinates				Length	v	v	θ_R
	As Read		Rectangular			Length

b	-21.7	69.6	-27.3	66.1	71.5	59.4	4247	112.4
f	67.8	26.8	65.7	25.5	70.5	60.5	4265	21.2
g	17.3	-64.8	22.5	-61.6	65.6	62.7	4115	290.0
p	-21.1±0.8	86.0±0.5	-28.0	81.7	86.4±0.9			108.9±0.5
Average							4217	±25
c	31.3	-75.9	37.4	-72.1	81.2		4426	297.3
d	68.3	37.2	65.3	35.3	74.2		4408	28.4
h	27.8	-67.6	33.2	-64.2	72.3		4375	297.3
k	-64.0	-31.1	-61.5	-29.5	68.2		4276	205.7
q	83.8±0.4	38.3±0.7	80.7	36.4	88.5±0.8			24.3±0.4
Average							4371±24	

$f = 1.09 \times 10^6 \pm 0.5\%$ cycles per second.

$H/I = 25.0 \pm 1.5\%$ gauss per ampere in d-c field coils.

$dR/dI = 1.55 \pm 0.5\%$ ohms/amp. at $I = 16.1$ amp.

$R =$ d-c resistance of bismuth wire.

$i = 0.0178 \pm 1\%$ d-c amp. flowing in bismuth wire.

$A = 0.810 \pm 2.5\%$ sq. cm, area of turn D , Fig. 1.

Temperature = that of liquid air (about -185°C).

$H_{d-c} = 400$ gauss, approximately.

$v = 1.5$ volts r.m.s., approximately.

$H = 27$ gauss r.m.s., " "

The experimental precision of the length of the test vectors a, b, c, d , etc. was about ± 0.5 percent and of the angles θ_R , $\pm 0.25^\circ$, making the precision of the average values of $v \pm 1$ percent. The estimated precision of A is large because of its uncertainty due to immersing the turn in liquid air. Any contraction occurring would increase the calculated value in Table III, which will bring the ratio of measured to calculated values nearer unity.

The calculated high frequency field is

$$H = \frac{v}{2\pi f A} \times 10^8 \text{ gauss}$$

and the high frequency voltage appearing across the bismuth should be

$$e = ir = iH \frac{dR}{dH} = i \frac{dR}{dH} \frac{v}{2\pi f A} \times 10^8.$$

Substituting the above figures: $e = 0.0199 \times v$ volts. The precision of e as calculated from those of its various factors is ± 3.5 percent.

The measured value of the length of the vectors p and q must be corrected for the drop due to the compensator, which in this set of measurements had a resistance of 5700 ohms and a capacity of about 45×10^{-12} farads, including capacity of leads. Since the resistance of the bismuth was about 100 ohms, the compensator reduced the a.c. voltage across it by $1/58$ and rotated its

phase -1.6° . Also, calculation shows that the average field of the oscillating coil on the surface occupied by the bismuth wire was 1.2 percent higher than the average linking turn D which was used to measure the field (see Appendix). Making these corrections to the lengths of the vectors p and q for the compensator and field we have the following results: $p = 86.9$, $q = 89.0$.

From the value of the *coordinates*—as Read of Table II, the values of α and m may be calculated³, using both the a, b, c, d set of vectors and the f, g, h, k set. The former gives $\alpha = -0.086$ and $m = 0.944$, and the latter $\alpha = -0.099$, and $m = 0.950$, the average being $\alpha = -0.092$ and $m = 0.947$. Using these values of α and m to find the correction for the $\alpha^2 m^2$ terms, it is found that for both sets of vectors the correction to α is $+0.008$ and that to m is $+0.004$. Thus the true values are $m = 0.95$, the correction to m being almost negligible; and $\alpha = -0.092 + 0.008$, or -4.8° . It may be noted that no phase correcting resistances R' of Fig. 5 were used in series with the C dial of the potentiometer in this instance. In regard to the $\phi\beta$ corrections, they may be shown to be negligible. The angles θ, β and ϕ may be found from Table II, and are: $\theta = 21^\circ$, $\beta = 6^\circ$, $\phi = -1^\circ$ in the a, b, c, d case and $\phi = +1^\circ$ in the f, g, h, k case.

The phase of the magnetic field is determined from that of vectors f and h since these are the vectors for a test circuit of two mica condensers in series. Such circuits introduce very little phase shift due to the small phase angle of the condensers. The phase of vector p with respect to the field is then $108.9^\circ - (90 + 21.2) = -2.3^\circ$ and similarly that of q is -3.0° . Taking into account the phase shift of -1.6° produced by the compensator as noted above, these angles become -0.7° and -1.4° , respectively.

The following table gives the above two results as *III* and *IV* and two others obtained similarly on a different date as *I* and *II*. In the latter case it was found that the calculated $e = 0.0200 \times v$. The columns marked *equivalent e—Bi* give the values of the lengths of the calculated and measured vectors multiplied by the proper ratio to make the calculated length 100.0.

TABLE III. Results.

Result	v	$e - \text{Bi}$		Equivalent $e - \text{Bi}$		Phase resp. to field
		Calc.	Meas.	Calc.	Meas.	
I	4300	86.0	88.9 ± 1.5	100.0 ± 3.5	103.4 ± 1.7	$0.3^\circ \pm 0.9^\circ$
II	4400	88.0	91.1 ± 1.0	100.0 ± 3.5	103.5 ± 1.1	$-0.6^\circ \pm 0.6$
III	4217	83.9	86.9 ± 0.9	100.0 ± 3.5	103.6 ± 1.1	$-0.7^\circ \pm 0.6$
IV	4371	87.0	89.0 ± 0.8	100.0 ± 3.5	102.3 ± 0.9	$-1.4^\circ \pm 0.5$
Average				100.0 ± 3.5	103.2 ± 0.6	$-0.6^\circ \pm 0.5^\circ$

$$\frac{\text{Measured}}{\text{Calculated}} = 1.032 \pm 3.5 \text{ percent}$$

$$\text{Phase} = -0.6 \pm 0.5^\circ.$$

It is thus seen that the change in resistance of bismuth at 10^6 cycles per second is normal in magnitude and phase.

V. MEASUREMENTS AT 55 KILOCYCLES, ROOM TEMPERATURE

The above method was first developed at 55 kilocycles, but this work will be described only briefly here. In place of the arrangement of Figs. 1 and 2 a magnet was made from four rings of Western Electric dust core cemented together. This core was cut into two parts to facilitate winding and an air gap formed by cutting away three rings to make the area of the gap that of a single ring, or approximately 1 sq. cm. The oscillating circuit consisted of a mica condenser and two coils in series, one on each side of the air gap, driven by a 50 watt tube in a suitable circuit. Fields up to 700 gauss r.m.s. were easily obtained but those used ranged from 100 to 300 gauss since no cooling system was employed at the bismuth wire. Two coils as close to the air gap as the oscillating coils would allow supplied the d.c. field. These were supplied from the 110 volt d.c. lines with series resistance, a wave trap being employed in series to prevent them from short circuiting the high frequency circuit. The bismuth wire was wound on a mica form which slipped into the air gap. A single turn corresponding to D of Fig. 1 was shellacked to one of two sheets of mica covering the bismuth wire. The connections to the potentiometer were similar to those at the higher frequency except that instead of using the compensator a small coil in series with the leads to the bismuth wire was coupled loosely to the coil of the wave trap. The result obtained was that the resistance of the bismuth wire behaved normally both in phase and magnitude in 55 kilocycle fields, at room temperature.

In conclusion I wish to express my thanks to Professor M. I. Pupin for allowing me the use of The Marcellus Hartley Research Laboratory and for his interest in the work.

APPENDIX

Note on the field in the solenoid

The ideal condition would be that the a.c. field within the oscillating coil in Fig. 1 is uniform, which would be strictly true only for a very long solenoid. Considerations of efficiency of the coil require that its length be not too long with respect to its diameter. In order to determine what correction would be required due to non-uniformity of the field, its average values over the bismuth wire and turn D were calculated. Briefly the calculation is as follows: The increment of field at p due to an element of circular turn perpendicular to the X axis and with center on that axis is

Fig. 6.

$$\begin{aligned} dh &= \frac{I}{C^3} \mathbf{c} \times (i \times \mathbf{r}) d\theta \\ &= \frac{I r d\theta}{C^3} [i(r - a \cos \theta) - j b \cos \theta - k b \sin \theta] \end{aligned}$$

where $c^2 = b^2 + r^2 + a^2 - 2ra \cos \theta = A - B \cos \theta$. Integrating around the complete turn, the Z component vanishes and

$$\frac{h_i}{I} = \frac{2}{\sqrt{(A+B)}} \left[F\left(k, \frac{\pi}{2}\right) + \frac{2r^2 - A}{A - B} E\left(k, \frac{\pi}{2}\right) \right] \quad (1)$$

$$\frac{h_j}{I} = \frac{2b}{a \sqrt{(A+B)}} \left[F\left(k, \frac{\pi}{2}\right) - \frac{A}{A - B} E\left(k, \frac{\pi}{2}\right) \right] \quad (2)$$

where

$$\begin{aligned} k &= \sqrt{(2B/(A+B))} \\ F\left(k, \frac{\pi}{2}\right) &= \int_0^{\pi/2} \frac{dZ}{(1 - k^2 \sin^2 Z)^{1/2}} \end{aligned}$$

the complete elliptic integral of the first order,

$$E\left(k, \frac{\pi}{2}\right) = \int_0^{\pi/2} (1 - k^2 \sin^2 Z)^{1/2} dZ$$

the complete elliptic integral of the second order.

In obtaining the above expressions for the components of h , the following integrals are used:

$$\begin{aligned} \int_0^\pi \frac{d\theta}{(A - B \cos \theta)^{1/2}} &= \frac{2}{\sqrt{(A+B)}} F\left(k, \frac{\pi}{2}\right) \\ \int_0^\pi \frac{d\theta}{(A - B \cos \theta)^{3/2}} &= \frac{2\sqrt{(A+B)}}{A^2 - B^2} E\left(k, \frac{\pi}{2}\right). \end{aligned}$$

The latter is found by writing for $A - B \cos \theta$

$$(A - B) \cos^2 \theta/2 + (A + B) \sin^2 \theta/2.$$

Eqs. (1) and (2) were plotted for various values of b , with a = radius of turns of bismuth wire and were integrated by planimeter for three points on the wire, the average field on the wire being found from these values. Similarly the average field in turn D was found.

The result was that the average value of the field on the bismuth wire is 1.2 percent higher than the average field linking turn D .

STRAIN AND DIAMAGNETIC SUSCEPTIBILITY

BY H. E. BANTA

RICE INSTITUTE, HOUSTON, TEXAS

(Received January 20, 1931)

ABSTRACT

The magnetic susceptibility of copper and silver wires has been measured by the Gouy method before and after various annealing processes. Also, the susceptibility has been measured before and after straining specimens beyond the elastic limit, the strains being either twists or stretches. The susceptibilities are found to be increased by as much as 20 percent for copper and 3 percent for silver by annealing at red heat for 15 minutes in an atmosphere of CO_2 . This increase is probably due to release of occluded gases or to oxidation or recombination of impurities. Straining the specimens beyond the elastic limit is found to produce no measurable change of susceptibility. Francis Bitter has observed a large effect due to straining these metals beyond the elastic limit. The reason for Bitter's results is not clear, but it is pointed out that no effect is to be expected in copper, at least, because crystals of this metal are isotropic magnetically and have no observable magnetostriction.

RECENTLY Francis Bitter¹ has made the surprising and important observation that annealed copper (impure, paramagnetic) and silver wires suffer a very appreciable change of magnetic susceptibility when strained beyond the elastic limit. This result is surprising for the following reasons. Straining a wire beyond the elastic limit may have the effect of breaking up large crystals into smaller ones. Slipping occurs along cleavage planes, crystal boundary planes are distorted, segregated impurities are redistributed, and new orientations may result for the axes of the tiny crystals. In addition to these effects certain parts of the wire will be left elastically extended, other parts elastically compressed as a result of the unequal slipping of various sections of the wire. These residual strains in a wire have for years been a source of annoyance to users of the Eötvös torsion balance.

It appears, therefore, that the change of susceptibility of a wire when stretched might be explained by two factors: (1) the orienting effect on the small crystals, and (2) the setting up of a strained condition in the wire. In the case of copper the first factor must be ruled out because Montgomery² has shown that copper crystals are isotropic magnetically. The second factor is also inadequate for the following reason: the reciprocal relations between strain and magnetization may be expressed by the equation $\partial I / \partial p = \partial e / \partial H$, where I , H , p , and e are, respectively, intensity of magnetization, magnetic field, applied stress, and strain $\partial l / l$. The last two quantities are along the H direction. This equation is based on thermodynamical principles and according to Honda³ has been verified experimentally even in the case of iron

³ Honda, *Magnetic Properties of Matter*, p. 46.

and nickel, where hysteresis would tend to make the equation inapplicable. It should hold accurately where hysteresis is negligible, as in copper. In copper, however, magnetostriction is so small that it has never been detected; thus $\partial e/\partial H$ is negligible and therefore $\partial I/\partial p$, or $H\partial K/\partial p$ must be very small. The absence of magnetostriction in copper thus shows that the susceptibility K is unaffected by applied pressures. Hence the second factor given above must be ruled out as an explanation. Accepting Bitter's experimental results, the only conclusion appears to be that the above description of the processes involved in stretching a wire is incomplete.

Accordingly, a series of tests on the effect of strain on the susceptibility of copper and silver was made. As in Bitter's experiments, the Gouy method was used. An analytical balance was mounted about half a meter above an electromagnetic with pole-pieces (truncated cones) 1 cm in diameter and 4 mm apart. The specimen, in the form of a wire about 15 cm long and 2 or 3 mm in diameter, was suspended from one arm of the balance by a silk thread. The lower end of the wire being centered with respect to the pole-pieces. The force on the wire is given by the equation $F = KH^2a/2$ where K , H , and a are the volume susceptibility, magnetic field intensity at the lower end of the wire, and cross-sectional area of the sample, respectively.

When the specimen was suspended 15 cm above the poles of the magnet the balance was not deflected by a measurable amount. Therefore the above equation requires no correction for the field at the top of the specimen. All samples were diamagnetic.

The first set of results was obtained for commercial copper wire about 2.6 mm in diameter. Forces on the samples were measured; they were then twisted beyond the elastic limit by various amounts and the forces again measured. A representative part of these results is shown in Table I. These

TABLE I. *Effect of twist on susceptibility.*

Sample	F_1 dynes	Angle of twist	F_2 dynes	ΔF
1	7.44	0	7.53	+ .09
2	7.15	$\pi/2$	7.26	+ .11
3	7.20	π	6.95	- .25
4	7.08	2π	7.11	+ .03
4	7.11	30π	7.00	- .11

wires did not all have the same diameter, so the forces are different for the different samples. The samples had been well annealed, first in a flame, then in an electric furnace in air. The oxide coating consequent to annealing was removed by sand-papering the surface. It appears that the values of ΔF are within the limits of experimental error. The average value of ΔF is -0.03 dyne and there are both positive and negative values. Furthermore in this experiment it is doubtful whether F could be determined accurately to more than 0.2 dyne. We conclude therefore that K is unaffected by twisting the copper wire greatly beyond the elastic limit. The average specific susceptibility cal-

culated for these samples is 0.5×10^{-7} . For pure copper Montgomery gives 0.85×10^{-7} .

A series of experiments on stretched copper wire was then made. The order of magnitude of F (corrected for changes in diameter) was about the same as in the set of observations shown in Table I. This degree of accuracy was at first considered sufficient, since Bitter got ΔF as large as $\frac{1}{2}F$; but later, pole pieces with larger areas (in order to minimize errors of adjusting the specimen between the pole-pieces) were put on the electro-magnet, and crossed telescopes fastened to its frame to provide accurate control over the position of the specimen. The measurement of the force on a specimen which had been removed and replaced could then be repeated to 0.1 dyne.

The preliminary work showed that annealing a copper wire affected its susceptibility. For example, the force on a specimen was measured, it was heated to redness in CO_2 for about three minutes, cooled slowly, and the force again measured. Successive forces, each determined after a three minute heat treatment, were -6.0 , -6.5 , -7.0 , -7.3 , and -7.3 dynes. Similar effects due to annealing have been obtained by Davies and Keeping⁴ for copper-antimony alloys. They attribute the phenomenon to changing of the nature of the compounds of copper and antimony. Some samples in the present experiments were heated to a bright red heat in a vacuum, and gave off a gas which, at ordinary pressure, had about half the volume of the copper. The nature of this gas is not known. Therefore it was possibly the presence of impurities or freeing of adsorbed gas which produced the increase of F noted above. The foregoing results indicate that an annealing at red heat for about fifteen minutes is necessary in order to secure the final stable value of the susceptibility. Therefore all further annealings were done in CO_2 , holding the specimen above red heat for fifteen minutes and allowing it to cool slowly. All further cleanings are by immersion in boiling HCl for about two minutes, unless otherwise stated.

A second specimen of copper which was slightly paramagnetic when uncleaned was obtained. With its surface sand-papered $F = 0.0$ dyne. Annealed, $F = -3.04$ dynes. This is sample *A* in Table II. Another sample was not annealed, but was cleaned with acid and a value $F = -5.1$ dynes found; some of the surface was then removed with sand-paper and F found to be -5.4 dynes. Thus it appears that paramagnetic impurities were removed from the surface by sand-papering. It is therefore possible that some of the increase of F at annealing is due to the removal (possibly by oxidation) of impurities at or near the surface. When thoroughly annealed this specimen had a value of $F = -6.4$ dynes.

Chemically pure samples of copper and silver were obtained from Baker and Company. These are shown as *C* and *D*, respectively, in Table II. The procedure with each sample of Table II was as follows: the force F was measured (except sample *B*); the wire was annealed and cleaned, and its force F_1 again measured. It was then stretched till its length changed permanently

⁴ G. W. Davies and E. S. Keeping, *Phil. Mag.* 7, 145 (1929).

by the fraction $\Delta l/l$, cleaned, and the force F_2 again measured. Again it was annealed and cleaned, and the force F_3 again measured. The forces in this table are shown in mg, the units in which they were measured. The d 's are diameters of the samples. Multiplying by $(d_1/d_2)^2$ corrects F_2 for the change in cross-sectional area consequent to stretching; so $F_1 - F_2(d_1/d_2)^2$, shown in the table as ΔF , is a measure of the change of K when the sample is stretched.

TABLE II. *Effect of stretching on susceptibility.*

Sample	F mg	F_1 mg	d_1 mm	$\Delta l/l$	F_2 mg	d_2 mm	F_3 mg	$F_2(d_1/d_2)^2$ mg	ΔF mg	$K \times 10^6$
A	0.0	3.1	2.61	.10	2.9	2.48	—	3.2	+0.1	-0.22
B*	5.4	—	2.58	.12	4.7	2.43	5.7	5.3	-0.1	-0.48
C	8.0	9.2	3.00	.10	8.6	2.85	8.5	9.4	+0.2	-0.51
C'	—	8.6	2.85	.195	7.2	2.61	7.2	8.6	0.0	-0.51
D	28.7	30.0	3.00	.235	24.3	2.70	24.3	29.9	-0.1	-1.62

* Note: This specimen was annealed in a flame for about one minute at less than red heat before F was obtained. It was given no further annealing before being stretched. Specimen C' is the specimen C after all the data following C were obtained. (F_1 for C' should be the same as F_2 for C except for experimental error.)

Since ΔF is within the limit of experimental error it seems reasonable to conclude that K is unaffected by the stretch. Also, since F_3 is the same as F_2 (except for B), we conclude that annealing a wire of copper or silver which has been hardened by severe stretching does not affect its magnetic susceptibility, provided proper heat treatment has stabilized the wire magnetically before it is strained.

The data on B show that straining a wire which has been imperfectly annealed does not affect its susceptibility. In these experiments the specimens were given permanent strains as large as were used in Bitter's experiments, and the accuracy of measurement was sufficient to detect an effect at least 1/10 as large as Bitter observed. In no case has Bitter's effect been detected. Furthermore, as pointed out in the introduction, there is reason for disbelieving in the reality of the effect because of the absence of magnetostriction in copper and silver.

The conclusion may therefore be drawn that the magnetic susceptibility of copper and silver is not appreciably affected by straining wires of copper and silver beyond the elastic limit. The reason for Bitter's results is not evident.

It is indeed a pleasure to thank Dr. C. W. Heaps for many helpful suggestions and criticisms throughout the investigation.

SOME PHYSICAL PROPERTIES OF COMPRESSED GASES I. NITROGEN*

BY W. EDWARDS DEMING AND LOLA E. SHUPE

FERTILIZER AND FIXED NITROGEN INVESTIGATIONS BUREAU OF
CHEMISTRY AND SOILS, WASHINGTON, D.C.

(Received January 11, 1931)

ABSTRACT

The writers have adjusted and extrapolated the *compressibility data* obtained by Bartlett and his collaborators on nitrogen, so that very accurate p - v - T data from -70 to 600° and up to 1200 atm. are available. A suitable graphical scheme has been devised for obtaining the derivatives $(dv/dp)_T$, $(dv/dT)_p$, $(d^2v/dT^2)_p$ at any point in order that some of the physical properties of the gas can be calculated. This graphical scheme depends on the relation of $\alpha \equiv RT/p - v$ and $\Delta \equiv v(pv/RT - 1)$ to p, v, T , and on the relations of the derivatives of α and Δ to the derivatives of v . Errors in the estimation of the slope of an α or Δ curve at any point introduce much smaller errors into the derivatives of v , since the derivatives of α and Δ enter as correction terms to the derivatives of v just as α and Δ are corrections to v itself.

A graphical process is used as originally in MS for adjusting the p - v - T data and all the physical properties derived from it. This process is based on the assumption that surfaces such as p - v - T ; α - v - T ; or Δ - v - T are smooth and hence that the curves in any family of isotherms or isobars show related characteristics. It throws most of the adjustment on v , where it belongs, since the measurements of p and T are much more accurate than those of v . Such an adjustment enhances the precision of the compressibility data and of the calculations made from it.

The specific volume, density, coefficients $(-p/v)(dv/dp)_T$ and $(T/v)(dv/dT)_p$, fugacity, C_p , $C_p - C_v$, C_v , and μ are calculated and shown in curves and a table for the fourteen pressures and twelve temperatures in the range studied. Inversion pressures and temperatures are read from the μ vs. p isotherms and the μ vs. T isobars.

The calculations of C_p agree well with the experimental values of Krase and Mackey, who worked at 30, 100, 125, 150° up to 700 atm. and at 50° to 800 atm. The agreement is probably within the experimental error, but the trends of the two sets suggest that a real difference may exist. At 30° the calculated C_p drift below the experimental values at pressures above 400 atm., becoming 0.13 cal/mole·deg low at 700 atm. At 50° the agreement is good to 800 atm. At 100, 125, 150° the calculated C_p drift above the experimental values, but the disagreement reaches only 0.2 cal/mole·deg at 600 and 700 atm.

As one might expect, $C_p - C_v$ approaches R at all temperatures as the pressure approaches zero. In general, $C_p - C_v$ increases at any particular pressure as the temperature decreases. $C_p - C_v$ shows a strong maximum at about 200 atm. at the lowest temperatures. With increasing temperature this maximum comes at higher and higher pressures, and gradually disappears. The C_v vs. T isobars show some curious tendencies. C_v along the 20 atm. isobar stays constant and equal to $2.50 R$ from -70 to 100°C , then it rises slowly to 5.15 cal/mole·deg at 600° . Along the 40, 60, 80, and 100 atm. isobars, C_v drops a few hundredths of a cal/mole·deg below $2.50 R$ at -70° , the drop being greater the greater the pressure. Along the 200 atm. and higher pressure isobars, C_v rises as the temperature falls below 50° , and the rise is steeper the greater the pressure. At 600°C , is about 5.18 cal/mole deg or $2.61 R$ for all pressures.

* An abstract of this paper appeared in the program for the Chicago meeting of the American Physical Society, November 28 and 29, 1930.

RECENT extensions of compressibility data on several gases to 1000 atm. from -70 to 300° and 400° published by Bartlett¹ and his collaborators at this laboratory have made possible the calculation of such physical properties as pressure and temperature coefficients of volume expansion, fugacity, change in heat capacity with pressure, difference between the heat capacity at constant pressure and that at constant volume, Joule-Thomson coefficient, and inversion temperatures and pressures, all at the various temperatures and pressures throughout the range of experimentation and as much further as extrapolations can safely be made.

With extrapolations made by a method to be described, we have reliable compressibility data on nitrogen from -70 to 600° up to 1200 atm. The physical properties of this gas might be expected to show some interesting properties over such a wide range, and we have endeavored to investigate them.

In order to calculate these physical properties from compressibility data it is necessary to evaluate the derivatives $(dv/dp)_T$, $(dv/dT)_p$, $(d^2v/dT^2)_p$ wherever desired. Analytical or graphical methods can be devised for this purpose. Perhaps the best analytical method of getting $(dv/dp)_T$ over a limited pressure range is to write pv as a power series in p along an isotherm. However, no set of coefficients can be found that will satisfactorily follow the trend of pv for nitrogen through the whole range of pressures along any isotherm; one set of constant seems to hold fairly well to some intermediate pressure, depending on the temperature, and another set is necessary from this pressure on up to 1000 atm. This introduces a discontinuity, and the intermediate pressure is thus at the ends of the two ranges. End points are the least trustworthy and we usually get two values for $(dv/dp)_T$ at the discontinuity, and it is then necessary to resort to graphical methods to smooth out the disagreement. The same difficulty exists in getting $(dv/dT)_p$; v^2 expressed as a power series in T seems to fit at low pressures, v as a power series in T seems to fit at high pressures; so there is a break at the intermediate pressure again. These empirical formulas are satisfactory for first derivatives but not for second derivatives except over a limited range. Jakob² used them to get the change in heat capacity of air up to 200 atm. from -80 to 250° . He recognized that at the highest temperatures his calculation of $(d^2v/dT^2)_p$ showed evidence of being untrustworthy. Drs. E. P. Bartlett and H. L. Cupples of this laboratory used Jakob's scheme with nitrogen up to 1000 atm. and the difficulties mentioned above were encountered, but by calling on graphical determinations at certain points they obtained results that were valuable, though probably not as reliable as those gotten by the method to be described. We have made free use of some of the ideas in their unpublished manuscript.

The ideal way to obtain these physical properties would be through an

equation of state, but this should not be attempted at pressures and temperatures where it appears not to give trustworthy results. Extensive calculations have been made only with the Beattie-Bridgeman^{3,4} formula, but the ranges of temperature and pressure covered in the present paper probably far exceed the limits of validity of any existing equation of state. Since the calculation of the constants in the Beattie-Bridgeman formula for high pressure data on nitrogen were made, further work by the writers⁵ has shown that its constants are different above and below the critical density for hydrogen and a 3:1 mixture of hydrogen and nitrogen. The calculations with nitrogen⁴ were carried only a trifle beyond the critical density and it is possible that if higher densities had been included a different set of constants would have been indicated for densities above critical. If this second set had been introduced the formula would doubtless have been found to fit better at high pressures than was concluded in our paper, but calculations of the desired physical properties at medium and high pressures are surely more reliable when made by the graphical method about to be described. By it no discontinuities are introduced and the precision can be estimated by the regularity of the graphs of the quantities evaluated.

The authors of the Beattie-Bridgeman equation of state have used it to find the heat capacities and Joule-Thomson coefficients of air and ammonia⁶ at ordinary temperatures and relatively low pressures, where the increase ΔC_p in heat capacity is usually a small fraction of the heat capacity at 1 atm. C_p is computed by calculating the change ΔC_p in heat capacity with pressure and adding it to the value of C_p at 1 atm., and when $\Delta C_p/C_p$ is small, large errors in ΔC_p are overlooked when observed and calculated values of C_p are compared.

After studying the α and Δ curves for nitrogen, we decided that it is expecting too much of any formula that it should follow the trends of the p - v - T data as faithfully through the whole range as is desired for determining the physical properties sought after. The following graphical process was developed in the hope of obviating some of the difficulties with analytical methods.

The v vs. T isobars are nearly straight lines from -70 to 600° even to 1200 atm., but by plotting residuals their curvature can be measured easily. If the gas were perfect, the v vs. T isobars would be straight lines through the origin having slopes inversely proportional to the pressure. Any departure from the perfect gas law is evidenced by residuals such as

$$\Delta \equiv v(pv/RT - 1) \quad (1)$$

and

$$\alpha \equiv RT/p - v \quad (2)$$

being different from zero; likewise any departure of $(-p/v)(dv/dp)_T$ and $(T/v)(dv/dT)_p$ from unity is evidenced by $(d\Delta/dp)_T$, $(d\alpha/dp)_T$, $(d\Delta/dT)_p$, $(d\alpha/dT)_p$ being different from zero. Fig. 1 shows how straight the 200 atm. v vs. T isobar is, how much curvature the corresponding Δ and α curves have, and that their shapes are different. There are relations between the slopes

Fig. 1. Graphs of v , Δ , and α vs. T with p constant. This shows that the Δ and α curves have great curvature compared with the v vs. T curve, and that the Δ and α curves are of very different shape.

of the v vs. T , Δ vs. T , and α vs. T isobars; likewise there are relations between the slopes of v vs. p , p vs. p , Δ vs. p , α vs. p , Δ vs. ρ (density) isotherms. The relations between these are as follows:

$$(T/v)(dv/dT)_p = \frac{pv/RT + (T/v)(d\Delta/dT)_p}{1 + 2\Delta/v} \quad (3)$$

$$(T/v)(dv/dT)_p = RT/pv - (T/v)(d\alpha/dT)_p \quad (4)$$

$$(-p/v)(dv/dp)_T = 1 - \rho(dp/dp)_T \quad (5)$$

$$(-p/v)(dv/dp)_T = RT/pv + (p/v)(d\alpha/dp)_T \quad (6)$$

$$(-p/v)(dv/dp)_T = \frac{pv/RT - (p/v)(d\Delta/dp)_T}{1 + 2\Delta/v} \quad (7)$$

$$(-p/v)(dv/dp)_T = -pv/RT(2\Delta/v + 1 + \rho^2(d\Delta/d\rho)_T) \quad (8)$$

$$(d^2v/dT^2)_p = -(d^2\alpha/dT^2)_p \quad (9)$$

$$(2\Delta/v + 1)(d^2v/dT^2)_p = (d^2\Delta/dT^2)_p - \frac{2p}{RT} \frac{(\Delta/T - (d\Delta/dT)_p)^2}{(2\Delta/v + 1)^2} \quad (10)$$

A 1 percent error in estimating the slope of an α vs. T or a Δ vs. T isobar may mean only a few hundredths percent error in $(dv/dT)_p$, since by Eqs. (3) and (4) the slopes $(d\alpha/dT)_p$ and $(d\Delta/dT)_p$ enter as correction terms to the

slope that the v vs. T isobar would have if the gas were perfect, just as α and Δ are correction terms to v by Eqs. (1) and (2). Likewise, any error in the determination of $(-p/v) (dv/dp)_T$ is diminished according to Eqs. (5), (6), (7), (8). The different families of isobars and isotherms have quite different appearances, so the effect on $(-p/v) (dv/dp)_T$ or $(T/v) (dv/dT)_p$ of any personal error in estimating the slope of a curve on account of its having a particular shape may be balanced out at that point by a determination from some other curve of different shape. It was not noticeable that the determinations of these derivatives from the α curves were consistently higher or lower than those from the Δ curves or any others.

In order to determine $(d^2v/dT^2)_p$ one can plot $(dv/dT)_p$ vs. T isobars and read the slope at the desired point. Or, one can plot $(d\alpha/dT)_p$ or $(d\Delta/dT)_p$ vs. T isobars, and from the slope of these curves and the relations between $(d^2v/dT^2)_p$ and $(d^2\alpha/dT^2)_p$ or $(d^2\Delta/dT^2)_p$, one can determine $(d^2v/dT^2)_p$. Both methods were used; the results agreed well, and their averages at the various points are shown in Fig. 2.

The most probable positions of observed points lie on the most plausible graph (curve or surface) that can be drawn from them. The most probable values are not uniquely determined by a graphical method, because they depend on the weight assigned by the investigator to various essentials. An adjustment by least squares depends on the weights assigned to the observations so it, too, is subject to the taste and judgment of the computer or observer. Schemes of curve fitting or adjusting that give unique results are incapable of weighting the observations and of throwing the adjustment where it belongs. This has been discussed in two papers by the senior author.⁷

We adopted as a working principle that, in the range investigated, all surfaces such as $p, v, T; \Delta, p, T; \alpha, p, T; (d\alpha/dT)_p, p, T$; etc.; have no sharp ridges nor breaks; accordingly all families of isobars and isotherms should be smooth curves without sharp bends or cusps. All the curves in a given family should show their relationship one to another since they can be considered as sections all cut from the same surface, so that each helps to regulate the drawing of the others. The p - v - T data themselves were adjusted by first drawing smooth curves through the Δ vs. p isotherms and reading off Δ from them, then by plotting these Δ against T with p constant and smoothing these curves for the final values of Δ . The specific volumes were calculated from these final values of Δ . The precision of adjusted observations is strengthened by a wide range of temperature and pressure, such as that studied in this work.

The final values shown in the table and curves were smoothed with respect to temperature and pressure, except where they had been derived from others that had already been smoothed. The regularity of the points on the Δ and α curves attests to the high precision of the compressibility data and gave promise that thermodynamic calculations derived from them should be reliable.

⁷ W. Edwards Deming, Proc. London Phys. Soc. 42, 97 (1930); Phil. Mag. 11, 146 (1931).

In most p - v - T determinations, the measurement of v is subject to greater error than those of p and T . The Δ and α curves are large scale deviation graphs of residuals of volume and they greatly magnify any error in v , so it is possible to smooth out any irregularities that may be in the original data, and put the adjustment where it belongs. Δ can probably be smoothed to within 0.005 cc/g; and since $(dv/d\Delta)_{p,T} = 1/(2pv/RT - 1)$, the smoothed specific volumes should be accurate to within 0.005 cc/g except in the extrapolated region and in the small range where $pv < RT$.

After considerable practice in laying a straight edge tangent at various points along a curve where the slopes are definitely known, it was found possible to estimate the slope at any point within half a percent, in trial after trial. It thus seemed that our various families of curves represented the most likely course of the p - v - T relations, and that the required derivatives could be gotten very accurately by mechanical means.

The tables published by Bartlett *et al.* show compressibility factors $pv/(pv)_s$ at the different pressures and temperatures. The denominator $(pv)_s$ is the value of pv at S.T.P. In order to find the specific volume of the gas it is required to know the volume of 1g at S.T.P. Birge gives 22414.1 cc as the volume of a mole of an ideal gas at S.T.P.

$pv/(pv)_s$ at 1 atm. is close to 1/1.00046. The gas used by Bartlett contained 0.9993 nitrogen and 0.0007 inert gas, presumably argon; the apparent molecular weight is therefore taken as 28.025. The volume adopted for 1

g at S.T.P. is accordingly $22414.1/1.00046 \times 28.025 = 799.42$ cc, and the value of RT at 0° is $22414.1/28.025 = 799.79$ cc atm./g. When one of Bartlett's compressibility factors is divided by the pressure and multiplied by 799.42 the result is the volume in cc of 1 g of the gas at the given temperature and pressure.

Some of the temperatures listed by Bartlett *et al.* were not integral; further a calibration of their thermocouple by the Bureau of Standards showed that the temperatures published¹ as -25° , -50° , -70° should have been -24.99° , -49.93° , -69.90° . We have made the slight alterations necessary to change his data to integral temperatures by a sensitive method of interpolation.⁵

At pressures below 100 atm. we used a compilation deduced by Dr. Bartlett from all the available data, chiefly from Amagat, the Reichsanstalt, and the cryogenic laboratory at Leiden, since Bartlett worked at the low pressures only to tie his results with those of previous observers. This compilation was kindly furnished us by Dr. Bartlett in a private communication. Our Δ vs. p isotherms give an easy and reliable means of interpolating to even pressures—one has only to read off Δ at any desired p and calculate v therefrom; accordingly we list results at 20, 40, 60, 80, 100 atm. rather than at the odd pressures one gets by converting meters of Hg to atm.

The Δ vs. p isotherms also give a reliable method of extrapolating to higher pressure; since the original ten isotherms constitute a family of curves, one can not go far wrong in extending them a reasonable distance. This was done and values of Δ were read at 1100 and 1200 atm. The specific volumes calculated at these pressures are probably not in error by 0.01 cc/g, judging from the regularity of the Δ vs. p isotherms and the values of $(dv/d\Delta)_{p,T}$ in this region. In the same way the Δ vs. T isobars give a means of extrapolating to temperatures higher than 400° . Values of Δ were read from the extended isobars at 500 and 600° . In order to estimate the error of the extrapolations, the Δ vs. T isobars were first plotted only to 300° and were extrapolated to 400° and the Δ read at that temperature. Later the observations at 400° were plotted and the smoothed Δ read. The two sets of specific volumes calculated from these two sets of Δ agreed closely, the probable error being 0.17 percent.

The value of these extrapolations, if they are reliable, must be considerable. To extend the experiments to 1200 atm. and 600° would entail enormous expense and labor. Calculations at 1100 atm. and 500° were included, because with them, at least, there should not be any risk. All the calculations in the extrapolated region tied on to the others satisfactorily, so it seems safe to assume that they were made successfully.

The final values of the physical properties at the twelve temperatures and fourteen pressures are shown in the table, or in the figures. Their preparation and implications will now be discussed.

Column 3 shows the specific volumes, which were calculated from the adjusted values of Δ through Eq. (1). The densities in column 4 are the reciprocals of the specific volumes.

The fugacities in column 5 were computed from the smoothed values of α by Lewis and Randall's⁸ graphical method.

In columns 6 and 7 the pressure and temperature coefficients of volume expansion are shown. The reason for listing $-(p/v) (dv/dp)_T$ and not $-(1/v) (dv/dp)_T$ is that the former is dimensionless, and this fact facilitates changing units. Thus if one wishes to get the pressure coefficients at 100° for pressures in meters Hg, one has only to plot the values in column 6 for the 100° isotherm against p in atmospheres, and then graduate the scale of abscissas in the new units of pressure; one can then read $-(p/v) (dv/dp)_T$ for any number of meters Hg. The ordinates need not be changed in any way because they are dimensionless. Another advantage is that we can see at a glance how far this coefficient departs from unity, which is the value it would have if the gas were perfect. $(T/v) (dv/dT)_p$ was listed for the same reasons. The pressure coefficients of column 6 were adjusted from determinations given by the p vs. p , α vs. p , Δ vs. p , and Δ vs. p isotherms through Eqs. (5), (6), (7), (8); the temperature coefficients of column 7 were adjusted from determinations given by the α vs. T and Δ vs. T isobars through Eqs. (3) and (4). The unsmoothed values at any point determined by the different methods nearly always agreed closely; when they disagreed more than 1 percent even at the highest pressures we went back and reconsidered the curves. Particular care was given to the determinations of $(T/v) (dv/dT)_p$, because this derivative enters to the second power in the calculation of $C_p - C_v$ and because it is used to get $(d^2v/dT^2)_p$, which enters into the calculation of ΔC_p .

Probably the most important properties that result from these calculations are C_p and C_v . For this reason extreme care was exercised to obtain the greatest possible precision for ΔC_p , which is shown in column 8. This depends on $(d^2v/dT^2)_p$ through the thermodynamic equation

$$(dC_p/dp)_T = -T(d^2v/dT^2)_p, \quad (11)$$

which when integrated along an isotherm gives

$$C_p = C_{p'} + \int_{p'}^p -T(d^2v/dT^2)_p dp. \quad (12)$$

$C_{p'}$ is the heat capacity at pressures p' . The $-T(d^2v/dT^2)_p$ vs. p isotherms are shown in Fig. 2. The area under a given isotherm between any two abscissas is the change in C_p between those abscissas. The values of ΔC_p obtained by Eq. (12) from the curves in Fig. 2 were smoothed with respect to temperature and pressure before being listed in column (8).

In drawing the curves of Fig. 2 it was necessary to know something about their course in the region $0 < p < 20$, since p' was 1 atm. In an extremely rarefied condition the gas would have some characteristics of a perfect gas. The question has been raised by the writers⁹ whether $(d^2v/dT^2)_p$ and $(dC_p/dp)_T \rightarrow 0$ as $p \rightarrow 0$, as they would if the heat capacity of the actual gas at very low pres-

⁸ Lewis and Randall, *Thermodynamics*, pp. 192 to 195, McGraw-Hill (1923).

⁹ Deming and Miss Shupe, *Phys. Rev.* **37**, 220 (1931).

sure behaves like that of a perfect gas. For the calculations in this paper we have assumed that $(dC_p/dp)_T \neq 0$ at $p=0$, and for its value we have used, wherever it seemed feasible, the one given by the Beattie-Bridgeman equation of state with constants determined⁴ from these same compressibility data. In Fig. 2 are shown the graphs of $-T(d^2v/dT^2)_p$ vs. p isotherms. The points are the averages of determinations made from the α vs. T and Δ vs. T isobars through Eqs. (3), (4), (9), (10). The curves given by Beattie's formula⁶ are shown dashed and they are drawn as far as the equation of state might be expected to hold, namely, as far as the critical density. At 100, 200, 300, and 400° the dashed curves seem to be the best curves that could be drawn to the points shown.

The curves in Fig. 2 for 20, 50, and 100° are not quite flat from 20 to 100 atm. This is the range of pressure considered by Hoxton¹³ in discussing the

Fig. 2. $(dC_p/dp)_T$ vs. p isotherms. The full lines are drawn to the points determined from the p - v - T data. The dashed curves are given by the Beattie-Bridgeman equation of state, and are drawn as far as the critical density. Where only the dashed line is shown, the Beattie-Bridgeman values were accepted. To avoid confusion, some of the curves are not drawn at high pressures. The area under a particular curve between any two pressures is the change in heat capacity (in cc atm./g deg.) between these two pressures, at that temperature.

variation of the heat capacity of oxygen at 26° obtained in the experiments of Workman.¹¹ Hoxton speaks of a "change in c_p per atmosphere relative to its value at one atmosphere, the temperature being constant and taken as 26°C," and says that Workman found this quantity $\delta \equiv (dC_p/dp)_T/C_p'$ to be constant and equal to 0.00165 parts per atm. This implies that for oxygen the $(dC_p/dp)_T$ vs. p 26° isotherm is flat. There are reasons to expect C_p for nitrogen and oxygen to be similar in some ranges of temperature and pressure; e.g., their C_p values at one atmosphere for various temperatures are sometimes¹² expressed by the same formula, and Jakob's results for air are very similar to ours for nitrogen in some respects (*vide infra*). Our curves in Fig. 2 show that δ for nitrogen should decrease slightly with pressure. Taking 0.0178 and 0.0125 as the average ordinates for the 20° and 50° isotherms from

¹² E. D. Eastman, Specific Heats of Gases at High Temperatures, Bureau of Mines Techn. Paper 445 (1929).

20 to 100 atm. in Fig. 2, and interpolating linearly to 26°, δ turns out to be 0.00164 parts per atm. for nitrogen, very nearly what it is for oxygen.

In order to find C_p from Eq. (12) it is necessary to adopt values of C_p' at some pressure p' for the different temperatures. Several formulas have been devised to express C_p at 1 atm. as a function of T . As far as we know none of these is expected to extend to temperatures much below 20°. For C_p' at the low temperatures we finally accepted Brinkworth's¹³ three values, which are 6.91, 6.92, 7.20 at 10, -78, -183°. A smooth curve through these points met Partington and Shilling's¹⁴ formula very well at 30°, so we constructed a curve through Brinkworth's three points and points calculated from Partington and Shilling's formula above 30°, and from this curve read the values for C_p' that are listed below.

$t^\circ\text{C}$	-70	-50	-25	0	20	50
C_p' (1 atm.)	6.92	6.91	6.91	6.91	6.91	6.92
$t^\circ\text{C}$	100	200	300	400	500	600
C_p'	6.94	6.98	7.01	7.05	7.09	7.13

Eastman's formula would not join on to Brinkworth's points satisfactorily. At 200° Eastman's and Partington and Shilling's formulas differ by 0.1 cal/mole·deg. As the temperature increases the disparity widens even more, which shows that more precise direct calorimetric measurements of C_p at 1 atm. are needed.

It is difficult to estimate the accuracy of the ΔC_p , which are shown in column 8. The relation of the curves and points in Fig. 2 suggests that the precision of the calculations is greatest at the highest pressures. The calculated values of C_p agree well with the experimental values of Mackey and Krase.¹⁵ They worked to 700 atm. at 30, 100, 125, 150° and to 800 atm. at 50°. Their points have been inserted in Fig. 4, so that observed and calculated values can be compared at a glance. The dashed curves represent calculated values obtained by interpolating along C_p vs. T isobars. At 50° the agreement is excellent through the entire range of experiment. At 30° the calculated values run below the experimental ones above 400 atm., and at 100, 125, 150° the calculated values lie above the experimental ones throughout the entire range. While the discrepancy is probably not greater anywhere than the experimental error of the calorimetric measurements, the trend of the calculated curves is definitely away from the experimental points above and below the 50° isotherm. An incorrect assumption for C_p at 1 atm. would result in a constant distance between an experimental and a calculated isotherm. A constant difference above, say, 100 atm. might mean that the corresponding isotherm in Fig. 2 is incorrectly drawn between 0 and 100 atm. But we are at a loss to account for the *constantly widening* gap between the calculated and experimental points at 30° above 350 atm., and for that at 100, 125, and 150°. The precision of the points in Fig. 2 does not diminish

¹³ J. H. Brinkworth, Proc. Roy. Soc. A111, 124 (1926).

¹⁵ B. H. Mackey and Norman W. Krase, J. Ind. and Eng. Chem. 22, 1060 (1930).

with increasing pressure, and they could hardly be *consistently* in error by so great an amount as to account for the widening gaps. It thus seems impossible that the discrepancy can be laid to the calculations from the p - v - T data.

Witkowski's curves¹⁶ for air go only to 100 atm., but it is interesting to note that the hump that appears in Fig. 3 at the lowest temperatures appears

Fig. 3. Variation of C_p for nitrogen with pressure. Mackey and Krase's values \circ 30° , σ 50° , τ 100° , ω 125° , ϕ 150° .

in his curves for -100° and lower temperatures; also that the pressure at which the hump appears decreases as the temperature decreases with both air and nitrogen.

Comparison with Jakob's² calculations of C_p for air show agreement within a few percent at 100 and 200° through 200 atm., and within a few percent at -50° and 50 atm.

$$C_p - C_v = -T(dv/dT)_p^2/(dv/dp)_T. \quad (13)$$

Since the derivatives used in Eq. (13) have already been evaluated, $C_p - C_v$ can be calculated at each pressure and temperature. The results are shown in Fig. 4. In view of the precision claimed for the first derivatives, the error in $C_p - C_v$ should not exceed 0.3 percent, which is about as close as the graph can be read. It will be noticed that these curves all run toward the ordinate

¹⁶ Witkowski, Phil. Mag. 42, 1 (1896). These curves are shown in Partington and Shilling's book, p. 154.

R as p approaches zero. It was found that our values of $C_p - C_v$ for nitrogen agree closely with Jakob's for air; for example, our 100 atm. isobar almost

Fig. 4. The variation of $C_p - C_v$ for nitrogen with pressure at various temperatures.

coincides with his for 100 kg/cm² throughout his entire range of temperature. Our $C_p - C_v$ values were smoothed with respect to temperature and pressure.

The values of $C_p - C_v$ from which Fig. 4 was plotted were subtracted from the values of C_p in Fig. 3 to get the C_v graphed in Fig. 5. It will be seen that

Fig. 5. Variation of C_v for nitrogen with temperature at constant pressure. The numbers on the isobars denote atmospheres.

C_v at 20 atm falls from 5.15 cal/mole·deg (2.59 R) at 600° to 2.50 R at 100°, and it stays there as the temperature is lowered to -70°. An increase in pres-

sure lowers C_v at -70° until 100 atm. is reached; at 200 atm. and higher, C_v rises as the temperature falls below 20° , and the rise is steeper the higher the pressure. Above 400° it is evident that C_v is approaching the same value for all pressures; at 600° C_v is about 5.18 cal/mole-deg or $2.61 R$ from 20 to 1200 atm. Jakob's calculated values of c_v for air, when plotted, show the same behavior at low temperatures for his entire pressure range, which included 200 kg/cm². His 200 kg/cm² isobar would fall off faster than his 100 kg/cm², instead of rising like the 200 atm. isobar in Fig. 5; but 200 kg/cm² is at the end of his pressure range and he lays no claim for accuracy there, so it can only be conjectured how C_v for air compares with C_v for nitrogen above 100 atm. Various explanations of this behavior in Fig. 5 have been considered, but they will not be discussed here because we prefer to present results only.

The Joule-Thomson coefficient can be calculated from the equation

$$\mu C_p = T(dv/dT)_p - v \quad (14)$$

by using the values already found for C_p and $(dv/dT)_p$. They are listed in column 9. The inversion temperatures for the various pressures are where

Fig. 6. Inversion curve for nitrogen. The points were read from the μ vs. T isobars and the μ vs. p isotherms. μ denotes Joule-Thomson coefficient $\mu = (dT/dp)_H$. x denotes Roebuck's inversion points for air.

the μ vs. T isobars cross the ordinate $\mu = 0$, and the inversion pressures for the various temperatures are where the μ vs. p isotherms cross the ordinate $\mu = 0$. The inversion curve, Fig. 6, is plotted from the inversion points so obtained. There are no existing data on the Joule-Thomson coefficient for nitrogen, so a comparison with observed values is not yet possible. Roebuck's¹⁷ values for air give the inversion points marked x on Fig. 6.

If the results derived in the present paper are a step toward the determination of the heat capacity and other physical properties of gases, the importance of compressibility data must be recognized. The calculations in this paper were made by two people in nine weeks time. Compressibility data on a number of gases are now available; their physical properties will be determined as rapidly as possible and will appear in subsequent papers. The method will doubtless undergo changes that will result in greater precision.

This work was undertaken at the suggestion of Dr. Edward P. Bartlett, formerly of this laboratory. We have enjoyed the encouragement and willing cooperation from him and the staff at this laboratory throughout the course of the work. We wish also to acknowledge indebtedness to Professor James A. Beattie of the Massachusetts Institute of Technology for his interest in the work, especially in the heat capacity at low pressures, and to Professor L. G. Hoxton of the University of Virginia for his encouragement and many helpful suggestions.

Note added in proof, February 16, 1931: Some results on C_p for nitrogen to be read by E. J. Workman at the New York meeting of the American Physical Society on February 26, 1931 make possible further comparison between the present calculations and experimentally obtained results. Workman has obtained $C_p:C_p'$ at 30, 60, 90, 130 kg/cm² at 26° and 60°C. C_p read from the original tracing of Fig. 3 at these points gives the following comparison. W denotes Workman, D denotes Deming and Miss Shupe. 6.916 and 6.926 cal/mole deg were adopted for C_p' at 26° and 60°.

numerical value given for the quantity $\Sigma(\nu_i s_{0i})'$ has been found incorrect. Eq. (13) should read: $\Sigma(\nu_i s_{0i})' = -22.9850$. The entropy constant (s_{0i}') for ammonia appearing in Table III should be -22.9809. This requires several corrections in Table IV, which when revised is as follows.

Reflection of High Velocity Electrons from Solid Surfaces

Bothe¹ has derived an expression for the angular distribution of electrons which are transmitted by matter and which have penetrated sufficient thickness to become completely diffused, and finds fair agreement with experimental work done with β -particles. It becomes of interest² to know the angular distribution of electrons emitted backwards from solid surfaces, since it is possible that the two distributions are similar. This question, together with the determination of absolute values of reflection, was studied during an investigation on scattering of high velocity electrons by thin foils.

If we call the half-angle of the solid cone about the normal to the surface, θ_1 , and the half-angle subtended by the opening through

which the electrons emerge, θ_2 , then experimentally all electrons, due to an originally homogeneous beam, emitted between these two cones are collected in a field-free space. The ratio of this number to the total number incident on the surface will be called ρ' . A small correction (less than 2 percent) may be made to ρ' for the electrons which come back between θ_2 and 0°. The corrected value, ρ , is then plotted as a function of θ . The following elements have been tested: Pb, Sn, Cu, Al, C, Be. The curve showing the variation of ρ with angle, for the heavier elements and voltages above 100,000, agrees with the curve $\rho_0 \sin^2 \theta$ to within 1 percent, where ρ_0 is the

¹ W. Bothe, Zeits. f. Physik 54, 161 (1929).

value of ρ at $\theta=90^\circ$. The intensity at any angle is therefore given by the simple cosine law. Small deviations from this law are found for the lighter elements such as C and Be, especially at voltages below 70,000. More investigations are being conducted. Bothe's expression for the angular distribution of transmitted electrons which are completely diffused, deviates from the distribution found experimentally for electrons emitted in a backward direction, by about 5 percent at $\theta=45^\circ$, both curves coinciding at 0° and 90° .

For beryllium ρ_0 , or the "rediffusion constant" of Webster,² is found to be 0.0291 for 70,000 volt electrons and decreases to 0.0248 at 130,000 volts, instead of being 0.043 which

he deduces. These values include all electrons emitted. In the case of beryllium, only 2 percent of the emitted electrons have energies below 2,000 volts.

A decrease in ρ is found for all the lighter elements with increase of voltage. In the range between 45,000 and 130,000 volts, this decrease amounts to 7 percent in the case of aluminum, becomes 0.6 percent for tin and less than 0.1 percent for lead.

The Extrapolation of Atomic Structure Factor Curves

In a recent¹ note under the above title, D. K. Froman has derived an extrapolation formula for atomic structure factors on the basis of "electron distributions indicated by the wave equation." Although it is certainly true that quantum mechanics can be taken as the basis for deriving such formulas, it is of interest to note that Froman's result can be obtained without any appeal to a specific theory of the electron distribution causing the atomic structure factor. We have in mind simply the fact that repeated integrations-by-parts of Froman's Eq. (2) which defines the structure factor of the n^{th} order gives us at once the result that:

$$F_n = \sum_k a_{kn} \left(\frac{D}{n}\right)^{2k} = \sum_k a_{kn} \left(\frac{2 \sin \theta}{\lambda}\right)^{-2k}$$

¹ D. K. Froman, Phys. Rev. 36, 1339 (1930).

Nuclear Spin of Aluminum

The recent letter by J. H. Bartlett, Jr. on nuclear spin has been read with a great deal of interest, and in view of the importance of the subject the writers would like to point out an apparent discrepancy. After a careful survey of the work done on the hyperfine structure of the lines of various elements, the writers had reached the same general conclusions as Bartlett. It was disconcerting, however, to find that Janicki (Ann. 29, 833, (1909)) and Wali-Mohammed (Astrophys. J. 39, 185, (1914)) had both photographed the Al lines 3944A and 3961A using Lummer-Gehrcke plates and found them "very sharp and simple."

Recently, while studying different light sources for the purpose of finding the most

where:

$$a_{kn} = \frac{(-1)^k}{(2\pi)^{2k}} \left[\left(\frac{U(r)}{r} \right)^{(2k-2)} \cos \frac{2\pi nr}{D} \right]_{r=0}^{r=D/2},$$

the notation being that used by Froman.

The first equation is clearly identical with Froman's Eq. (8), and his Eq. (12) can be derived similarly. It is thus seen that Froman's extrapolation formula is the general consequence of the definition of the structure factor, being in fact, the asymptotic expansion for F_n , and is independent of any wave-mechanical interpretation of the electron distribution.

MORRIS MUSKAT

Gulf Research Laboratory,
Pittsburgh, Pennsylvania

suitable source for use in analyzing the hyperfine structure nitrogen lines, occasion presented itself for photographing the following Al lines in a Schüller hollow cathode discharge cooled by liquid air.

A Fabry-Perot interferometer, with fixed etalons, was used in conjunction with a Zeiss triple prism spectrograph for analyzing the lines. Several exposures, made under different conditions and with different etalons, were made on each line. Mirrors having a reflection coefficient of 90 percent or greater were used, so that the resolving power of the interferometer was about 10^6 . Under these conditions all four Al lines were found to be sharp and lacking in structure.

Typical microphotometer curves of these

lines are shown in Fig. 1. From a careful study of all the curves obtained from various Al lines, and from the lines of various other elements in which structure is clearly present, it is estimated that if these Al lines have structure the average separation is not greater than 0.006A.

(Naturwiss. 17, 673 (1929)) assume, the electron in the nucleus loses its power to determine what the statistics of the nucleus shall be, then the 27 protons determine the nuclear moment and an odd number of $(1/2) \cdot (h/2\pi)$ units would be expected. If the electron does not lose this power, the nuclear moment would

Fig. 1. Microphotometer curves of interferometer patterns.
(a) Al I λ 3961. (b) Al II λ 4663.

As is shown in Table I, the lines 3944A and 3961A constitute the first member of the sharp series of Al I and result from an electron transition s to p . According to other hyperfine structure data (White, Phys. Rev. 35, 1146 (1930) *et al.*) such a transition should give wide hyperfine structure separations. The line

be determined by the 27 protons plus 14 electrons, and one would still expect an odd number of $(1/2) \cdot (h/2\pi)$ units for the nuclear spin. But the available data indicate that this moment is zero.

Recent data on the value of the nuclear moment for nitrogen still leave some doubt

TABLE I. Aluminum arc and spark lines which show no hyperfine structure.

	λ	Classification	Total line width
Al I	3944.025	$3p^2P_{1/2} - 4s^2S_{1/2}$	0.032A
Al I	3961.537	$3p^2P_{1/2} - 4s^2S_{1/2}$	0.029A
Al II	4226.812	$3s4d^3D_3 - 3s9f^3F_4$	0.034A
Al II	4663.054	$3s3d^1D_1 - 3s4p^1P_1$	0.037A

4663A results from a p to d electron transition and although this would probably not show as wide a hyperfine structure as the s to p transition, it should be observable if the nuclear moment of Al was different from zero.

Since Aston (Phil. Mag. 49, 934 (1923)) reports Al to have only one isotope at 27, the present data indicate that Al in no way fits any of the proposed schemes of the building-up process in the nucleus or the theories of nuclear moments. For, if as Heitler and Herzberg

as to what the real value is. Al and N may, then, be considered as disturbing exceptions to present theories of nuclear structure.

We are indebted to Mr. A. Rosenblum for preparing the microphotometer curves used in this analysis.

What Requirements must the Schrödinger ψ -Function Satisfy?

In a recent paper with the above title, G. Jaffé¹ contends that the proper solutions of the wave equation must be everywhere finite and continuous, and that the condition of quadratic integrability is not enough. In support of the latter point he shows that a solution for the angle part of the wave function of the central field problem for the case $m=0$, may be obtained for non-integral values of l : this solution is quadratically integrable but has a logarithmic singularity. Since this would result in a continuum of spectroscopic terms quite unknown in experiment, Jaffé concludes that the condition of finiteness and continuity is required.

The authors are presenting a paper in which this question is of central importance and therefore find it advisable to point out that Jaffé's conclusion is not at all necessary and in fact is surely too stringent for many problems in atomic structure.

The reason a solution such as that mentioned by Jaffé is possible, is that when the wave equation is expressed in polar coordinates some of the coefficients have singularities not brought in by the potential energy. If the equation is written in Cartesian coordinates there are no singularities except those of the potential energy function. We see then that the singularities are introduced into the equation by the transformation from Cartesian to polar coordinates. This is substantiated by the fact that at the singular points in question the Jacobian of the transformation from Cartesian to polar coordinates vanishes, showing that the transformation at these points is not legitimate.

Of all possible coordinate systems the Cartesian is to be preferred in the wave equation because of its simplicity, homogeneity (volume element constant), and isotropy (line element diagonal with constant coefficients). From the form of the equation we are led to expect that a proper wave function should have no singularities except at those of the potential function. Hence in the case of the hydrogen problem a quadratically integrable singularity is permissible at the origin, but not elsewhere.

Without giving up the condition of quadratic integrability as being sufficient restriction on the wave function, one can rule out Jaffé's example for the following reason: The wave equation is not the best starting point for the theory. The fundamental thing is the integral

$$J = \int \left(\frac{\hbar^2}{4\pi^2} T \left(q, \frac{\partial \psi}{\partial q} \right) + V \psi^2 \right) d\tau$$

where $T(q, p)$ is the classical expression for kinetic energy in terms of coordinates and momenta and V is the potential energy.

The function ψ is determined by the condition that J be a minimum. Its minimal values are the energy levels. The Euler equation corresponding to this variational integral is the wave equation. However, satisfying the wave equation is necessary but not sufficient to make this integral a minimum.² From the wave equation $H\psi = E\psi$, we can obtain the integral form $\int \psi_n H \psi_n d\tau = E_n$ which in Cartesian coordinates can be shown to be the equivalent of J . This comes from the fact that the condition of quadratic integrability is sufficient to insure the vanishing of the surface integral by which J differs from $\int \psi H \psi d\tau$. In polar coordinates the two need not be equal when singularities arise at the boundaries.

In the case which Jaffé mentions, if l is not an integer, not only is J not a minimum but it is *infinite* and therefore the solutions for this case can have no physical significance.

In general if the wave function has a singularity the energy integral will be infinite except possibly if the potential function has a singularity in the same place. The ultimate criterion then for an acceptable wave function is that J be finite (and a minimum). As a rough working rule we may demand of the function that it be integrable in the square and that it be finite and continuous wherever the potential energy is finite. If we introduce singularities (physically non-existent) in the potential energy we must be prepared to put up with singularities in the wave function at those points. When, in the future, we get a deep enough insight into the nature of the physical problems so that we can replace the singular values of the potential energy by their true finite values, the singularities of the wave functions will also be removed. But until then we must be content with results which differ from the facts to the same degree as do the assumptions from which we start.

BOOK REVIEWS

Magnetic Phenomena. SAMUEL ROBINSON WILLIAMS. Pp. xxii+230. 150 figures. McGraw-Hill, New York, 1931. Price \$3.00.

Professor Williams has been deeply interested in magnetic phenomena for many years and has already contributed much to their study, both personally and by stimulating others to independent research. His attempt in the present monograph to enlist additional recruits for the attack upon magnetic strongholds is therefore of especial interest. He has decided that the college undergraduate should be approached and now offers him a text-book of an unusual kind in which almost undue emphasis is laid upon the unfinished and provisional character of much of the available information. His choice of audience naturally limits him somewhat both in the total content of his book and in the mode of presentation. He has cut down the mathematics required of the reader to such an extent that he often loses desirable rigor and even, in several places, falls into confusing errors. It would have been much better, in the opinion of this reviewer, to expect a good working knowledge of the calculus in all cases.

Under one or other of the chapter headings "magneto-magnetics, magneto-mechanics, magneto-acoustics, magneto-electrics, magneto-thermics, magneto-optics, cosmical magnetism, magnetic theories and experimental facts" will be found some account, however brief, of almost everything known about magnetism. The topics selected for most detailed comment are, as they should be, those with which the author is personally most familiar. The bibliography, especially in these selected parts, is unusually rich in the earlier references. In other places the treatment is much more sketchy, and some omissions from the index (e.g. crystal!), make it hard to discover how much of the most recent work has been covered. Some of the omissions are surprising. The most careful search, after a critical reading of the entire text, fails to disclose any reference to the great electromagnet at Bellevue or to the magneto-caloric effect and related phenomena. The postponement of magneto-crystallic effects to some future treatise also seems most unfortunate.

The publisher's part of the work is well done, unless the rather numerous misprints in the text and disagreements in lettering between figures and text are attributable to his staff.

The reviewer has tried to convey the mixture of pleasure and disappointment which affected him during his review. A reader to whom more of the phenomena are wholly new would probably derive a larger proportion of pleasure and, perhaps, be incited to straighten things out for himself. This, of course, is just what the author wishes.

L. W. MCKEEHAN

Gmelin's Handbuch der Anorganischen Chemie. 8 Auflage; herausgegeben von der Deutschen Chemischen Gesellschaft; System Nummer 59. Eisen; Teil A, Lieferung 3: Pp. 313-586. Verlag Chemie G. m. b. H. Berlin, 1930, price RM 40 (subscription price RM 32).

The above volume is of a more technical character than most of the other of Gmelin's Handbooks; a complete literature review with bibliography on the passivity of pure and technical iron (written by Dr. E. Liebreich), its chemical behavior and its corrosion (by Dr. M. Rudolph, Dr. A. Eisner and Dr. A. Kotowski) and its metallurgy (Prof. R. Durrer, Dr. H. Lueb and Dr. M. W. Neufeld) are given. The material has been collected in a non-critical way, thus giving the book a compilatory character as in the other issues of the same edition. It seems to the reviewer that with the five previous volumes the present one comprises the most complete monograph we have at present on the physical, chemical and metallurgical properties of iron and it forms a worthy addition to the Gmelin series.

I. M. KOLTHOFF

The Quantum Theory. FRITZ REICHE. Translated by H. S. Hatfield and Henry L. Brose. Pp. viii+218. Figs. 15. E. P. Dutton and Company, Inc., New York, 1931. Price, \$2.10.

The first English edition of this book, dated 1922, was a translation of the German original the preface of which bears the date October 1920. To the present edition the translators have

contributed a chapter of twenty-four pages which together with nine pages of notes and references covers developments since 1920. The result is that nine of the ten chapters are written from the point of view of ten or more years ago, while the tenth, covering developments since that date, must, because of its brevity, devote to any important topic an amount of space "less than ϵ " in the sense in which mathematicians often use that phrase. What constituted a clear exposition in the light of the day when it was written will, in many instances, prove misleading for the student of today, while the last chapter will surely be almost unintelligible to one whose knowledge of the subject is based upon reading the first nine.

A. ELLETT

Photoelectric Cells and Their Applications. A discussion at a joint meeting of the Physical and Optical Societies (of London), June 4 and 5, 1930. Editor, JOHN S. ANDERSON. Published by the Physical and Optical Societies, London, 1930. Price, 12 s 6 d.

Physicists and engineers in general will welcome a condensed account of some of the recent developments in the technique of manufacturing and using photoelectric cells. The present volume is a compilation of 31 papers on this subject presented at the London symposium, and includes a report of the interesting and lively discussion which followed. While such a book may lack the unity and completeness of a treatise by an individual author, it has the advantage of allowing the presentation of many specialized problems by those most familiar with them, and of bringing out many different, and sometimes conflicting, points of view.

Following an opening paper by H. S. Allen on the early history of photoelectric cells, there is a paper by N. R. Campbell discussing Fowler's recent wave-mechanical theory of the selective photoelectric effect. There are then seven papers dealing with the manufacture, characteristics, and uses of various types of modern cells. The papers by P. Selenyi on the sodium cell, by L. J. Davies and H. R. Ruff on the thin-film caesium cell, and by T. W. Case on the barium cell are of especial interest, since they give considerable data on the characteristics of these cells. The five papers on the technique of measuring and amplifying photoelectric currents will be of particular value to those interested in photoelectric sound reproduction. A number of problems connected with the distortionless amplification of rapidly varying photo-currents are discussed in detail. Many physicists will be disappointed to find no discussion of the methods of amplifying *unvarying* currents.

We find next a series of ten papers covering the fields of photoelectric photometry, microphotometry, and spectrophotometry. K. S. Gibson contributes a particularly comprehensive review of modern methods in spectrophotometry, with an excellent critical survey of the advantages and limitations of photoelectric cells in this field. Finally, there are two papers on biological applications and four on selenium cells. In one of the latter H. Thirring presents considerable data to support the contention that the "frequency response" of well-designed selenium cells is sufficiently good, contrary to common belief, to make them superior to gas-filled alkali metal cells for sound reproduction. In the discussion reported at the end of the volume one finds a heated argument over this point, with the selenium cell adherents somewhat outnumbered, but not outdone.

On the whole the volume contains a surprising amount of useful information. It has been carefully edited and printed, though one feels that it is of sufficient worth to have merited a better binding.

L. A. DUBRIDGE

The New Physics. Third English edition. ARTHUR HAAS. Pp. 172, figs. 7. E. P. Dutton and Co., New York, 1930. Price \$2.15.

This small volume contains seven lectures, in which the author endeavors to "describe the picture of Nature revealed by modern physics in the most intelligible manner possible, and without the use of any mathematical formulae". The subjects treated are the electromagnetic theory of light, molecular statistics, electron theory, quantum theory, the theory of the chemical elements, relativity and gravitation, and quantum mechanics. The lecture last mentioned appears for the first time in this edition. Several others have been revised.

The style is simple and direct. The educated layman will be able to read the book with understanding. The professional physicist will find it too elementary to warrant more than a cursory scanning of its pages.

H. H. MARVIN

Laboratory Manual of Physics. C. M. KILBY. Pp. 129, figs. 75. D. Van Nostrand Co., New York, 1930. Price, \$1.75.

The manual contains descriptions of sixty-five experiments which can, for the most part be performed with inexpensive apparatus. The several fields of physics all are well represented. The experiments are described in the briefest form possible, adequate for the experiment, but not calculated to lead the thoughtful student beyond the immediate result sought. A tabular form for observations and results is given, in every case. The illustrations are well drawn, with the exception of the electrical wiring diagrams. The manual is adapted fairly well to the needs of students who have not had physics in the high school.

H. H. MARVIN

Cours D'Optique. G. BRUHAT. Pp. 756, figs. 657. Masson and Cie, Paris, 1931. Price, 100 francs.

This advanced text-book in optics begins with the usual introductory survey of the fundamental principles. The following two sections give an excellent treatment of interference and diffraction with many good figures and numerical illustrations. Experimental applications receive a good deal of attention. Part four deals with polarization and the electromagnetic theory of light. Here the classical ideas on vibrations of electrons due to electromagnetic waves are repeated without apology. Part five, on the optics of anisotropic and disymmetric media, is especially complete. In particular, experimental technique is not overlooked. Part six, on spectroscopy, is merely a descriptive resumé using the language of the Bohr-Sommerfeld theory. The treatment is carried no farther than in the early editions of Sommerfeld's "Atom-bau." Prominent among the omissions are: the theory of optical instruments, thermal radiation, and the optics of moving media. As an advanced text, dated 1931, it is disappointing in its conservatism, although as a treatise on classical optics and its experimental application, it is one of the very best.

J. VALASEK

A Treatise on Physical Chemistry. A Cooperative Effort by a Group of Physical Chemists. Edited by HUGH S. TAYLOR. Second edition, 1931. D. Van Nostrand Company, Inc., New York. Two volumes. Vol. I, XV+852+48 pp. (indices); Vol. II, XII+865+48 pp. (indices). Price \$15.00 (not sold separately).

The scope and authority of this outstanding cooperative work on physical chemistry are evident from the list of chapter headings and authors. I, The Atomic Concept of Matter, Hugh S. Taylor; II, The Energetics of Chemical Change, Hugh S. Taylor; III, The Kinetic Theory of Gases and Liquids, K. F. Herzfeld and Hugh M. Smallwood; IV, Imperfect Gases and the Liquid State, K. F. Herzfeld and Hugh M. Smallwood; V, The Solid State of Aggregation, Robert N. Pease; VI, Thermochemistry, A. L. Marshall; VII, The Laws of Dilute Solutions, J. C. W. Frazer; VIII, Homogeneous Equilibria, Graham Edgar; IX, Heterogeneous Equilibrium, Arthur E. Hill; X, The Measurement of Electrical Energy, G. A. Hulett; XI, Conductance, Ionization and Ionic Equilibria, J. R. Partington; XII, The Electrochemistry of Solutions, Herbert S. Harned; XIII, Electrometric Methods in Analytical Chemistry, N. Howell Furman; XIV, Reaction Velocity in Homogeneous Systems, Francis Owen Rice; XV, Reaction Velocity in Heterogeneous Systems, Hugh S. Taylor; XVI, Quantum Theory and Atomic Structure, Saul Dushman; XVII, The Third Law of Thermodynamics and the Calculation of Chemical Constants, Worth H. Rodebush; and in part by T. Jefferson Webb; XVIII, Photochemistry, Hugh S. Taylor; XIX, Infrared Radiation in Chemical Processes, H. Austin Taylor; XX, Colloids, Elmer O. Kraemer; XXI, Radioactivity, S. C. Lind.

Since the publication of the first edition in 1924 important advances have been made in most of the fields covered by the treatise. This has necessitated the more or less thorough re-

vision of chapters VI, XI, XII, XIII, XIV, XV, XVII, XVIII, XIX, and XXI. The important chapters II, IV, XVI, and XX have been written anew, three of them by authors other than those of the former edition. The remaining chapters, reprinted practically unchanged from the first edition, deal with topics in which little advance has been made in recent years, with one exception, discussed below.

In chapters III and IV, 175 pages, an admirable treatment of the kinetic theory of gases and liquids has been presented by Herzfeld and Smallwood. Dushman has given in the 277 pages of chapter XVI a well-balanced introduction to quantum theory and atomic structure which in my opinion has no rival for the purpose for which it was intended, to provide the student in physical chemistry, who usually has a none too extensive preparatory training in mathematics and theoretical physics, with a working knowledge of the fundamental facts of this field. The recent developments in quantum mechanics have not been grafted onto the article written in 1924; instead they have been thoroughly incorporated in the chapter, which has been completely rewritten from the new point of view provided by them.

The careful selection of mathematical methods adapted to the capacity of the readers for whom the treatise is primarily intended, physical chemists and students of physical chemistry, shown in these chapters and in most of the others is not always evident. In chapter XVII the condensed treatment of statistical mechanics and its application to entropy calculations makes difficult reading. This fault is more strikingly shown in the treatment of the Bose-Einstein and Fermi-Dirac statistics, consisting of page after page of equations, with interspersed remarks which are hardly clarifying, such as "—if it is assumed that cells, but not molecules have identity, then the number of ways in which this association can be realized is—" A modern treatment of this topic, following a sound and sufficiently extensive discussion of statistical mechanics, could be made understandable. This chapter also suffers from the emphasis laid on the unnecessary and often confusing chemical constant.

The fourth new chapter, XX, provides an excellent, thorough, and up-to-date discussion of colloids.

Structural chemistry lies within the scope of this treatise, as is recognized in the inclusion of a long chapter on atomic structure. And yet the important field of the structure of solids, in which great advances have been made in recent years, is dismissed in a chapter of 30 pages, reprinted practically without change from the 1924 edition, and in which there are almost as many incorrect as correct statements. Thus to the sodium chloride arrangement is attributed a simple cubic lattice, and to caesium chloride a body-centered lattice. The fundamental cell of the hexagonal close-packed arrangement is said to be a prism with an equilateral triangle as its base. The very simple zinc oxide arrangement is described as "difficult to visualize or to draw." The carbon rings in naphthalene and anthracene are said to be staggered. Half a page, including a figure, is devoted to a description of the staggered-plane graphite structure, although the correct structure was discovered in 1924. Despite the fact that the structure of hexamethylenetetramine had been determined before 1924 and those of hexamethylbenzene, nonacosane, urea, and others since then, the discussion of organic compounds is restricted to Bragg's early incorrect work on naphthalene and anthracene and Astbury's inconclusive study of tartaric acid.

Band spectra and results derived from them, which are becoming more and more important to physical chemistry, are mentioned briefly in several chapters. Some of the discussion is not calculated to provide much enlightenment to the student; in chapter XIX it is stated that the molecule HI is not ionic, but instead "forces exist between the two nuclei." A unified and more extensive treatment of band spectra would be a desirable addition to the book.

The revisions and additions, which increase the treatise 36 percent in length over the first edition, change it from a valuable to a more valuable reference book for the physical chemist and student of physical chemistry. Selected chapters might be successfully used as texts for courses in physical chemistry; in any case the treatise should admirably supplement the more elementary and condensed texts customarily used, inculcating the research viewpoint and indicating the lines of work in which research is being actively carried on. The physicist should find the treatise useful when he becomes involved in work bordering on physical chemistry.

LINUS PAULING

THE PHYSICAL REVIEW

THEORY OF HYPERFINE STRUCTURE SEPARATIONS*

By S. GOUDSMIT

DEPARTMENT OF PHYSICS, UNIVERSITY OF MICHIGAN

(Received February 4, 1931)

ABSTRACT

Expressions are derived for the hyperfine structure separations of the levels of complicated electron configurations in different types of coupling. The few available experimental data are in distinct disagreement with the theoretical calculations. This undoubtedly means that our present knowledge of the interaction with nuclear spin is incomplete. The expressions in this article are derived by the well-known method of the invariance of energy sums.

1. DESCRIPTION OF METHOD

FORMULAE for the interaction energy of a nuclear magnetic moment with a single electron outside of closed electron groups have been given by Fermi,¹ Casimir,² Hargreaves,³ and Breit.⁴ If more than one electron is present besides complete groups the formulae are only known for a special case. They have been derived when only *s*-electrons interact appreciably with the nuclear magnetism and the interaction of other electrons may be neglected.⁵ This paper is a first attempt to treat the general case of the interaction of several electrons with the nuclear magnetic moment.

The method followed in this paper is very analogous to the one used to derive expressions for multiplet separations.⁶ It therefore is the well-known method of the energy sums, which originally goes back to work of Pauli⁷ and which found its representation in modern quantum mechanics in an important article by Slater.⁸ We will follow closely Slater's procedure, as it shows especially clearly the restrictions of the validity of the results to be obtained.

* The problem studied in this paper was started in the spring of 1927 at Copenhagen in cooperation with L. Pauling, with whom I later corresponded occasionally about the questions involved and to whom I owe many valuable suggestions.

¹ E. Fermi, *Zeits. f. Physik* 60, 320 (1930).

² H. Casimir, quoted in Pauling and Goudsmit, *Structure of Line Spectra*, page 225. Also *Phys. Rev.* in preparation.

³ Hargreaves, *Proc. Roy. Soc. A* 127, 141 (1930).

⁴ G. Breit, *Phys. Rev.* 37, 51 (1931).

⁵ S. Goudsmit and R. F. Bacher, *Phys. Rev.* 34, 1501 (1929).

⁶ S. Goudsmit, *Phys. Rev.* 31, 946 (1928).

⁷ W. Pauli, *Zeits. f. Physik* 16, 155 (1923).

⁸ J. C. Slater, *Phys. Rev.* 34, 1293 (1929).

The application of the method of sums goes as follows. One thinks the interaction between the electrons to be removed, in order that each electron can be treated as independent of the others. For certain purposes one may also imagine the interaction between the spin of each electron and its own orbit to be absent. One can think this done by the introduction of a fictitious very strong magnetic field, which should break all couplings between the electrons or their quantum vectors. One now calculates under these circumstances the perturbation energy in which one is interested for each electron separately.⁹

Each state of the complete atom is now characterized by a large set of quantum numbers, each of which can be said to refer to a particular electron.¹⁰ For this state one finds the total perturbation energy by simply adding together the perturbations of the individual electrons. If one next considers the *sum* of the perturbation energies for *all* states having the same total projection of angular momentum M (in units $\hbar/2\pi$) on the direction of the fictitious field, this sum will remain unaltered after one introduces again the proper interactions, which were at the start thought to be absent (or, which is the same, after one reduces the applied strong fictitious magnetic field to a weak one).

This last sentence contains the fundamental principle of the sum rules, as it can be derived from quantum mechanics. It holds only for first order perturbations and moreover as it stands it does not give much information, because the sums are to be taken over *all* states of the atom. In order to get further results out of this sum rule one must make, according to Slater, certain approximations. It is assumed then that the above stated sum rule will hold if one takes the sum only over the states belonging to one electron configuration.¹¹ This may become quite incorrect when the levels arising from the configuration considered intermix with those of other configurations. This, for instance, is one of the reasons why the relations derived by Slater are not fulfilled very well in the actual spectroscopic data.¹² For special perturbations one can sometimes even go one step further with approximations. Slater, in his above quoted paper, purposely neglects the spin-orbit interaction of each electron. This causes the spins to be independent of the orbital angular momenta. Instead of considering the sum of the perturbation energies for a fixed value of the total projection M , he may consider the sum for the states which

⁹ In the above quoted paper of Pauli this was the interaction energy with an external magnetic field, giving rise to the g -sum rule. In the paper on multiplet separations by the present author the spin-orbit interaction was considered, resulting in the Γ -sum rule. Slater treated the interaction between the electrons and it is clearly seen from his paper that his results are obtained by first calculating this interaction for each pair as if it did not disturb the approximate independence of the different electrons. The sum rules finally gave the generally valid relations between multiplet distances.

¹⁰ In the case of a nuclear moment $I\hbar/2\pi$ the nuclear quantum numbers I and m_I must be added also to this set.

¹¹ One calls a configuration the assembly of states for which each electron has the quantum numbers n and l fixed. Two states for which one of the electrons has a different n or l are said to belong to different configurations.

¹² Compare on this point a recent paper by E. U. Condon, *Phys. Rev.* **36**, 1121 (1930).

have a fixed value of both M_S and M_L , the total projection of all spins and all orbits respectively. Each of these sums, which are a part of the total sum for a fixed M , will be invariant. This approximation holds only when the spin-orbit interaction is indeed negligibly small compared to the interaction between different electrons, the case in which Slater is interested. This means that one expects to obtain extreme Russell-Saunders coupling.¹³

In order to make use of the method described here it is obviously necessary to know the effect of the perturbation on one single electron considered as independent of the others.¹⁴ This will be considered in the following section.

In most cases the hyperfine structure is smaller than any other one of the interactions present in the atom. It is possible to apply a magnetic field which will just decouple the nuclear spin from the rest of the atom, giving each an independent projection on the field direction, M_I and M_J . From the theory of the Zeeman effect of hyperfine structure¹⁵ one knows that the interaction between the nucleus and the electron core under those circumstances is given by

$$W = A(J) \cdot M_I M_J. \quad (1)$$

The constant A in front is exactly the one which will govern the magnitude of the hyperfine multiplet of that particular level after one removes the magnetic field. That is, the levels of the hyperfine multiplet are given by

$$W_J = A(J) I J \cos(I, J) = \frac{1}{2} A(J) \{F(F+1) - I(I+1) - J(J+1)\} \quad (2)$$

Here F denotes as usual the resultant of I and J .

As we are finally interested in the magnitude of just that factor A , we may all the time think that there is such a field present which causes M_I and the total projection of the core to be independent. This simplifies our calculation very much. We do not need to calculate the sums for all states with the same total $M_F = M_I + M_J$. According to Slater the sum rules will also be valid for the smaller group of states which have a fixed value for both M_I and M_J . We take therefore in the following procedure a particular value of M_I in our mind and extend the sums over levels with a fixed value of M_J .

It has to be kept in mind that the independence of M_I and M_J can only be used in case their interaction is indeed very much smaller than any of the other interactions which are to be taken into account. One can not use it, for instance, in the case of ionized Lithium. Here the hyperfine structure happens to be of the same order of magnitude as the multiplet splitting.¹⁶

2. INTERACTION BETWEEN A SINGLE ELECTRON AND A NUCLEAR MAGNETIC MOMENT

The interaction of a magnetic nucleus and an electron in an s -state has been treated in detail before. The energy happens to be simply proportional

¹³ If one needs information about the interaction between electrons in a case of (j, j) coupling one has to alter the procedure followed by Slater somewhat.

¹⁴ In Slater's special case one needs it for each electron pair.

¹⁵ E. Back and S. Goudsmit, *Zeits. f. Physik* **47**, 174 (1928), see also Pauling and Goudsmit, reference 2, p. 215.

¹⁶ S. Goudsmit and D. R. Inglis, *Phys. Rev.* **37**, 283 (1931).

to the Landé cosine between the spin s of the electron and the nuclear moment I . It is therefore possible to treat the cases where an s -electron is a part of a configuration, completely with the vector model. We will now consider the case of a non- s electron.

We think the spin-orbit interaction to be removed (or apply a fictitious strong magnetic field). In the classical theory the interaction energy consists of two parts. The nuclear magnetic moment is acted upon by a magnetic field caused by the orbital motion of the electron and also by a field produced by the electron spin. According to perturbation theory one must write down the instantaneous values for the interaction energy and must average this over the unperturbed motion. The expression for this interaction energy is:¹⁷

$$W_l + W_s = a[l\cos(I, l) - Is\cos(I, s) + 3Is\cos(I, r)\cos(r, s)]. \quad (3)$$

The factor a in front of this expression governs the absolute magnitude of the interaction energy. We are not interested in it for our problem. For a hydrogenic orbit its value is given by

$$a = \left(\frac{eh}{4\pi m_0 c}\right)^2 g(I) \left(\frac{1}{r^3}\right) = \frac{Rh c \alpha^2 Z^3}{n^3 l(l + \frac{1}{2})(l + 1)} g(I). \quad (4)$$

The symbols used in Eqs. (3) and (4) have the usual meaning, r denotes the radius vector combining the nucleus with the electron, $g(I)$ stands for the Landé g value of the nucleus and as the nuclear magnetism is believed to arise from protons, one expects $g(I)$ to be only of the order $1/1840$.

We start out with the case where we neglect all interactions between the quantum vectors; these will each have independent projections on the direction of the fictitious field H . These projections we denote by M_I , m_l and m_s , the nuclear, the orbital and the spin moment respectively. The vectors I , l and s will have independent Larmor precessions about the field direction and we can therefore expand the cosines of Eq. (3) and obtain:

$$W_l + W_s = a[M_I m_l - M_I m_s \{1 - 3 \overline{\cos^2(H, r)}\}]. \quad (5)$$

Our problem thus reduces to finding the average of $\cos^2(H, r)$. In the classical picture with a plane orbit the vector r would be at any time perpendicular to the angular momentum vector l . This, however, is no longer true in quantum mechanics. The relative probability that r makes an angle θ with the field direction is given by the square of the tesseral harmonic $P_l^{m_l}(\cos \theta)$. Thus the required average becomes

$$\begin{aligned} \overline{\cos^2(H, r)} &= \frac{\int_0^\pi \cos^2 \theta [P_l^{m_l}]^2 \sin \theta d\theta}{\int_0^\pi [P_l^{m_l}]^2 \sin \theta d\theta} \\ &= \frac{2(l^2 - m_l^2) + 2l - 1}{(2l - 1)(2l + 3)}. \end{aligned} \quad (6)$$

¹⁷ L. Pauling and S. Goudsmit, reference 2, p. 205.

Substituting this in Eq. (5) gives finally

$$W = W_l + W_s = aM_I \left\{ m_l - m_s \frac{6m_l^2 - 2l(l+1)}{(2l-1)(2l+3)} \right\}. \quad (7)$$

One verifies easily that for large values of l Eq. (6) approaches the classical result: $\frac{1}{2} \sin^2(l, II) = (l^2 - m_l^2)/2l^2$.

Expression (7) will be the fundamental formula for all further applications. It is, however, not valid for s -electrons.

3. THE SUM RULE APPLIED TO ONE ELECTRON

The application of the sum rule and Eq. (7) to the case of a single electron provides a very simple derivation of the results obtained by Fermi, Casimir, Hargreaves and Breit. It also gives an illustration of the method before we apply it to the many electron case. A single electron gives rise to a doublet state, one level with $j_1 = l + \frac{1}{2}$, the other with $j_2 = l - \frac{1}{2}$. In a weak magnetic field, which just decouples the nuclear spin, the interaction with the nuclear magnetism is (compare Eq. (1)):

$$W_{j_1} = a'M_I m_{j_1} \quad \text{and} \quad W_{j_2} = a''M_I m_{j_2}. \quad (8)$$

In a very strong magnetic field this interaction is (Eq. (7)):

$$W = aM_I \left\{ m_l - m_s \frac{6m_l^2 - 2l(l+1)}{(2l-1)(2l+3)} \right\}. \quad (9)$$

The sum rule says that, keeping M_I fixed, the sums of the energies for all levels with a given value of $m_j = m_s + m_l$ must come out the same, whether we use Eq. (8) or (9). We choose first $m_j = l + \frac{1}{2}$. This occurs only once; in (8) for j_1 and in (9) when $m_l = l$ and $m_s = +\frac{1}{2}$. The sum rule states

$$a'M_I \cdot (l + \frac{1}{2}) = aM_I \left\{ l - \frac{1}{2} \frac{6l^2 - 2l(l+1)}{(2l-1)(2l+3)} \right\}. \quad (10)$$

One obtains at once

$$a' = a \frac{l(l+1)}{(l + \frac{1}{2})(l + \frac{1}{2})} = a \frac{l(l+1)}{j_1(j_1+1)}. \quad (11)$$

Next we choose $m_j = l - \frac{1}{2}$. This occurs twice, namely in (8) both for j_1 and j_2 , and in (9) for $m_l = l$, $m_s = -\frac{1}{2}$ and $m_l = l-1$, $m_s = +\frac{1}{2}$. Applying the sum rule gives

$$\begin{aligned} & a'M_I \cdot (l - \frac{1}{2}) + a''M_I \cdot (l - \frac{1}{2}) \\ &= aM_I \left\{ l + \frac{1}{2} \frac{6l^2 - 2l(l+1)}{(2l-1)(2l+3)} \right\} + aM_I \left\{ (l-1) - \frac{1}{2} \frac{6(l-1)^2 - 2l(l+1)}{(2l-1)(2l+3)} \right\} \end{aligned} \quad (12)$$

As we know a' already we can solve for a'' and find

$$a'' = a \frac{l(l+1)}{(l - \frac{1}{2})(l + \frac{1}{2})} = a \frac{l(l+1)}{j_2(j_2+1)}. \quad (13)$$

These expressions for a' and a'' are indeed identical with the results obtained by other authors. Substituting them in Eq. (2) gives the hyperfine structure in the absence of a field. The result shows that for the two levels of a doublet the interval constant of the hyperfine structure is inversely proportional to $j(j+1)$. The absolute magnitude can only be given when the constant a can be calculated. This would require an exact knowledge of the eigenfunctions of the state under consideration. For penetrating orbits one can make the same kind of an approximation as was applied by Landé to the calculations of doublet separations. One obtains for such cases, instead of Eq. (4), the approximate expression

$$a = \frac{Rhca^2Z_iZ_o^2}{n_e^3l(l + \frac{1}{2})(l + 1)} g(I). \quad (14)$$

In this expression Z_i and Z_o stand for the effective nuclear charge in the inner and outer part of the orbit respectively, n_e represents the "effective" quantum number or Rydberg denominator.

4. THE SUM RULE APPLIED TO CONFIGURATIONS

We will give as an illustrative example the case of three equivalent p -electrons. The first column of Table I gives the values of m_s and m_l for the individual electrons, chosen in agreement of course with the Pauli exclusion principle. The quantum numbers l and n are supposed to be the same for all three electrons and are therefore omitted from the table. We need only to consider the states which give rise to positive values of the total projection M_J , given in the second column, negative values of M_J do not give any additional information. The last column gives the interaction with the nuclear magnetism obtained by applying Eq. (9) to each electron individually and adding the result for the three together. As they are equivalent electrons they have the same constant a .

TABLE I. Interaction for p^3 in strong field.

m_{s_1}	m_{l_1}	m_{s_2}	m_{l_2}	m_{s_3}	m_{l_3}	M_J	Eq. (7)	
$\frac{1}{2}$	1	$\frac{1}{2}$	0	$-\frac{1}{2}$	1	$2\frac{1}{2}$	$2\frac{2}{5} aM_I$	
$\frac{1}{2}$	1	$\frac{1}{2}$	0	$-\frac{1}{2}$	-1	$1\frac{1}{2}$	$0 aM_I$	
$\frac{1}{2}$	1	$\frac{1}{2}$	0	$-\frac{1}{2}$	0		$\frac{4}{5} aM_I$	sum
$\frac{1}{2}$	1	$\frac{1}{2}$	-1	$-\frac{1}{2}$	1		$\frac{4}{5} aM_I$	$3\frac{1}{5} aM_I$
$\frac{1}{2}$	1	$-\frac{1}{2}$	0	$-\frac{1}{2}$	1		$1\frac{2}{5} aM_I$	
$\frac{1}{2}$	1	$\frac{1}{2}$	0	$-\frac{1}{2}$	-1	$\frac{1}{2}$	$\frac{2}{5} aM_I$	
$\frac{1}{2}$	1	$\frac{1}{2}$	-1	$-\frac{1}{2}$	0		$-\frac{4}{5} aM_I$	
$\frac{1}{2}$	0	$\frac{1}{2}$	-1	$-\frac{1}{2}$	1		$\frac{2}{5} aM_I$	sum
$\frac{1}{2}$	0	$-\frac{1}{2}$	1	$-\frac{1}{2}$	0		$1\frac{1}{5} aM_I$	$2\frac{2}{5} aM_I$
$\frac{1}{2}$	1	$-\frac{1}{2}$	1	$-\frac{1}{2}$	-1		$1\frac{1}{5} aM_I$	

The states in the table are ordered according to their values of M_J . The configuration gives rise to five levels, one with $J=2\frac{1}{2}$, three with $J=1\frac{1}{2}$ and one with $J=\frac{1}{2}$. We want to know the constants A for each of these levels and shall denote them by $A(2\frac{1}{2})$, $A(1\frac{1}{2})$, $A'(1\frac{1}{2})$, $A''(1\frac{1}{2})$ and $A(\frac{1}{2})$ respectively.

The sum rule applied to the projection $M_J = 2\frac{1}{2}$, which occurs only once, gives

$$A(2\frac{1}{2}) \cdot M_I \cdot 2\frac{1}{2} = 2\frac{2}{5}aM_I. \quad (15)$$

The projection $M_J = 1\frac{1}{2}$ occurs four times, namely $J = 2\frac{1}{2}$ as well as all three levels with $J = 1\frac{1}{2}$ can give this projection on the field direction. It also occurs four times in Table I. The sum rule gives

$$\{A(2\frac{1}{2}) + A(1\frac{1}{2}) + A'(1\frac{1}{2}) + A''(1\frac{1}{2})\} M_I \cdot 1\frac{1}{2} = 3\frac{1}{5}aM_I. \quad (16)$$

Finally $M_J = \frac{1}{2}$ occurs five times, giving

$$\{A(2\frac{1}{2}) + A(1\frac{1}{2}) + A'(1\frac{1}{2}) + A''(1\frac{1}{2}) + A(\frac{1}{2})\} M_I \cdot \frac{1}{2} = 2\frac{2}{5}aM_I. \quad (17)$$

Solving these equations one obtains finally

$$\left. \begin{aligned} A(2\frac{1}{2}) &= 2\frac{4}{25}a \\ A(1\frac{1}{2}) + A'(1\frac{1}{2}) + A''(1\frac{1}{2}) &= 1\frac{13}{75}a \\ A(\frac{1}{2}) &= 2\frac{2}{3}a \end{aligned} \right\} \quad (18)$$

Exactly as in the case of the well-known g -sum rule we are only able to obtain the sum of the A 's for the levels with the same value of J . That we find the individual values for the levels with $J = 2\frac{1}{2}$ and $J = \frac{1}{2}$ is because there is only one level with each of these J values.

The values of the individual A 's will in general depend upon the type of coupling between the quantum vectors of the electrons, just as in the case of g -values. The method to obtain their values for extreme couplings will be described in following sections of this paper.

It is not at all difficult to make a table like Table I for any other example. When the electrons are not equivalent each has a different constant a which one has to carry along into the final result. We want to mention once more that most of the formulae used here are only valid for the interaction of a non- s electron with the nuclear magnetism. For an s electron one has to replace Eq. (7) by the simple expression

$$W = bM_I m_s. \quad (19)$$

Here follow the results for a number of configurations

TABLE II. Hyperfine structure sums.*

p and p^5	$J = 1\frac{1}{2}$	$A = \frac{8}{15}a$ $\Sigma A = 2\frac{2}{3}a$	ps and p^5s	$J = 2$ 1	$A = \frac{2}{3}a + \frac{1}{3}b$ $\Sigma A = 2a + \frac{1}{3}b$
p^2 and p^4	$J = 2$ 1	$\Sigma A = 1\frac{1}{3}a$ $A = 0a$	p^2s and p^4s	$J = 2\frac{1}{2}$ $1\frac{1}{2}$ $\frac{1}{2}$	$\Sigma A = 1\frac{7}{25}a + \frac{2}{3}b$ $\Sigma A = 1\frac{23}{25}a - \frac{1}{15}b$ $\Sigma A = 0a + 1\frac{2}{3}b$
p^3	$J = 2\frac{1}{2}$ $1\frac{1}{2}$ $\frac{1}{2}$	$A = \frac{24}{25}a$ $\Sigma A = 1\frac{13}{75}a$ $\Sigma A = 2\frac{2}{3}a$	p^3s	$J = 3$ 2 1	$A = \frac{4}{3}a + \frac{1}{3}b$ $\Sigma A = 2a + \frac{7}{12}b$ $\Sigma A = 2\frac{2}{3}a - \frac{1}{4}b$

* The constant a refers to the p - and b to the s -electron.

5. HYPERFINE STRUCTURE FOR EXTREME (j, j) COUPLING

The above described method gives only the sums of the factors which govern the hyperfine structure separations. Their individual values for each level are only determined completely in extreme couplings. The simplest case is that of extreme (j, j) coupling which we shall now discuss with the example of the p^3 configuration. We mean by extreme (j, j) coupling that the spin vector s of each electron is strongly coupled to its own orbital vector l and that therefore one can ascribe to each one of the electrons of the configuration its own resultant vector j . The spin-orbit coupling has to be considerably stronger than the interaction energy between the different electrons. It is then possible to think of an applied magnetic field which is strong enough to decouple the different electrons so as to make them independent of each other, but not yet strong enough to decouple the s and l for each of the electrons.

Under these ideal circumstances the quantum state of each electron will be characterized by the quantum numbers j and m_j , its resultant moment and the projection on the field, rather than by m_s and m_l . We now have to make again a table similar to Table I but now with the different designation for each electron. We also need to know what the interaction with the nucleus will be for each electron, when its state is characterized by j and m_j , that is when its spin and orbit are coupled. But this is just the problem solved in Section 3. Eq. (8) is the one we must use now, especially after we introduce for a' and a'' the results of Eqs. (11) and (13).

TABLE III. Configuration p^3 in (j, j) coupling.

j_1	m_{j_1}	j_2	m_{j_2}	j_3	m_{j_3}	M_J	Eq. (8)	
$1\frac{1}{2}$	$1\frac{1}{2}$	$1\frac{1}{2}$	$\frac{1}{2}$	$1\frac{1}{2}$	$-\frac{1}{2}$	$1\frac{1}{2}$	$1\frac{1}{2}a'M_I$	
	$1\frac{1}{2}$		$\frac{1}{2}$		$-1\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{2}a'M_I$	
$1\frac{1}{2}$	$1\frac{1}{2}$	$1\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{2}$	$2\frac{1}{2}$	$(2a' + \frac{1}{2}a'')M_I$	
	$1\frac{1}{2}$		$\frac{1}{2}$		$-\frac{1}{2}$	$1\frac{1}{2}$	$(2a' - \frac{1}{2}a'')M_I$	sum
	$1\frac{1}{2}$		$-\frac{1}{2}$		$\frac{1}{2}$		$(a' + \frac{1}{2}a'')M_I$	$3a'M_I$
	$1\frac{1}{2}$		$-1\frac{1}{2}$		$\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{2}a''M_I$	sum
	$1\frac{1}{2}$		$-\frac{1}{2}$		$-\frac{1}{2}$		$(a' - \frac{1}{2}a'')M_I$	$(a' + \frac{1}{2}a'')M_I$
	$\frac{1}{2}$		$-\frac{1}{2}$		$\frac{1}{2}$		$\frac{1}{2}a''M_I$	
$1\frac{1}{2}$	$1\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{2}$	$-\frac{1}{2}$	$1\frac{1}{2}$	$1\frac{1}{2}a'M_I$	
	$\frac{1}{2}$		$\frac{1}{2}$		$-\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{2}a'M_I$	

Table III represents the equivalent of Table I for the extreme (j, j) coupling. The example chosen is again the configuration p^3 . For reasons to be discussed later the values for a' and a'' have not been substituted.

In the ideal extreme case the electrons are quite independent of each other. Following Slater we therefore need not take the sums over all levels with a fixed value of the total M_J . The sum-rule will hold already for the levels which are designated by a special set of values of j and m_j for each of the electrons. If we choose a set of values for these quantum numbers it

happens that we find only one state in our table which possesses just this set. Thus we do not need to consider any sums at all and the third column of the table gives at once the correct value of the interaction with the nuclear spin for this extreme case.

We are, however, not yet finished. When we now gradually remove the field which decoupled the electrons, the quantum numbers m_j for the individual electrons will lose their significance and be converted together into the total M_J . In the extreme (j, j) coupling the values of j for each electron will keep their meaning. This means that for this last transition the sum rules will hold within each group of levels characterized by fixed values of the individual j , but no longer for the individual m_j . Table III has been arranged accordingly.

Fig. 1. Schematic representation of Paschen-Back effect for p^3 in extreme (j, j) coupling. (a) without field, quantum numbers: j_1, j_2, j_3, J . (b) weak field, quantum numbers: j_1, j_2, j_3, J, M_J . (c) strong field, quantum numbers: $j_1, j_2, j_3, m_{j_1}, m_{j_2}, m_{j_3}$.

Figure 1 may help to understand the situation described above. At the left is shown the p^3 configuration in extreme (j, j) coupling. The highest level arises when all three electrons have maximum energy, that is when they all have $j = 1\frac{1}{2}$. The next lower group occurs when one of the electrons has $j = \frac{1}{2}$. The lowest level has two electrons with $j = \frac{1}{2}$ and one with $j = 1\frac{1}{2}$.¹⁸ The hyperfine structure is not included in the figure. Going to the right in Fig. 1 the effect of an applied magnetic field is represented. In a weak field each level splits into its Zeeman components. With increasing field strength each level group will undergo a Paschen-Back transition and the result is rep-

¹⁸ There exists here no lower state with all three electrons having $j = \frac{1}{2}$, because our example consists of equivalent electrons for which the Pauli principle allows only two with $j = \frac{1}{2}$. This also will be clear from considering Table III where all states are gathered which do agree with the Pauli principle. Compare Pauling and Goudsmit, l.c., page 257.

resented at the right of Fig. 1. Notice that the field does not yet break the coupling of each spin with its orbit, the three level groups are still distinctly separated. A further increase in the field would also break up this last coupling, all couplings would be broken and one would have the case represented in Table I. One sees that the right side of Fig. 1 is to be correlated with Table III. The sum rule as applied in Table III means simply that we may assume the sum rule for fixed M_J to hold within each level group separately in this extreme coupling. This gives us a means to go from the strong field to the intermediate field and to obtain our final information.

In this intermediate field, which we suppose just to decouple the nuclear spin from the rest of the atom, the interaction with the nucleus for each level will be given again by Eq. (1):

$$W = AM_I M_J.$$

Our problem is to find the value of A for each one of the many levels.

Applying the sum rule to the states which have $j_1=j_2=j_3=1\frac{1}{2}$, that is the upper level, we find at once

$$A(1\frac{1}{2}) = a'.$$

This result is found by choosing M_J either $1\frac{1}{2}$ or $\frac{1}{2}$.

For the middle group of levels, $j_1=j_2=1\frac{1}{2}$, $j_3=\frac{1}{2}$, one finds the following sums

$$\begin{aligned} M_J = 2\frac{1}{2}: & \quad A(2\frac{1}{2})M_I \cdot 2\frac{1}{2} = (2a' + \frac{1}{2}a'')M_I, \\ M_J = 1\frac{1}{2}: & \quad \{A(2\frac{1}{2}) + A'(1\frac{1}{2})\}M_I \cdot 1\frac{1}{2} = 3a'M_I, \\ M_J = \frac{1}{2}: & \quad \{A(2\frac{1}{2}) + A'(1\frac{1}{2}) + A(\frac{1}{2})\}M_I \cdot \frac{1}{2} = (a' + \frac{1}{2}a'')M_I. \end{aligned}$$

From this one obtains

$$A(2\frac{1}{2}) = \frac{4}{3}a' + \frac{1}{3}a''; \quad A'(1\frac{1}{2}) = 1\frac{1}{3}a' - \frac{1}{3}a''; \quad A(\frac{1}{2}) = a''.$$

Finally the lowest level gives

$$A''(1\frac{1}{2}) = a'.$$

After one substitutes the values of a' and a'' from Eqs. (11) and (13) the results become

$$A(1\frac{1}{2}) = \frac{8}{15}a; \quad A(2\frac{1}{2}) = \frac{24}{25}a; \quad A'(1\frac{1}{2}) = \frac{8}{75}a; \quad A(\frac{1}{2}) = \frac{2}{3}a; \quad A''(1\frac{1}{2}) = \frac{8}{15}a.$$

As is to be expected the sums agree with those given in Section 4 and Table II.

6. USE OF THE VECTOR MODEL FOR EXTREME (j, j) COUPLING

When the spin and orbit of an electron are coupled the interaction with the nuclear magnetism is given by the Eq. (2)

$$W = a'Ij \cos(I, j) \quad \text{or} \quad a''Ij \cos(I, j). \quad (20)$$

The choice of a' or a'' depends on whether one considers the state with $j=l+\frac{1}{2}$ or the one with $j=l-\frac{1}{2}$. This simple expression brings it about that one often can use the vector model with advantage in extreme (j, j) coupling.

For several electrons the total interaction with the nucleus is

$$W = \sum a_k I j_k \overline{\cos(I, j_k)}. \quad (21)$$

The sum has to be extended over all electrons, which we shall distinguish by the index k . As all j_k form together the resultant J one can average over their precession about this resultant and obtains

$$W = \sum a_k I j_k \cos(I, J) \overline{\cos(J, j_k)}. \quad (22)$$

We may write this

$$W = A I J \cos(I, J) \quad (23)$$

in which expression we finally want to know the value of

$$A = \sum a_k \frac{j_k}{J} \overline{\cos(J, j_k)}. \quad (24)$$

The problem is thus to evaluate the average cosines of each of the individual j_k with the resultant J . This can be done easily when only two j_k form the resultant J , but with more electrons it is in general impossible, unless we use again the method of sums instead of the vector model. For a restricted but interesting number of cases we can find relations between these cosines and the g values of the levels. The magnetic moment gJ of a state is given by the sum of the magnetic moments $g_k j_k$ of each electron resolved along the resultant J , thus

$$gJ = \sum g_k j_k \overline{\cos(J, j_k)} \quad \text{or} \quad g = \sum g_k \frac{j_k}{J} \overline{\cos(J, j_k)}. \quad (25)$$

This defines the g value for this level. Furthermore, as J is the resultant of all j_k we have

$$J = \sum j_k \overline{\cos(J, j_k)} \quad \text{or} \quad 1 = \sum \frac{j_k}{J} \overline{\cos(J, j_k)}. \quad (26)$$

If we now restrict ourselves to the case of equivalent electrons the sums in expressions 24, 25 and 26 fall apart into two sums, one over the electrons with $j' = l + \frac{1}{2}$ and one over those with $j'' = l - \frac{1}{2}$. We shall again denote these two kinds by a prime and a double prime. The formulae become

$$A = a' \sum \frac{j_k'}{J} \overline{\cos(J, j_k')} + a'' \sum \frac{j_k''}{J} \overline{\cos(J, j_k'')} \quad (24a)$$

$$g = g' \sum \frac{j_k'}{J} \overline{\cos(J, j_k')} + g'' \sum \frac{j_k''}{J} \overline{\cos(J, j_k'')} \quad (25a)$$

$$1 = \sum \frac{j_k'}{J} \overline{\cos(J, j_k')} + \sum \frac{j_k''}{J} \overline{\cos(J, j_k'')} \quad (26a)$$

For equivalent electrons a' , a'' , g' and g'' can be placed before the summation, as they have the same value for each of the electrons inside any one sum.

We next can eliminate the two unknown sums between the three expressions and obtain finally

$$A = a' \frac{g - g''}{g' - g''} + a'' \frac{g - g'}{g'' - g'} \quad (27)$$

The values of g' and g'' are the known g values for a single electron, the values of g to be used are those for the extreme (j, j) coupling of the configuration which we consider.¹⁹ For our standard example of the p^3 configuration the results are again:

$$\begin{array}{llll} g' = 1\frac{1}{2} & g'' = \frac{2}{3} & & \\ J = 2\frac{1}{2} & g = 1\frac{1}{2} & A = \frac{4}{5}a' + \frac{1}{5}a'' & \\ J = \frac{1}{2} & g = \frac{2}{3} & A = a'' & \\ J = 1\frac{1}{2} & g = 1\frac{1}{2} & A = a' & \text{upper level.} \\ 1\frac{1}{2} & g = 1\frac{7}{15} & A' = 1\frac{1}{3}a' - \frac{1}{3}a'' & \text{middle level.} \\ 1\frac{1}{2} & g = 1\frac{1}{2} & A'' = a' & \text{lower level.} \end{array}$$

The addition of a single s electron to a level of which A is known can always be done with the vector model, provided the coupling is of the extreme (j, j) type. We denote with A^+ and J^+ the values for the state to which we add the s electron. The s electron itself is characterized by b and s , the resulting level finally by A and J . One obtains with the vector model

$$A = A^+ \frac{J^+}{J} \cos(J, J^+) + b \frac{s}{J} \cos(J, s). \quad (28)$$

Substituting the Landé cosines this becomes

$$\begin{aligned} A = A^+ & \frac{J(J+1) + J^+(J^++1) - s(s+1)}{2J(J+1)} \\ & + b \frac{J(J+1) + s(s+1) - J^+(J^++1)}{2J(J+1)}. \end{aligned} \quad (29)$$

One can simplify this formula if one considers that $s = \frac{1}{2}$ and that therefore J can only be $(J^+ + \frac{1}{2})$ or $(J^+ - \frac{1}{2})$. One can also again express A in terms of the g -values.

Table IV gives the results for a few configurations in extreme (j, j) coupling.

¹⁹ For equivalent electrons the g values for extreme (j, j) coupling can be obtained in general only with the help of the method of sums. This Section does therefore in reality not avoid the use of the sum rule, but it gives a connection between the hyperfine structure constants and the g values. The latter are considered to be better known and more easily derivable.

TABLE IV. Hyperfine structure for (j, j) coupling.*

	j_k	J^+	J	g	A
p^2	$1\frac{1}{2}$		2	$1\frac{1}{3}$	a'
	$1\frac{1}{2}$		2	$1\frac{1}{6}$	$\frac{2}{3}a' + \frac{1}{3}a''$
	$1\frac{1}{2}$		1	$1\frac{1}{2}$	$1\frac{1}{2}a' - \frac{1}{2}a''$
p^3	$1\frac{1}{2}$		$1\frac{1}{2}$	$1\frac{1}{3}$	a'
	$1\frac{1}{2}$		$2\frac{1}{2}$	$1\frac{1}{3}$	$\frac{2}{3}a' + \frac{1}{3}a''$
	$1\frac{1}{2}$		$1\frac{1}{2}$	$1\frac{7}{15}$	$1\frac{1}{2}a' - \frac{1}{2}a''$
	$1\frac{1}{2}$		$1\frac{1}{2}$	$2\frac{2}{3}$	a''
	$1\frac{1}{2}$		$1\frac{1}{2}$	$1\frac{1}{3}$	a'
ps	$1\frac{1}{2}$	$1\frac{1}{2}$	2	$1\frac{1}{2}$	$\frac{3}{4}a' + \frac{1}{4}b$
	$\frac{1}{2}$	$\frac{1}{2}$	1	$1\frac{1}{6}$	$1\frac{1}{2}a' - \frac{1}{2}b$
	$\frac{1}{2}$	$\frac{1}{2}$	1	$1\frac{1}{3}$	$\frac{1}{2}a'' + \frac{1}{2}b$
p^2s	$1\frac{1}{2}$	2	$2\frac{1}{2}$	$1\frac{7}{15}$	$\frac{4}{3}a' + \frac{1}{3}b$
	$1\frac{1}{2}$	0	$1\frac{1}{2}$	$1\frac{1}{5}$	$1\frac{1}{2}a' - \frac{1}{2}b$
	$1\frac{1}{2}$	2	$2\frac{1}{2}$	2	b
	$1\frac{1}{2}$	2	$1\frac{1}{2}$	$1\frac{1}{3}$	$\frac{2}{3}a' + \frac{1}{3}a'' + \frac{1}{3}b$
	$\frac{1}{2}$	1	$1\frac{1}{2}$	1	$\frac{9}{10}a' + \frac{3}{10}a'' - \frac{1}{10}b$
	$\frac{1}{2}$	1	$1\frac{1}{2}$	$1\frac{2}{3}$	$\frac{2}{3}a' - \frac{1}{3}a'' + \frac{1}{3}b$
	$\frac{1}{2}$	0	$1\frac{1}{2}$	$1\frac{1}{3}$	$\frac{2}{3}a' - \frac{1}{3}a'' - \frac{1}{3}b$

* The values of j_k are given for the p electrons only, the s electron has $j_k = \frac{1}{2}$. Levels with $J=0$ are omitted. The results for the configurations p^2 , p^3 , p^2s , p^3s , are similar to the following ones in the same order p , p^2 , ps , p^2s .

7. HYPERFINE STRUCTURE FOR EXTREME RUSSELL-SAUNDERS COUPLING

When the interaction between the different electrons of a configuration is very large compared to the interaction between the spins of the electrons and their orbital motion, one speaks of Russell-Saunders coupling. The spin vectors form together a resultant spin moment S , the orbital moments l form a resultant L and the total angular momentum vector J is the resultant of these two. To this one the nuclear spin I is again added to form the resultant F . This type of coupling yields the ordinary multiplet structure.

In the case of Russell-Saunders coupling one can imagine an applied magnetic field which is strong enough to overcome the coupling between the spins and orbits; that is, between the resultant S and the resultant L , but not yet strong enough to decouple the different electrons from each other. This situation is represented at the right of Fig. 2. The left of Fig. 2 gives the levels without magnetic field, whereas the middle shows them in an intermediate field. The strong field has caused a complete Paschen-Back effect for each of the multiplets, but the splitting up which it causes is supposed to be still small compared to the distances between the different multiplets. In this strong field each state will be characterized by the projections M_S and M_L of S and L on the field direction. As these two are supposed to have a negligible interaction under these circumstances, they will be independent and will restrict our sum rules. According to Slater's procedure the sums will now be invariant over states which have the same value of the pair of quantum numbers M_S , M_L . Table V shows the states of the example p^3 arranged in this order. This configuration yields a $4S$, a $2D$ and $2P$ state. When we increase the field more

and more until it breaks the electron coupling, the total projection M_S of the resultant spin will remain invariant and can finally be interpreted as the sum

Fig. 2. Schematic representation of Paschen-Back effect for p^3 in extreme Russell-Saunders coupling. (a) without field, quantum numbers: L, S, J . (b) weak field, quantum numbers L, S, J, M_J . (c) strong field, quantum numbers: L, S, M_L, M_S .

of the m_s of the electrons. In the same way M_L will be converted into the sum of m_l of the individual electrons. It is in this way that a certain pair M_S, M_L can be correlated to each of the states in Table V, simply

$$M_S = \sum m_s, \quad M_L = \sum m_l. \quad (30)$$

TABLE V. Configuration p^3 in Russell-Saunders coupling.

m_{s_1}	m_{s_2}	m_{s_3}	m_{l_1}	m_{l_2}	m_{l_3}	M_S	M_L	M_J	Eq. (7)
$\frac{1}{2}$	$\frac{1}{2}$	$-\frac{1}{2}$	1	0	1	$\frac{1}{2}$	2	$2\frac{1}{2}$	$2\frac{2}{5} aM_I$
$\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{2}$	1	0	-1	$1\frac{1}{2}$	0	$1\frac{1}{2}$	$0 aM_I$
$\frac{1}{2}$	$\frac{1}{2}$	$-\frac{1}{2}$	1	0	0	$\frac{1}{2}$	1	$1\frac{1}{2}$	$\frac{4}{5} aM_I$
			1	-1	1				$\frac{4}{5} aM_I$
$\frac{1}{2}$	$-\frac{1}{2}$	$-\frac{1}{2}$	1	0	-1	$-\frac{1}{2}$	2	$1\frac{1}{2}$	$1\frac{3}{5} aM_I$
$\frac{1}{2}$	$\frac{1}{2}$	$-\frac{1}{2}$	1	0	-1	$\frac{1}{2}$	0	$\frac{1}{2}$	$-\frac{2}{5} aM_I$
			1	-1	0				$-\frac{4}{5} aM_I$
			0	-1	1				$-\frac{4}{5} aM_I$
$\frac{1}{2}$	$-\frac{1}{2}$	$-\frac{1}{2}$	0	1	0	$-\frac{1}{2}$	1	$\frac{1}{2}$	$1\frac{1}{5} aM_I$
			1	1	-1				$1\frac{1}{5} aM_I$

With this table we hope to get information about the interaction with the nucleus for each multiplet if placed in a strong magnetic field. If we knew

this we could again apply the sum rule to each multiplet separately and obtain the interaction in a weak field or without field. Table V does not help us much in this respect, however. The different states are labeled with M_S and M_L only and we do not know the values of S and L to which they belong. For instance the pair $M_S = \frac{1}{2}$ and $M_L = 0$ occurs three times. We do not know which one of these three belongs to the 4S , the 2D or the 3P , which can each give this pair in a strong field. The answer to this question is that neither of the three belongs to any one of the multiplets. In the language of Slater's paper we should say that the energies entered in the last column of Table V have been calculated with eigenfunctions which do not take into account the interaction between the electrons. The correct eigenfunctions which can be associated with each multiplet are certain linear combinations of the ones which give the perturbation energies used here. The straightforward way to get further results is to use these linear combinations, which can be found in the literature,²⁰ and to use the quantum mechanics method for first order energy perturbations. In the following section we will describe a method, however, which does not involve the knowledge of the correct linear combinations of unperturbed eigenfunctions but uses certain general properties of multiplets.²¹

8. HYPERFINE STRUCTURE OF A MULTIPLY

The properties of a multiplet are in many respects a generalization of the properties of a doublet arising from a single electron. Darwin²² was very successful in explaining every detail of the magnetic properties of a multiplet by treating it as if it were a single electron with an orbital moment L and a spin moment S . It is obvious that not all characteristics of a multiplet state can be obtained in this way; for instance, one would find with Darwin's method that the transition $L \rightarrow L$ is forbidden, whereas in the correct theory it is not. As we are interested here in the magnetic interaction with the nucleus, it is possible that we may use again Darwin's simplification.

For the magnetic interaction with the nucleus we assume a generalization of Eq. (7):

$$W_L + W_S = \lambda M_I M_L - \sigma M_I M_S \frac{6M_L^2 - 2L(L+1)}{(2L-1)(2L+3)}. \quad (31)$$

Before using this expression two important remarks have to be made. This formula does not apply to the interaction between the nucleus and an unbalanced s -electron in the configuration. The interaction with an s -electron is of the simple cosine form and gives therefore

$$W_S = \beta M_I M_S. \quad (32)$$

²⁰ J. A. Gaunt, Phil. Trans. A228, 184 (1929); J. H. Bartlett, Jr., Phys. Rev. 34, 1247 (1929).

²¹ Table V, as it is now, does not give us much more information than we obtained with the general sum rule data of Table I. The only additional information one gets is by considering the state with $M_S = 1\frac{1}{2}$, $M_L = 0$. This pair can only arise from the 4S ; the table gives an interaction energy zero, thus the 4S will have $A = 0$ in extreme Russell-Saunders coupling. So the sum of the energies belongs to the $^2D_{1\frac{1}{2}}$ and the $^2P_{1\frac{1}{2}}$, but further separation is not possible with this method.

²² C. G. Darwin. Proc. Roy. Soc. A115, 1 (1927).

If the configuration to which the multiplet belongs contains such an *s*-electron one must add a term like Eq. (32) to Eq. (31). The second remark concerns the factors λ and σ . For the case of one single electron these were both equal to a . For a more complicated configuration one should not expect the coefficient for the orbital part to be the same as for the spin part. As we shall see later on it is possible to obtain a relation between λ and σ in certain simple cases.

In order to find the values of $A(J)$ for each level of the multiplet we must again consider the sums of the results of Eq. (31) for a fixed choice of $M_J = M_S + M_L$. One takes first $M_J = S + L$, which occurs only once, next $M_J = S + L - 1$, occurring twice, and so on. The procedure is exactly the same as that followed in Section 3, but of course much longer, depending upon the values of S and L . It is possible to do it for general values of S and L and one obtains finally the general formula

$$A(J) = \lambda(2 - g) - \sigma \frac{6\Gamma(2 - g) - 2(g - 1)L(L + 1)}{(2L - 1)(2L + 3)} + \beta(g - 1). \quad (33)$$

The last term occurs only when there is an unbalanced *s*-electron. In this formula g is the ordinary Landé g value, and Γ stands as usual for²³

$$\Gamma = SL \cos(S, L) = \{J(J + 1) - L(L + 1) - S(S + 1)\}/2. \quad (34)$$

The derivation of this formula is elementary but too cumbersome and long to be given here, but I am willing to give personal information about it to anyone who really might need it.

In the preceding sections of this paper we have always taken together the interaction W_S with the spin and W_L with the orbital moment. It is quite simple, however, to go back to Eq. (7) and keep these two separate. If we then know these interactions for only one level of a multiplet, we can determine λ and σ and find A for all other levels of the same multiplet. The sum rule of Table I or Table V will, in practically all cases, furnish us with sufficient information to do this. We shall show this again with the p^3 example.

For p^3 the sum rule gives that for ${}^2D_{3/2}$ $A = 24/25a$. If we go back to Eq. (7) via Table I we find that this is divided as follows between the interactions with spins and orbits:

$$\text{with spins: } 4/25a, \text{ with orbits: } \frac{4}{5}a,$$

Furthermore, we know that for ${}^2D_{3/2}$: $\Gamma = +1$, $g = 1\frac{1}{5}$ and we find from Eq. (33) (omitting the last term):

$$\frac{4}{5}a = \lambda \frac{4}{5}, \quad \frac{4}{25}a = -\sigma \frac{\frac{4}{5} - 2\frac{2}{5}}{21}$$

from which

$$\lambda = a, \quad \sigma = -1\frac{2}{5}a.$$

²³ Γ is the displacement of the level from the center of gravity of the multiplet.

With these values we find for the A of ${}^2D_{1\frac{1}{2}}$, for which $\Gamma = -1\frac{1}{2}$, $g = \frac{4}{5}$,

$$A({}^2D_{1\frac{1}{2}}) = \lambda 1\frac{1}{5} - \sigma \frac{-10\frac{4}{5} + 2\frac{2}{5}}{21} = 1\frac{6}{25}a.$$

It is possible to find relations between λ and σ for the different multiplets of a configuration, or for the multiplets which arise after the addition of an s -electron. Lack of material to test such formulae make it useless to go into more detail, also with respect to the remarks made in the following section.

For intermediate coupling one can apply to a great extent the same method as used in a previous paper.²⁴

9. SERIOUS DISCREPANCIES

The hyperfine structure is in many spectra caused by a deeply penetrating s electron, the influence of other electrons being negligibly small. For such cases the theory is simple, hyperfine structure separations can be expressed in terms of Landé cosines and the experimental data have been shown to agree with the theory.²⁵ For non- s electrons no such check has been obtained until now.

The following enumeration of data shows that there are large discrepancies between the theory and the observations for non- s electrons. Though the experimental results are very scarce and often uncertain, the reality of these discrepancies in the example of bismuth is beyond all doubt. The present material is quite insufficient, however, to give quantitative information about the deviations.

A part of the deviations will be due to higher order corrections. The method used in this paper assumes that it is sufficient to consider only first order perturbations for the interaction between the electrons and the spin orbit interactions. This means that our results are obtained by using only zeroth order eigenfunctions in the correct stabilized linear combinations. For heavy elements one must also consider the first order terms of the spin-orbit perturbation in the eigenfunctions. This will cause the hyperfine structure formulae to contain correction terms which are of exactly the same nature as those derived by Fermi²⁶ for the anomalies in the alkali doublet intensities. An estimate of the order of magnitude of these corrections shows that they are probably not large enough to account for the deviations.

Bismuth I ²⁷ ($I = 4\frac{1}{2}$)

$$6s^2 6p^3 {}^2D_{2\frac{1}{2}}: \frac{4}{5}a' + \frac{1}{5}a'' = 0.081 \pm 0.002$$

$${}^2P_{\frac{1}{2}}: a'' = 0.375$$

$$({}^2D_{1\frac{1}{2}}: 1\frac{1}{5}a' - \frac{1}{5}a'' = -0.040 \pm 0.002).$$

²⁴ S. Goudsmit, Phys. Rev. 35, 1325 (1930).

²⁵ S. Goudsmit and R. F. Bacher, Phys. Rev. 34, 1501 (1929).

²⁶ E. Fermi, Zeits. f. Physik 59, 680 (1930). This remark about the second order terms I owe to Dr. H. Casimir, with whom I discussed the discrepancies during his stay here last summer. Phys. Rev. in preparation.

²⁷ P. Zeeman, E. Back and S. Goudsmit, Zeits. f. Physik 66, 1 (1930).

The coupling is not of the extreme (j, j) type. This does not, however, affect the validity of the formulae given for the first two levels, as they are the only ones with $J=2\frac{1}{2}$ and $\frac{1}{2}$ in this configuration. The two first equations give

$$\begin{aligned} 6p\ J = \tfrac{1}{2}: a'' &= 0.375 \\ 1\frac{1}{2}: a' &= 0.007 \pm 0.003. \end{aligned}$$

The second order corrections for this case are uncertain, a study of the levels of Bi III makes one believe that they should decrease a'' and increase a' by not more than about 5 percent. One sees that a' is much too small for the theory predicts that $a' = \frac{1}{5}a''$. Though the formula given for ${}^2D_{1\frac{1}{2}}$ is not strictly valid here, the negative value of its separation factor corroborates our conclusion that a' is much too small.

*Bismuth II*²⁸

$$\begin{aligned} 6s^2\ 6p_{\frac{1}{2}}7s\ 2_1^0: \tfrac{1}{2}a'' + \tfrac{1}{2}b &= 0.391 \pm 0.001 \\ 6p_{\frac{1}{2}}7s\ 9_2^0: \tfrac{3}{4}a' + \tfrac{1}{4}b &= 0.109 \pm 0.007. \end{aligned}$$

One expects the values for a'' and a' of the $6p$ electron in Bi II to be about the same as in Bi I. The above equations are indeed in agreement with this and give both for b about 0.38. If one assumed, however, that a' were really $\frac{1}{5}a''$ one would obtain an impossible negative value for b and a too large value for a' and a'' .

Bi III

$$\begin{aligned} 6s^2\ 7p\ {}^2P_{\frac{1}{2}}: a'' &= 0.102 \pm 0.003 \\ {}^2P_{\frac{1}{2}}: a' &= 0.021 \pm 0.004. \end{aligned}$$

The second order corrections for the $7p$ electron are expected to be somewhat larger than for the $6p$. They tend to increase a'' by perhaps 10% and to decrease a' by about 5%. We have here a case where indeed the theoretical ratio between a' and a'' is close to the observed one, but one has to keep in mind that a' is not known with accuracy.

*Manganese*²⁹ ($I=2\frac{1}{2}$). Most of the hyperfine structure in manganese is caused by the $4s$ electron. For a few levels the hyperfine structure is due to the $3d$ and $4p$ electrons, but for these levels the separations are not known with sufficient accuracy to check any formulae.

Indium.³⁰ The measurements on the principal doublet of the indium spectrum made by McLennan and Allin and by Jackson differ so entirely from each other that they are useless.³¹ This example would have been a very significant check of the theory.

²⁸ New observations on Bi II and III made by R. A. Fisher and the present author, to be published shortly. Classification and notation from J. C. McLennan, A. B. MacLay and M. F. Crawford, Proc. Roy. Soc. A. 129, 579 (1931).

²⁹ H. E. White and R. Ritschl, Phys. Rev. 35, 1146 (1930).

³⁰ J. C. McLennan and E. J. Allin, Proc. Roy. Soc. A128, 508 (1930). D. A. Jackson, Proc. Roy. Soc. A129, 208 (1930).

³¹ The fair agreement which Jackson seems to obtain between his measurements and the theory is caused by an unfortunate error in a paper by Fermi. Fermi (ref. 2) gives formulae for the hyperfine splitting of a ${}^2P_{1\frac{1}{2}}$ level in case $I \geq 1\frac{1}{2}$. He mentions in the text how these formulae change for a case where $I < 1\frac{1}{2}$ and just this sentence happens to be incorrect. Jackson's results again give a' too small.

Thallium I. ($I=\frac{1}{2}$). Only one of the two lines³² of the principal doublet of thallium has been studied in detail.³² The present data on the other line are insufficient to draw any certain conclusions, though they also seem to indicate for this case that a' is too small.

*Thallium III.*³³

$$7p\ ^2P_{1/2}: a'' = 0.375$$

$$^2P_{3/2}: a' = 0.218.$$

The second order corrections are rather large in this case, namely about 15%. They would increase a'' and decrease a' . For this example a' is much larger than the theoretical value.

CONCLUSION

Though the experimental data are scarce we come to the conclusion that the present theory of the hyperfine structure separations is incorrect or at least incomplete. The method used in this paper is not the cause, for it has been applied very successfully to many other problems, but the use of the classical Eq. (3),

$$W_l + W_s = a[I l \cos(I, l) - I s \cos(I, s) + 3 I s \cos(I, r) \cos(r, s)].$$

The correct quantum mechanical expression for the spin-spin interaction will perhaps contain different terms. The generalizations of the Dirac theory for the two-body problem given by Gaunt³⁴ and Breit³⁵ contain indeed extra terms for the spin-spin interaction. From a study of the helium triplet, with which one can test a part of these extra terms, Breit³⁶ concluded that their presence was in disagreement with the experimental data on the spin-spin interaction of two electrons. Perhaps such terms do have a real significance for the interaction between nuclear and electron spin³⁷.

This discussion shows the importance of the study of hyperfine structure as a guide for the further development of the quantum theory, especially for the generalization of the Dirac equation. Let us, therefore, hope that experimental physics will soon provide us with at least one doublet state for which the hyperfine structure of both levels can be given with certainty and accuracy.

APPENDIX

Just before sending off this paper I received a letter from Dr. John Wulff, National Research Fellow at Tübingen, in which he describes important new measurements on the hyperfine structure as well as the Zeeman effect of the principal thallium doublet. The $6p_{1/2}$ level has $a''=0.708$, whereas the $6p_{3/2}$ level is unresolvably small. The value for a' is probably of the order 0.015, thus about ten times too small.

THE VAN DER WAALS FORCES IN GASES

BY JOHN C. SLATER AND JOHN G. KIRKWOOD
MASSACHUSETTS INSTITUTE OF TECHNOLOGY

(Received February 5, 1931)

ABSTRACT

A calculation of van der Waal's potential of two atoms at large separation has been carried out for hydrogen and helium. The method depends upon a representation of the perturbed wave function of the system as

$$\psi = \psi_0 (1 + vR)$$

where ψ_0 is the unperturbed wave function, v the perturbing potential and R is a function of the radial coordinates of the electrons. The method is equally well adapted to the calculation of polarizabilities. A computation of the mutual energy of two hydrogen atoms confirms the results of Eisenschitz and London. The polarizability of helium is calculated as 0.210×10^{-24} cc which agrees well with the experimental value, 0.205×10^{-24} . The mutual energy of two helium atoms is found to be $-3.18 E_0 / (R/a_0)^6$. A correlation between the mutual energy of the two molecules, ϵ , and the polarizability, α , is obtained:

$$\epsilon = -1.36 \nu_0^{1/2} a_0^{3/2} \alpha^{3/2} E_0 / R^6$$

where ν_0 is the number of electrons in the highest quantum state in the molecule, E_0 the energy of the hydrogen atom in the normal state, and R is the separation of the molecules. By means of this formula, the van der Waals cohesive pressure constant is calculated for Ne, A, N₂, H₂, O₂, and CH₄.

I. INTRODUCTION

IT HAS been recognized for some time that the van der Waals forces in gases have their origin in a mutual polarization of the molecules. The idea was suggested by Debye,¹ but his calculation of intermolecular energies, based upon an electrostatic molecular model, did not meet with great success. This fact is not surprising in the light of recent work, which has shown that a rapidly pulsating field associated with the internal motion of the electrons in the molecule is the chief factor in determining the mutual energy of two molecules at separations sufficiently large to prevent the exchange of electrons. This fact was suggested, although not explicitly stated, in a calculation of the mutual energy of two hydrogen atoms by Wang.² Recently, Eisenschitz and London³ have presented a general method of calculating the mutual energy of two molecules at large separation. Their method depends upon an expansion of the wave function of the system in terms of a selected set of the unperturbed wave functions of the two molecules. They have confirmed the form of Wang's result for two hydrogen atoms, although they have shown

it to be numerically in error. Hassé,⁴ with a variational method, has calculated the polarizability of helium. The wave function obtained by Waller⁵ in a treatment of the quadratic Stark effect in hydrogen, serves as a basis for the calculation. An empirical extension of the method employed in this case permits him to calculate the mutual energy of two atoms at large separation both for hydrogen and helium.

The present method resembles that of Hassé in that use is made of the variation principle. However, his choice of wave function was more or less empirical and the perturbation energy was calculated as a part of the total energy. On the other hand, we have formulated the variation problem for a direct determination of the perturbation energy by itself, and from the original wave equation have obtained a simplified Euler equation for this variation problem, which when it cannot be solved directly, serves as a guide in choosing an approximate function. The method, while lacking the generality of that of London and Eisenschitz, is applicable to most non-polar molecules in the normal state.

II. POLARIZABILITY AND INTERATOMIC ENERGY OF HYDROGEN

We shall begin by considering a system of ν electrons with an unperturbed wave function ψ_0 , while the correct wave function under the influence of a perturbing potential v is ψ . The wave equations in the two cases may be written

$$\begin{aligned}\nabla^2\psi_0 + \kappa^2(E_0 - V_0)\psi_0 &= 0 \\ \nabla^2\psi + \kappa^2(E - V)\psi &= 0 \\ \kappa^2 &= 8\pi^2m/\hbar^2 \\ E &= E_0 + \epsilon \\ V &= V_0 + v.\end{aligned}\tag{1}$$

Here E_0 and V_0 are the initial total and potential energies of the system and ϵ is the energy acquired by virtue of the perturbation. The operator ∇^2 is understood to be referred to the 3ν dimensional configuration of the system of ν electrons. If we let

$$\psi = \psi_0(1 + \phi)\tag{2}$$

we obtain the following equation

$$\nabla^2\phi + 2 \sum_{j=1}^{3\nu} \frac{\partial \ln \psi_0}{\partial x_j} \frac{\partial \phi}{\partial x_j} + \kappa^2(\epsilon - v)(1 + \phi) = 0.\tag{3}$$

Since we shall not be interested in perturbation effects of higher order than the second, it is only necessary to retain terms of the first order in v and ϕ . Thus we can replace the factor $(1 + \phi)$ by 1, since it is multiplied by a small quantity. Further, in all the cases to which our method is applicable, the mean value of the perturbing potential over the unperturbed wave function

⁴ H. R. Hassé, Proc. Camb. Phil. Soc. 26, 542 (1930).

⁵ Waller, Zeits. f. Physik 38, 635 (1926).

is zero, the first order perturbation in the energy vanishes, and ϵ is small of the second order. For this reason we may replace $\epsilon - v$ by $-v$, obtaining an equation which does not contain an energy parameter at all. When we make these approximations, Eq. (3) becomes

$$\nabla^2 \phi + 2 \sum_{j=1}^{3n} \frac{\partial \ln \psi_0}{\partial x_j} \frac{\partial \phi}{\partial x_j} - \kappa^2 v = 0. \quad (4)$$

The polarization of the hydrogen atom in its normal state by an homogeneous electric field, F , affords the simplest example of the application of Eq. (4). Here

$$\begin{aligned} \psi_0 &= e^{-r} \\ v &= \sum_{j=1}^3 g_j x_j \end{aligned} \quad (5)$$

where r is the radial distance of the electron from the nucleus expressed in units of a_0 , the Bohr radius of the normal state, and

$$g_j = -eF x_j.$$

The components F_{x_j} of the field, F , are referred to a rectangular system of coordinates with origin in the nucleus of the atom. If we choose as new variables, r and v , and if we let

$$\phi = \frac{vR(r)}{E_0} \quad (6)$$

where E_0 is the absolute value of the energy of the hydrogen atom in the normal state, a separation of variables in Eq. (4) is effected and there results

$$\frac{d^2 R}{dr^2} + \left(\frac{4}{r} - 2 \right) \frac{dR}{dr} - \frac{2R}{r} - 1 = 0 \quad (7)$$

where r is measured in units of a_0 . The solution is

$$R = -\frac{1}{2} \left(1 + \frac{r}{2} \right) + C_1 \left(\frac{1}{r} + \frac{1}{r^2} + \frac{1}{2r^3} \right) + C_2 \frac{e^{2r}}{r}.$$

In order that the integral

$$\int \psi \bar{\psi} d\tau$$

may exist, it is necessary to set C_1 and C_2 equal to zero. The new wave function takes the form

$$\psi = e^{-r} \left(1 - \frac{v}{2E_0} \left[1 + \frac{r}{2} \right] \right).$$

If the original rectangular coordinate system is chosen with z -axis parallel to the field, $v = -eFz$, and the above wave function becomes identical with that obtained by Waller.⁶ The energy is given by

⁶ Waller, reference 5.

$$E = E_0 + \epsilon = -\frac{1}{\kappa^2} \frac{\int \bar{\psi} H \psi d\tau}{\int \psi \bar{\psi} d\tau}.$$

When ϕ has the form, $vR(r)$, and ψ_0 is a function of r alone, the integrals occurring in the evaluation of ϵ are of the form

$$\int v^n f(r) d\tau \quad n = 1, 2, 3.$$

If v is a harmonic function which vanishes when r is zero, the term for $n=1$ (and $n=3$) vanishes. That is, the first order perturbation energy is zero. Then the only term which we need consider is the one with $n=2$. This condition is of course fulfilled in the problem which we have just considered, and will be fulfilled in the subsequent problems to be treated. The expression for ϵ now becomes

$$\epsilon = \frac{\int v \phi \psi_0^2 d\tau}{\int \psi_0^2 d\tau} \quad (8)$$

with the neglect of perturbation terms in the normalization of ψ . These will contribute only to terms in ϵ of higher order than the second.

A computation of the polarization energy of the hydrogen atom using the wave function which we have obtained yields

$$\epsilon = -2.25 a_0^3 F^2$$

which corresponds to a polarizability

$$\alpha = 4.5 a_0^3.$$

These, values, of course, agree with those obtained by Waller.

In this simple case, the solution of Eq. (7) offers no difficulty. It is of interest, nevertheless, to see what value of the energy may be obtained, if our information is restricted to the fact that $\phi = vR(r)$. Let us try as a representation of $R(r)$ the expression, λr^n . The energy integral becomes

$$\epsilon = \frac{\int v \phi [1 - \rho[R]] \psi_0^2 d\tau}{\int \psi_0^2 d\tau} \quad (8)$$

where

$$\rho[R] = \frac{d^2 R}{dr^2} + \left(\frac{4}{r} - 2\right) \frac{dR}{dr} - \frac{2R}{r} - 1.$$

If we minimize the integral with respect to the parameters λ and ν , we obtain

$$\epsilon = -2.24a_0^3F^2$$

$$\lambda = -0.728/E_0; \quad \nu = 0.5.$$

This value agrees with the exact one to somewhat better than 0.50%.

The method may be applied with almost equal simplicity to the interaction of two hydrogen atoms. If the separation, R_0 , of the two atoms is sufficiently large to prevent electron interchange, the wave function of the system is

$$\psi_0 = \psi_{01}\psi_{02} = e^{-(r_1+r_2)}$$

where r_1 and r_2 are the respective radial distances of each electron from its own nucleus. When referred to two rectangular coordinate systems with their respective origins in the two nuclei and with z -axes directed along R_0 , the dipole term in the perturbing potential is given by

$$\frac{e^2}{R_0^3}[x_1x_2 + y_1y_2 - 2z_1z_2].$$

Terms due to multipoles of higher order will be neglected. If we let

$$\phi = \frac{vR(r_1, r_2)}{E_0}$$

and change the variables in Eq. (4) to v , r_1 and r_2 , a separation is again effected and we have

$$\frac{\partial^2 R}{\partial r_1^2} + \frac{\partial^2 R}{\partial r_2^2} + \left(\frac{4}{r_1} - 2\right) \frac{\partial R}{\partial r_1} + \left(\frac{4}{r_2} - 2\right) \frac{\partial R}{\partial r_2} - 2R \left(\frac{1}{r_1} + \frac{1}{r_2}\right) - 1 = 0 \quad (9)$$

The existence of a solution of this equation is assured by the negative value of the coefficient of R .⁷ A solution by successive approximation may be obtained in the following manner. Let us write Eq. (9) as

$$R = -\frac{1}{2} \frac{r_1 r_2}{r_1 + r_2} \left\{ 1 - \left[\frac{\partial^2 R}{\partial r_1^2} + \frac{\partial^2 R}{\partial r_2^2} + \left(\frac{4}{r_1} - 2\right) \frac{\partial R}{\partial r_1} + \left(\frac{4}{r_2} - 2\right) \frac{\partial R}{\partial r_2} \right] \right\}.$$

If the differential function is neglected

$$R = -\frac{1}{2} \frac{r_1 r_2}{r_1 + r_2}. \quad (10)$$

Substitution of this expression in the differential function will yield a second approximation. Repetition of this process will yield a still closer approximation. If we use merely the first approximation (10), we calculate a value of the energy,

$$\epsilon = -6.14 \frac{e^2 a_0^5}{R_0^6}.$$

⁷ Goursat, Cours d'Analyse Mathématique, vol. III, §249.

This is about 5 percent higher than the value

$$- 6.47 \frac{e^2 a_0^5}{R_0^6}$$

obtained by Eisenschitz and London.⁸ The use of higher terms in the expansion of R would permit us to approach the true value as closely as we pleased. Although no difficulty is encountered in the evaluation of the integrals occurring in the energy expression, the tedium of the calculation is reduced by using the variation method. Eq. (10) suggests as a representation of R , the expression

$$\lambda r_1^\nu r_2^\nu.$$

If the function is inserted in the energy integral and the latter is minimized with respect to the parameters λ and ν one obtains

$$\epsilon = - 6.49 \frac{e^2 a_0^5}{R_0^6}$$

$$\nu = 0.325.$$

This is in excellent agreement with the result of London and Eisenschitz. The fact that their value lies slightly higher instead of slightly lower than the one which has just been obtained is doubtless attributable to an error in estimating the contribution of the continuous spectrum in their expansion of ψ , since the variation method cannot give too low a value of the energy.

The fact that the wave function in the two cases which have been considered may be expressed as

$$\psi_0(1 + vR)$$

where R is a function of the radial distances of the electrons from their nuclei, is indeed logical from a physical point of view. In the absence of degeneracy, one would expect the distortion of the wave function to depend in some simple way upon the perturbing potential. Moreover, for a given value of the perturbing potential it is evident that the distortion will be greater, as the distance of the electron from the nucleus becomes greater, since the restoring force exerted by the nucleus will be smaller. The function R provides for this effect. The separation of the differential Eq. (4) in terms of v and the r 's appears to depend upon the linear properties of v in the rectangular coordinates of the electrons, and the spherical symmetry of the unperturbed wave function.

III. GENERALIZATION OF THE METHOD: POLARIZABILITY AND INTERATOMIC ENERGY OF HELIUM

For the helium atom, or in general for an atom with ν electrons each having a spherically symmetrical distribution, the wave function may be approximately represented by

$$\psi_0 = \prod_{j=1}^{\nu} \psi_j(r_j) \quad (11)$$

⁸ Eisenschitz and London, reference 3.

where the function ψ_j depends only upon the radial coordinate of the electron j . Such a function may be approximated by an expression

$$r^{n-1}e^{-(Z-s)r/n}$$

where n is an effective quantum number, s a screening constant, Z the total nuclear charge. If we wish to represent the wave function accurately in the region of its maximum, we may choose n and s by minimizing the total energy, as Zener has done. If, however, we are more interested in the value of the function for large values of r , we may choose s to be equal to the total number of electrons except for the one being considered, and use an effective quantum number which is non-integral. Thus for He, in the neighborhood of the maximum, we choose $Z-s=1.6875$ (or, for some purposes, 1.70), $n=1$; while for large r 's, we take $Z-s=1$, $n=0.745$.⁹ We use these formulas for approximate computation of polarizability and interatomic force.

A better representation of the wave function can be obtained by more complicated methods, as that of Hartree,¹⁰ or the method used by one of the authors on He.¹¹ These give almost identical results for He, as far as the purposes of this paper go, and for quantitative work we make use of the latter in one calculation of the polarizability and interatomic energy of helium.

We shall first consider the polarization of the molecule by an homogeneous field F . The perturbing potential is

$$v = \sum_{j=1}^{\nu} x_j$$

where

$$v = -e \sum_{k=1}^3 F_{xjk} x_{jk}$$

If we let

$$\phi = \frac{1}{E_0} \sum_{j=1}^{\nu} v_j R(r_j) \quad (12)$$

and make use of the facts that $\partial \ln \psi_0 / \partial r_j$ depends only upon r_j , the distance of electron j from the nucleus and that

$$\sum_{k=1}^3 x_{jk} \frac{\partial v}{\partial x_{jk}} = v_j$$

we find that Eq. (4) splits into ν equations of the form

$$\frac{d^2 R}{dr^2} + \left(\frac{4}{r} + 2 \frac{d \ln \psi_0}{dr} \right) \frac{dR}{dr} + \frac{d \ln \psi_0}{dr} \frac{R}{r} - 1 = 0. \quad (13)$$

If we use a wave function of the simpler type discussed above this equation becomes

⁹ C. Zener, Phys. Rev. 36, 51 (1930); J. C. Slater, Phys. Rev. 32, 349 (1928); J. C. Slater, Phys. Rev. 36, 57 (1930).

¹⁰ D. R. Hartree, Proc. Camb. Phil. Soc. 24, 89 (1928).

¹¹ J. C. Slater, Phys. Rev. 32, 349 (1928).

$$\frac{d^2 R}{dr^2} + 2 \left(\frac{n+1}{r} - \frac{Z-s}{n} \right) \frac{dR}{dr} + 2 \left(\frac{n-1}{r^2} - \frac{Z-s}{nr} \right) R - 1 = 0. \quad (14)$$

The energy given by Eq. (8) is

$$\epsilon = \frac{\int \sum_{j=1}^r \sum_{k=1}^r v_j \phi_k \psi_0^2 d\tau}{\int \psi_0^2 d\tau}.$$

Since upon integration all terms involving $v_j \phi_k$ with $j \neq k$ vanish

$$\epsilon = \sum_{j=1}^r \epsilon_j$$

and

$$\epsilon_j = \frac{\int v_j \phi_j \psi_0^2 d\tau}{\int \psi_0^2 d\tau}.$$

In the computation of ϵ_j it will be convenient to use the variation method rather than to solve Eq. (14) explicitly. The expression becomes

$$\epsilon_j = \frac{\int v_j \phi_j [1 - \rho[R_j]] \psi_0^2 d\tau}{\int \psi_0^2 d\tau}$$

where

$$\rho[R_j] = \frac{d^2 R_j}{dr_j^2} + 2 \left(\frac{n_j+1}{r_j} - \frac{Z-s_j}{n_j} \right) \frac{dR_j}{dr_j} + 2 \left(\frac{n_j-1}{r_j^2} - \frac{Z-s_j}{n_j r_j} \right) R_j - 1.$$

We shall try

$$R = \lambda e^{\beta(z-s)r/n}$$

which is analytically somewhat more convenient than the representation λr^n employed in the case of hydrogen. When the energy integral is minimized with respect to the parameter λ there results

$$\epsilon = \frac{1}{E_0} \frac{J_1^2}{J_2} e^2 F^2$$

where

$$\begin{aligned} J_1 &= \frac{\int r^{2n} \cos^2 \theta e^{\beta(z-s)\tau/n} \psi_0^2 d\tau}{\int \psi_0^2 d\tau} \\ &= \frac{(n+1)(n+\frac{1}{2})}{3} \left(\frac{n}{Z-s} \right)^2 a_0^2 \frac{1}{(1-\beta/2)} 2n+3 \end{aligned}$$

$$J_2 = \frac{\int \left\{ \left(\frac{n}{Z-s} \right)^2 (\beta^2 - 2\beta)r^{2n} + \frac{n}{Z-s} [(n+1)\beta - 1]r^{2n-1} + 2(n-1)r^{2n-2} \right\}}{\int \psi_0^2 d\tau}$$

$$e^{2\beta(z-s)\tau/n} \cos^2 \theta \psi_0^2 d\tau = -a_0 \frac{1 + (2n-5)\beta/3 + (2n^2 - n + 5)\beta^2/6}{(1-\beta)^{2n+3}}.$$

For the energy we have

$$\epsilon_j = -2 \frac{(n_j + 1)^2 (n_j + \frac{1}{2})^2 n_j^4}{9(Z-s_j)^4} a_0^3 F^2 (1 + \theta_j) \quad (13a)$$

where

$$\theta_j = \frac{(1-\beta)^{2n_j+3}}{(1-\beta/2)^{4n_j+6} [1 + (2n_j-5)\beta/3 + (2n_j^2 - n_j + 5)\beta^2/6]} - 1$$

Minimizing with respect to β shows that for $n=1$, $\theta_j=0.124$. In general $0.124 \leq \theta_j \leq 0$; $n_j \geq 1$. For the total polarization energy we may write

$$\epsilon = -2a_0^3 F^2 \sum_{j=1}^v \frac{n_j^4 (n_j + 1)^2 (n_j + \frac{1}{2})^2 (1 + \theta_j)}{9(Z-s_j)^4}$$

and for the polarizability

$$\alpha = 4a_0^3 \sum_{j=1}^v \frac{n_j^4 (n_j + 1)^2 (n_j + \frac{1}{2})^2 (1 + \theta_j)}{9(Z-s_j)^4}.$$

We shall first compute the polarizability of helium taking n as 1 and $Z-s$ as 1.6875, the values obtained by minimizing the total energy of the atom. We obtain

$$\alpha = 1.11a_0^3 = 0.164 \times 10^{-24} \text{cc.}$$

If on the other hand we use the limiting values at large distances for n and $Z-s$ we have $n=0.745$; $Z-s=1$, and we obtain

$$\alpha = 1.51a_0^3 = 0.222 \times 10^{-24} \text{cc.}$$

The value of α corresponding to measurements of the refractive index is 0.205×10^{-24} . As we should have anticipated it lies between the two values which we have calculated. The first wave function which emphasizes the smaller r 's at the expense of the larger gives a value of α about 20 percent below the experimental one, while the second wave function which emphasizes the larger r 's gives a value about 8 percent higher than the experimental one. The second wave function which is accurate only for large values of r gives a surprisingly good result.

A more exact determination of the polarizability of helium may be obtained with the use of the more accurate wave function mentioned above. After normalization and integration over the configuration space of one electron, the square of the wave function for each electron may be represented by

$$0.7604(1 + 1.440e^{-1.692r})e^{-3r+0.0214r^2}; r < 3$$

$$0.6048(1 + 1.440e^{-1.692r})e^{-2.688r}r^{-0.510} \left(1 + \frac{0.1414}{r} + \dots \right); r > 3.$$

We shall use as a representation of \mathcal{R} the function λr^ν . Minimizing the energy integral with respect to the parameter λ gives

$$\epsilon = \frac{1}{E_0} \frac{J_1^2}{J_2 J_0} e^2 d_0^2 F^2$$

where

$$J_0 = \int \psi_0^2 d\tau$$

$$J_1 = \int r^{\nu+2} \psi_0^2 d\tau$$

$$J_2 = \int \left\{ \nu(\nu+2)r^{2\nu} + 2(\nu+1) \frac{d \ln \psi_0}{dr} r^{2\nu+1} \right\} \psi_0^2 d\tau.$$

Properly, this expression should be computed for different ν 's and the minimum chosen. On account of the labor of the integration, however, we have arbitrarily chosen the value $\nu=0.5$. This was the value found for the simple wave functions used above, and moreover it was found that the result was so insensitive to ν that a variation of ± 0.1 in ν did not affect the final result by more than one percent. The above integrals have been computed graphically for $\nu=0.5$ and the polarizability of helium was found to be

$$\alpha = 1.43a_0^3 = 0.210 \times 10^{-24} \text{cc.}$$

This yields a value of the dielectric constant at 0° and 1 atm. of 1.0000715 which is slightly lower than the experimental value, 1.000074. It is however, somewhat higher than the square of the measured refractive index extrapolated to infinite wave-length, 1.000070. The agreement among the various values is not unsatisfactory when one remembers that the accuracy in the measured refractive index, and dielectric constant cannot be very great, in view of the experimental difficulties in such measurements.

A calculation of the mutual energy of two atoms may be carried out in a similar manner. The dipole term in the perturbation potential may be written

$$v = \sum_{j=1}^{\nu} \sum_{k=1}^{\nu'} v_{jk}$$

where the sum is understood to be taken over all possible electron pairs between the two atoms. Each v_{jk} has the form

$$\frac{e^2}{R_0^3} [x_k x_j + y_k y_j - 2z_k z_j].$$

If we let

$$\phi = \frac{1}{E_0} \sum_{j=1}^p \sum_{k=1}^p v_{jk} R(r_j, r_k).$$

Eq. (4) separates into p^2 equations of the form

$$\begin{aligned} \frac{\partial^2 R}{\partial r_j^2} + \frac{\partial^2 R}{\partial r_k^2} + \left(\frac{4}{r_j} + \frac{2 \partial \ln \psi_0}{\partial r_j} \right) \frac{\partial R}{\partial r_j} + \left(\frac{4}{r_k} + \frac{2 \partial \ln \psi_0}{\partial r_k} \right) \frac{\partial R}{\partial r_k} \\ + 2 R \left(\frac{1}{r_j} \frac{\partial \ln \psi_0}{\partial r_j} + \frac{1}{r_k} \frac{\partial \ln \psi_0}{\partial r_k} \right) - 1 = 0. \end{aligned} \quad (17)$$

Moreover the energy may be written

$$\epsilon = \sum_{j=1}^p \sum_{k=1}^p \epsilon_{jk}$$

where

$$\epsilon_{jk} = \frac{\int v_{jk} \phi_{jk} (1 - \rho_{jk}) \psi_0^2 d\tau}{\int \psi_0^2 d\tau}.$$

If an exact solution of Eq. (17) is used, ρ_{jk} which is the differential expression on the left hand side of Eq. (17) vanishes. We shall use the two representations

$$R_{jk} = \lambda r_j^r r_k^r; \quad R_{jk} = \lambda e^{\beta(r_j + r_k)}$$

which proved effective in the case of hydrogen, according to their analytical convenience in conjunction with the unperturbed wave function which is chosen. The parameters are determined by minimizing the energy integral. The details of the calculation are quite similar to those in the calculation of polarizabilities. With the simple wave function

$$\psi_0 = \prod_{j=1}^p r_j^{n_j-1} e^{-\gamma_j r_j / n_j}; \quad \gamma_j = Z - s_j$$

we obtain the following result

$$\epsilon = -\frac{13}{27} \frac{z^2 a_0^5}{R_0^6} \sum_{j=1}^p \sum_{k=1}^p \frac{n_j^4 n_k^4 (n_j+1)^2 (n_j+\frac{1}{2})^2 (n_k+1)^2 (n_k+\frac{1}{2})^2}{\gamma_j^2 \gamma_k^2 \{ \gamma_k^2 n_j^2 (n_j+1) (n_j+\frac{1}{2}) + \gamma_j^2 n_k^2 (n_k+1) (n_k+\frac{1}{2}) \}} \quad (18)$$

For convenience in representation certain factors $1+\theta_{jk}$ occurring in each term have all been assigned the value which they assume for 1-quantum electrons. Since

$$0 \leq \theta_{jk} \leq 0.07$$

the above formula will approximate the true one to within a few percent in every case. We shall calculate the mutual energy of two helium atoms first taking $Z-s=1.6875$ and $n=1$. We obtain

$$\epsilon = -1.13 \frac{e^2 a_0^5}{R_0^6}.$$

If we now take the values $n=0.745$, $Z-s=1$, which occur in the asymptotic form of the wave function we obtain as in the case of the polarizability a somewhat larger value:

$$\epsilon = -1.78 \frac{e^2 a_0^5}{R_0^6}.$$

The same calculation has been made with the use of the more accurate wave function for He. As a representation of the function $R, \lambda r_j^p r_k^p$ was selected. The integrals, similar to those encountered in the calculation of the polarizability, were evaluated graphically. The energy of two helium atoms was computed as

$$\epsilon = -1.59 \frac{e^2 a_0^5}{R_0^6} = -3.18 \frac{E_0}{(R_0/a_0)^6}.$$

This value lies between the two values obtained with the hydrogenic wave function. It is about 30 percent higher than that obtained with values of Z and n determined to give the best energy for the atom and about 13 percent below the value obtained with the asymptotic values of n and Z . Since the wave function which gave the above value also gives a good value of the polarizability, it is likely that the above value is correct within one or two percent. Hassé obtains a value

$$-2.93 \frac{E_0}{(R/a_0)^6}$$

which differs from our result by about 8 percent. Both of these values are slightly above the upper limit for the mutual energy of two helium atoms calculated by London:

$$\epsilon = -3/4 \alpha^2 V_i / R^6$$

where α is the polarizability and V_i the ionization potential. This has the value

$$-2.65 \frac{E_0}{(R/a_0)^6}.$$

The fact that both Hassé's and our values lie above London's upper limit is not to be considered as alarming. For London, in using the second order perturbation method, neglected a factor which has been rather consistently overlooked in such calculations: transitions in which two electrons are excited may contribute appreciably to the dispersion and similar terms, and they are connected with larger energy differences than the ionization potential, so that in the upper limit of such an expression as London's we should really have the highest potential connected with a double jump, much larger than V_i . The relation of our results to London's limit suggests that these double jumps are strong enough to shift the center of gravity of the term system beyond the ionization potential.

A result of considerable interest may be obtained from formulas (16) and (18). While neither of them gives particularly accurate representations of α or ϵ , it is possible to reach through them a correlation between these two quantities. First, it is to be noted that in both formulas only terms arising from electrons in the outer shell of the atoms contribute appreciably to the sums. Terms arising from inner shells (if any), are virtually nullified both through a decrease in the effective quantum number and by an increase in the effective nuclear charge. We may therefore write

$$\alpha = \frac{4.5\nu_0 a_0^3}{(Z - S_0)^4} \frac{n_0^4(n_0 + 1)^2(n_0 + \frac{1}{2})^2}{9}$$

$$\epsilon = - \frac{6.5\nu_0^2}{(Z - S_0)^6} \frac{e^2 a_0^5}{R_0^6} \frac{n_0^6(n_0 + 1)^3(n_0 + \frac{1}{2})^3}{27}$$

where ν_0 is the number of electrons in the outer shell of the atom; n_0 and S_0 are the effective quantum number and screening constant of these electrons. Elimination of n_0 and $(Z - S_0)$ gives

$$\epsilon = -\beta/R_0^6$$

where

$$\beta = 1.36\nu_0^{1/2} a_0^{3/2} \alpha^{3/2} E_0. \quad (19)$$

Corresponding to the empirically determined polarizability for He, this gives a value $\beta = 3.16a_0^6 E_0$. This is in excellent agreement with the value 3.18, calculated with the aid of the accurate wave function above.

IV. CORRELATION WITH THE EQUATION OF STATE

Although the computation of the last section applied only to atoms for which each electron had a spherically symmetrical distribution, still it is interesting provisionally to compute van der Waals forces in other cases from the polarizability. In cases where the whole atom is spherically symmetrical, though individual electrons are not, this seems fairly reasonable. Thus we obtain values of $\beta/a_0^6 E_0$ for the noble gases as listed in Table I:

TABLE I.

He	Ne	A	Kr	Xe
3.16	17.0	148	275	582

These values can be tested by calculating the equation of state. Of course, the attractive force is not the only interatomic force; there is also a repulsive force, increasing very rapidly as the atoms approach. This is often represented by assuming the atoms to be rigid, and if the van der Waals attraction is fairly large this is justified. For He, however, large errors are committed by this assumption. The repulsive potential has been computed for atomic hy-

drogen¹² and for helium.¹³ It appears possible to represent it in the range of importance in thermal interaction between gas molecules by the approximation formula

$$\epsilon_r = \lambda e^{-cR_0}.$$

It should therefore be possible to write approximately

$$\epsilon = \lambda e^{-cR_0} - \beta/R_0^6$$

for the total interaction energy of two molecules. If the equation of state of a gas is written in the familiar virial form

$$\frac{pV}{RT} = 1 + \frac{B}{V} +$$

where p is the pressure, V the volume, R the ideal gas constant, and T the absolute temperature, it is possible to show that at high temperatures

$$B = 2\pi N \int_0^\infty (1 - e^{-\epsilon/kT}) R^2 dR$$

under the assumption the molecules are spherically symmetrical. Here ϵ is the mutual potential energy of two molecules. If, further the molecules are treated as rigid spheres of diameter σ , and the exponential function in the above integral is expanded, it is found that approximately

$$B = B_0 - A/RT$$

where

$$B_0 = \frac{2\pi N \sigma^3}{3}$$

$$A = -2\pi N^2 \int_\sigma^\infty \epsilon R^2 dR$$

and the equation of state may be written in the van der Waals form

$$p = \frac{RT}{V - B_0} - \frac{A}{V^2}.$$

Moreover, if the repulsive potential is ignored when $R > \sigma$, we may replace ϵ by ϵ_a calculated from Eq. (19). The expression for A then becomes

$$A = 4.76 \times 10^{11} \beta / B_0 \text{ ergs cc/mol} \quad (20)$$

where B_0 is expressed in cc/mol. It is to be remembered that this is a very rough approximation, for in reality the repulsive potential cannot be adequately represented by a potential wall which rises to infinity when $R = \sigma$. This model is indeed entirely inadequate when the attractive field is very

¹² Heitler and London, *Zeits. f. Physik* **44**, 455 (1927); Sugura, *Zeits. f. Physik* **45**, 484 (1927).

¹³ J. C. Slater, reference 11.

weak as in the case of helium and hydrogen. This is illustrated in Fig. 1. The interatomic potential

$$\epsilon = \left\{ 7.7e^{-2.43R/a_0} - \frac{0.68}{(R/a_0)^6} \right\} \cdot 10^{-16} \text{ ergs}$$

which we have obtained for helium has been plotted as a function of the separation of the two atoms. The dotted line represents the attractive component alone and the distance marked σ on the R -axis represents the effective atomic diameter calculated from the van der Waals B_0 constant. In a later

Fig. 1. The mutual energy of two helium atoms plotted as a function of the interatomic distance.

paper a calculation of the second virial coefficient B of helium, based upon the above expression for the interatomic potential, will be presented. It leads to an equation of state and to a description of the thermodynamic properties of helium which are in striking agreement with experiment.

In the present paper, however, we shall content ourselves with the approximation of rigid molecules. We have calculated values of A for several gases by means of Eqs. (19) and (20), from the experimental values of the refractive index and the constant B_0 . We have not restricted ourselves to the noble gases, but have included several gases with poly-atomic molecules. The electron configuration in most non-polar molecules resembles that of the noble gases except in the particular case of spherical symmetry. It was thought

that Eq. (19) might still be approximately valid in these cases, since most of the characteristics of the wave function employed in the calculation of α and ϵ were eliminated in the formulation of this relation. The computed values of A are compared with the empirical values of Beattie and Bridgeman¹⁴ in Table II. The A constants for Kr and Xe were computed from viscosity

TABLE II.

	$\alpha \cdot 10^{24}$ (cc)	B_0 (cc/mol)	$A(\text{calc}) \cdot 10^{-12}$ (ergs cc)	$A(\text{exp}) \cdot 10^{-12}$ (ergs cc)
Ne	0.39	20.6	0.37	0.21
A	1.65	39.3	1.67	1.29
Kr	2.50	52.8	2.33	2.07
Xe	4.12	70.4	3.70	3.86
N ₂	1.74	50.5	1.58	1.34
H ₂	0.82	21.0	.55	0.20
O ₂	1.59	46.2	1.64	1.49
CH ₄	2.59	55.9	2.32	2.28

measurements. The agreement appears to be quite satisfactory. The computed values of A are of course somewhat larger than the empirical ones due to the neglect of the repulsive potential outside the sphere $R=\sigma$. However, as A becomes large, the error introduced by this approximation becomes less important just as we should expect. It is to be hoped that a method of calculating the repulsive potential may soon be developed, in order that a more adequate comparison with experiment may be made.

THE SCATTERING OF UNPOLARIZED X-RAYS

BY G. E. M. JAUNCEY AND G. G. HARVEY
DEPARTMENT OF PHYSICS, WASHINGTON UNIVERSITY

(Received February 4, 1931)

ABSTRACT

Unpolarized x-rays from an x-ray tube excited at 90 to 125 kv and filtered through aluminum and copper were scattered by paraffin at angles of 75° , $97^\circ 30'$ and 120° . The intensity of the scattered rays was measured by the ionization produced in a chamber containing air saturated with (1) methyl iodide (2) ethyl bromide. It was found very necessary to keep the temperature of the ionization chamber and the voltage on the x-ray tube constant during an experiment. The results are expressed by the ratios of the ionization currents produced at scattering angles of $97^\circ 30'$ and 120° respectively to the current produced at an angle of 75° . The wave-lengths present in the primary x-rays were determined by measuring the absorption of x-rays in a series of thicknesses of aluminum, the x-rays entering the same ionization chamber as that which was used in the scattering experiment. The absorption curve so obtained was found to consist of two exponential curves which correspond to two wave-lengths, the intensity of the shorter wave-length being much greater than that of the longer. With these wave-lengths and their relative intensities and taking account of the change of absorption in the ionization chamber due to the Compton change of wave-length the theoretical values for the above ratios were calculated by use of (1) the Dirac scattering formula and (2) the Compton formula. The agreement between the ratios calculated from the Dirac formula and the experimental ratios was excellent. The wave-lengths when methyl iodide was in the chamber were 0.205A and 0.39A and when ethyl bromide was in the chamber were 0.26A and 0.47A. At these wave-lengths the difference between the Dirac and the Klein and Nishina formulas is so small that experimental discrimination between them was not possible.

1. INTRODUCTION

IN 1923, A. H. Compton¹ and Jauncey² developed theoretical formulas for the spatial distribution of the intensity of scattered x-rays. The two formulas differ only in the higher powers of α , which is defined by

$$\alpha = h/mc\lambda \quad (1)$$

where λ is the wave-length of the primary x-rays and h , m and c have their usual significance. It is only in the region of γ -rays that the two formulas differ, and as this paper has to do only with the scattering of x-rays and not γ -rays, we shall use the Compton formula as also representing Jauncey's formula with sufficient exactness. According to Compton,¹ the scattering coefficient per unit solid angle in a direction ϕ with the direction of propagation of the primary x-rays is

$$s_\phi = \frac{NZpe^4}{Wm^2c^4} \frac{1 + \cos^2 \phi + 2\alpha(1 + \alpha) \text{vers}^2 \phi}{(1 + \alpha \text{vers} \phi)^5} \quad (2)$$

¹ A. H. Compton, Phys. Rev. 21, 491 (1923).

² G. E. M. Jauncey, Phys. Rev. 22, 233 (1923).

where N is Avogadro's number, Z the number of electrons in a molecule of the scattering substance, ρ its density, W its molecular weight and ϕ the angle of scattering. Eq. (2) is Compton's formula for the scattering of unpolarized x-rays. The minimum value of s_ϕ occurs when $ds_\phi/d\phi = 0$, that is, when

$$\cos \phi = -\alpha/2 \quad (3)$$

approximately, the square and higher powers of α being neglected.

In the Thomson³ theory of the scattering of x-rays, the minimum occurs at $\cos \phi = 0$, or at $\phi = 90^\circ$. In the case of x-rays for which $\alpha = 0.1$, the minimum according to Eq. (3) occurs at $\phi = 92^\circ 53'$, which is distinctly different from the position of the minimum on the Thomson theory.

Breit⁴ attacked the problem of the theoretical formula for the scattering of x-rays from the point of view of the correspondence principle and obtained a formula differing from Eq. (2). Later Dirac,⁵ using the principles of quantum mechanics, obtained a formula identical with that of Breit. The Dirac formula is

$$s_\phi = \frac{NZ\rho e^4}{Wm^2c^4} \cdot \frac{1 + \cos^2 \phi}{(1 + a \text{vers } \phi)^3} \quad (4)$$

According to Eq. (4), s_ϕ has a minimum at

$$\cos \phi = -3\alpha/2 \quad (5)$$

approximately, so that for $\alpha = 0.1$, the minimum occurs at $98^\circ 36'$. The minimum according to Dirac therefore occurs at an angle of $5^\circ 43'$ greater than according to Compton and Jauncey.

Recently, Klein and Nishina⁶ have derived a formula on the basis of the quantum mechanics which is somewhat different from Dirac's formula. The Klein and Nishina formula is obtained from the Dirac formula by multiplying the right side of Eq. (4) by the factor

$$k = 1 + \frac{\alpha^2 \text{vers}^2 \phi}{(1 + \cos^2 \phi)(1 + \alpha \text{vers } \phi)} \quad (6)$$

This factor has no effect on Eq. (5) as far as the first power of α is concerned.

In 1924 Jauncey⁷ derived a formula for the scattering of polarized x-rays. For scattering in the plane of the electric vector, the position of the minimum is given by

$$\cos \phi = \alpha \quad (7)$$

approximately, so that for $\alpha = 0.1$ the minimum occurs at $84^\circ 15'$. The formulas of Breit, Dirac and Klein and Nishina all agree in giving the minimum at $\phi = 90^\circ$, which is in accord with the Thomson classical theory.

⁶ Klein and Nishina, *Zeits. f. Physik* **52**, 853 (1929).

⁷ G. E. M. Jauncey, *Phys. Rev.* **23**, 313 (1924).

In an early experiment by Jauncey and Stauss⁸ on the scattering of polarized x-rays, the experimental position of the minimum appeared to agree with Eq. (7). This experiment was repeated by Barrett and Beardon,⁹ who found that the minimum occurred at angles somewhat greater than 90° and within experimental error of 90° . Another repetition was made by Jauncey and Hassler,¹⁰ who found the minimum to be at an angle slightly greater than 90° . The results of these experiments are uncertain due to (1) the difficulty of measuring the exact position of a minimum, (2) the lack of complete polarization, (3) the wide slits which are necessary in order to obtain sufficient intensity, (4) the uncertainty of the wave-length used, and (5) multiple scattering. The wide slits have the effect of flattening the minimum, and on that account making the position of the minimum still more difficult to determine. Referring to Eqs. (3) and (7), it is seen that the Compton-Jauncey formula gives the minimum for unpolarized x-rays at an angle greater than 90° , while their formula gives the minimum for polarized x-rays at an angle less than 90° . It is possible therefore with partially polarized x-rays to obtain a minimum at 90° on the Compton-Jauncey theory. Complete polarization can only be obtained by scattering at 90° or nearly 90° from a slab of some material such as paraffin, when the slab is very thin. Since, in experiments on polarized x-rays, the x-rays are scattered twice, the intensity of the doubly scattered x-rays is quite small unless both slabs of the scattering material are fairly thick. However, multiple scattering increases as the thickness of each slab increases. This multiple scattering increases the lack of complete polarization.

Due to the above objections, the present writers have made the test on unpolarized x-rays and have abandoned the attempt to determine experimentally the position of the minimum. Instead the writers have attempted to measure the relative scattering at the three angles 75° , 97.5° and 120° as accurately as possible and to compare the experimental values with the values predicted by the various theories. It should be mentioned that in 1922 Hewlett¹¹ published scattering curves for certain organic liquids and that these curves show minima at about 100° to 105° . As we shall show in the present paper, it is very necessary to take account of the Compton change of wave-length in regard to its effect on the ionization produced in the ionization chamber, and this Hewlett did not do, since his paper was published before the discovery of the Compton effect.

2. EXPERIMENTAL PROCEDURE

X-rays from the tube *A*, Fig. 1, after leaving the target almost tangentially and passing through a slit system, fall upon the paraffin slab *B*. Part of the x-rays are scattered by the slab *B* into the ionization chamber *D* and part penetrate through the slab *B* and then fall upon a paraffin slab *C*. Part

¹¹ C. W. Hewlett, *Phys. Rev.* 20, 688 (1922).

of the rays falling on slab *C* are scattered into the ionization chamber *E*. The slab *B* is mounted on the axis of an x-ray spectrometer and the ionization chamber *D* can be rotated about this axis. The angle which the slab *C* makes with the primary beam and the position of the chamber *E* remains fixed throughout the experiment. The width of the beam of x-rays entering the chamber *E* is controlled by the adjustable slit *S*. The outer electrodes of *D* and *E* are connected to +100 and -100 volts respectively. The inner electrodes are connected together and to the electrometer as shown in Fig. 1. Doubling and halving the voltages on the chambers *E* and *D* had no effect on the observed ionization currents, so that the voltages on the two chambers were always above the voltages necessary for saturation. The chamber *D* was first filled with air saturated with methyl iodide vapor. Later *D* was filled with air saturated with ethyl bromide vapor. A reservoir containing either liquid methyl iodide or ethyl bromide was permanently connected to *D*. The chamber *E* was filled with air alone. In order that the primary x-rays should be in effect completely unpolarized, the axis of the x-ray tube made an angle of 45° with the plane of scattering.

Fig. 1. Diagram of apparatus.

The angular scale of the spectrometer was graduated in quarter degrees so that settings of the ionization chamber could be made with an accuracy of 5 minutes of arc. A pin was mounted on the axis of the spectrometer and it was arranged that, when the primary beam of x-rays was observed by a fluoroscope, the shadow of the pin was in the center of the fluorescence produced by the beam. The target of the tube was turned so that the primary x-rays left the target nearly tangentially, the plane of the target being vertical. Under these conditions it was noted that the edge of the fluorescent image of the slit system as observed in the fluoroscope was sharp on one side but was somewhat indefinite on the other. Consequently we could not be certain that the axis of the spectrometer passed through the "center of gravity" of the primary beam. We therefore took readings for a given scattering angle with the chamber *D* set first on one side of the primary beam and then on the other. Also with a given setting of the ionization chamber we took one set of readings with the paraffin slab *B* in the Crowther¹² position and

¹² J. A. Crowther, Proc. Roy. Soc. A86, 478 (1912).

a second set with the slab B turned through 180° , so that it was again in the Crowther position but with the opposite side presented to the primary beam. For each angle of scattering there were thus two settings of the ionization chamber and four settings of the paraffin slab. In this way, any asymmetry of the primary beam with respect to the spectrometer was corrected.

The primary voltage of the x-ray transformer was supplied by two motor generator sets. The first set consisted of an a.c. motor and d.c. generator operated by Washington University power. By means of a voltage regulator connected to the field coils of the d.c. generator a constant d.c. voltage was obtained, irrespective of variations in the a.c. voltage driving the a.c. motor. This constant d.c. voltage was applied to the d.c. motor of the second set, so that the a.c. generator of the second set gave a constant a.c. voltage. This constant a.c. voltage was applied to the primary of the x-ray transformer. Full wave rectification of the high voltage was obtained by a system of four kenotrons. Care was taken to have the filaments of the kenotrons at a temperature such that the fall of voltage across the kenotrons was too small to produce any detectable x-rays. This was necessary because irregular results were first obtained due to stray x-rays from the kenotrons. In spite of the two motor generator sets, there were occasional variations of the primary voltage across the x-ray transformer and of the milliamperes through the x-ray tube. Accordingly, we placed a choke coil in the primary circuit of the x-ray transformer. By adjustment of the length of the iron core within the coil, any variation of the voltage could be annulled. The tube was operated at maximum voltages between 90 and 125 kilovolts and a current of 7 milliamperes. The voltages were measured by the spark length between spheres of 10 cm radius. The target was of tungsten and was not water-cooled. The corona discharge from the leads to the x-ray tube was reduced by making these leads of $\frac{3}{4}$ inch flexible piping. The x-rays were made more homogeneous by passing them through a filter F of aluminum or copper.

The intensity of the rays scattered by the slab B into the chamber D was compared with the intensity of the rays penetrating the slab B and entering the chamber E . By means of lead shutters, the rays were first allowed to enter D but not E and then were allowed to enter E but not D . Readings of the scattered and primary rays were thus taken alternately. The time for a deflection over a given part of the scale was measured. Due to the fact that the voltages across the chambers D and E were in opposite directions, it was not necessary to ground the electrometer during a set of readings. With a given setting of the chamber, 5 readings on the scattered rays and 5 readings on the primary rays were taken. The slab B was then turned through 180° and the procedure repeated. This was done with a slab of given thickness and with a given voltage on the x-ray tube for the chamber angles of 120° , 97.5° , and 75° on the right side of the spectrometer and 75° , 97.5° and 120° on the left side. Thus a total of 60 readings on the scattered rays and 60 on the primary rays were taken, making a total of 120 readings. In an effort to correct for multiple scattering, we then substituted a slab of different thickness and took 120 more readings. The whole of the 240 readings were taken without

interruption. Since the effect of change of temperature on the ionization produced in the saturated methyl iodide or ethyl bromide vapor is quite considerable, we kept the temperature of the room constant during the whole period of the 240 readings. Also, during the same period, the voltage across the x-ray tube and the current through the tube were kept constant.

Readings of the ionization in chamber *D* were also taken with the slab *B* removed so as to obtain any effect due to stray rays. Although this effect was small, it was not negligible. The effect was different for different settings of

Fig. 2. Absorption in aluminum. Methyl iodide, 90 kv.

the chamber *D*. For a given chamber angle on one side of the spectrometer and a given thickness of paraffin, the average of the readings for the scattered rays was determined. This average was corrected for the stray rays. The average for the primary rays was also determined. The ratio of this corrected average for the scattered rays to the average for the primary rays is determined for a given scattering angle on each side of the spectrometer. The average of the ratios for the two sides is then determined. These are the values shown in Tables I and II.

The linear width of the primary beam when crossing over the axis of the spectrometer was measured with the aid of the fluoroscope and was found to

be 4 mm. Since the distance of the axis to the target of the x-ray tube is 80 cm, the angular width of the primary beam is $17'$. The distance from the axis to the window of the ionization chamber D is 15 cm. This window is 1 cm wide. The angle of scattering when the chamber D is set at a given angle therefore has a range of $5^\circ 32'$. The angular height of the primary beam is $1^\circ 23'$, while the angular height of the scattered rays is $11^\circ 24'$. Calculation showed that the angular range of the scattering angle from a thin slab due to the height of the slits was about $30'$ at each of the angles 75° 97° $30'$ and 120° .

Fig. 3. Absorption in aluminum. Methyl iodide, 125 kv.

The inner electrode of the ionization chamber was placed so that no scattered rays from the slab could strike it. The diameter of the chamber was such that the rays did not strike the sides. The length of the ionization chamber was 43.5 cm.

After completing a run of 240 readings on the scattered rays and measuring the effect of the stray rays, the hardness of the primary rays was measured by placing the chamber D so as to receive the primary rays. In order to cut down the intensity the rays were passed through a pinhole in a sheet of lead. Different thickness of aluminum were placed in the primary. For each thickness several readings alternately with and without aluminum were taken.

The proportion of the rays penetrating each thickness are shown by the black circles in Figs. 2, 3 and 4. The absorption curve was obtained for the same voltage across the x-ray tube and with the chamber *D* at the same temperature as when the scattered rays were being measured.

Fig. 4. Absorption in aluminum. Ethyl bromide, 95 kv.

3. EXPERIMENTAL RESULTS

The experiment was first performed with the chamber filled with air saturated with methyl iodide vapor at a temperature of 17°C. The results are shown in Table I. Paraffin slabs of mass per unit area 0.365 gm/cm² and

TABLE I. *Scattering from paraffin. Methyl iodide in ionization chamber.*

Angle	Potential = 90 kv Mass/Area = 0.365	Scattering ratios		
		90kv 0.595	125kv 0.365	125kv 0.595
75°	0.531	0.837	0.477	0.760
97° 30'	0.573	0.926	0.550	0.804
120°	0.864	1.414	0.823	1.265

0.595 gm/cm² were used. The values under 125 kv are not comparable with the values under 90 kv. The 90 kv rays were filtered through 2.92 mm and the 125 kv rays were filtered through 7.22 mm of aluminum. The results of the absorption measurements for the 90 kv rays and the 125 kv rays are represented by the black circles in Figs. 2 and 3 respectively.

Later the experiment was performed with ethyl bromide in the chamber and the results shown in Table II were obtained. In this case the rays were

filtered through 0.1 mm of copper and 2.0 mm of aluminum. The temperature was maintained at 24.0°C.

The results of the absorption measurements with ethyl bromide in the chamber are represented by the black circles in Fig. 4.

4. COMPARISONS WITH THEORY

In order to compare the experimental results with theory it is necessary to obtain the wave-length of the primary rays. Since we used rays of the continuous spectrum filtered through aluminum or aluminum and copper, the rays were only approximately monochromatic.

Smooth curves (not the curves shown) were drawn through the experimental points shown in Figs. 2, 3, and 4. From the smooth curve in a given case values of I_t/I_0 were read off at each successive thickness of 1 mm of aluminum. It was found that after a thickness of about 4 mm the curve was almost exactly exponential. This exponential portion was produced back to zero thickness. Differences were then obtained between this exponential curve and the experimental curve for thicknesses less than 4 mm. It was found that these differences when plotted against thickness gave a fairly exponential curve. Thus the experimental curve appeared to be made up of two exponential portions. The solid curves shown in Figs. 2, 3 and 4 are curves calculated from the formula

$$I_t/I_0 = i_1 e^{-\mu_1 t} + i_2 e^{-\mu_2 t}. \quad (8)$$

The values of i_1 , i_2 , μ_1 and μ_2 are shown in Table III.

TABLE III.

kv	Vapor in D	i_1	μ_1 cm ⁻¹	i_2	μ_2 cm ⁻¹	λ_1 Å	λ_2 Å	I_1	I_2
90	methyl iodide	0.67	0.74	0.33	2.7	0.205	0.39	0.68	0.32
125	methyl iodide	0.815	0.74	0.185	2.7	0.205	0.39	0.82	0.18
95	ethyl iodide	0.806	1.03	.194	4.15	0.26	0.47	0.91	0.09

In Table III, μ_1 and μ_2 are the linear absorption coefficients in aluminum. From these the mass absorption coefficients can be found and the wave-lengths λ_1 and λ_2 can be determined from Compton's table of absorption

coefficients.¹³ Now i_1 and i_2 are the proportions of the two wave-lengths present as measured by the ionization produced in the chamber. These are not the proportions present in the primary x-rays. At first, we thought to obtain the proportions present in the primary rays by dividing by the amount of each wave-length absorbed in the gas in the chamber. These proportions are shown in the columns headed I_1 and I_2 . However, the energy of the x-rays which are absorbed in methyl iodide does not all give rise to ionization. By far the greater part of the energy goes into iodine K -radiation, and somewhere about 80 to 90 percent of this K -radiation leaves the chamber without producing ionization. According to Compton,¹⁴ the fluorescent yield is independent of the wave-length, so long as it is short enough to excite the fluorescent radiation. Thus the same proportion of the absorbed energy goes into producing ionization in the chamber D for all wave-lengths shorter than 0.375A, the K critical absorption wave-length for iodine. Let m_1 and m_2 be the respective mass absorption coefficients of the wave-lengths λ_1 and λ_2 in the gas of the chamber D . The saturated vapor pressure for methyl iodide at 17°C is 293 mm¹⁵, from which the density of the iodine in the methyl iodide is 0.00206 gm/cm³. The values of m_1 and m_2 for iodine can be obtained from Compton's table of mass absorption coefficients by interpolation and the fraction of the radiation of each wave-length absorbed in the ionization chamber D can be calculated. Let the fractions be represented by k_1 and k_2 for the wave-lengths λ_1 and λ_2 respectively. Of the fractions k_1 and k_2 , the fractions p_1 and p_2 respectively appear as ionization. In the case of methyl iodide p_1 and p_2 differ because λ_1 is shorter and λ_2 is longer than the K critical absorption wave-length of iodine. Hence the relative energies in the wave-lengths λ_1 and λ_2 as they enter the chamber D , but not as they are absorbed in the chamber, are i_1/p_1k_1 and i_2/p_2k_2 . These are taken as representing the energies of λ_1 and λ_2 in the primary beam.

Now let us consider the scattering experiment. The scattered intensity I_ϕ when the slab B is in the Crowther position is

$$\frac{I_\phi}{I} = \frac{As_\phi t \sec(\phi/2)}{R^2} \quad (8)$$

where I is the intensity of the rays penetrating the slab B and entering the chamber E . This intensity is proportional to the ionization in E , so long as the temperature of the room and the voltage across the x-ray tube is kept constant. s_ϕ in Eq. (8) is the scattering coefficient, t is the thickness of the slab, A the area of the window of chamber D , R the distance of the window from the spectrometer window and ϕ the scattering angle.

Let primed quantities (') represent values at ϕ' and doubly primed quantities (') represent values at ϕ'' . Then, since the same slab of thickness t is used at both angles, we have from (8)

$$J''/J' = (s''/s') \cdot (\sec \frac{1}{2}\phi'')/(\sec \frac{1}{2}\phi') \quad (9)$$

where $J = I_\phi/I$.

¹³ A. H. Compton, X-Rays and Electrons. p. 184.

¹⁴ A. H. Compton, Phil. Mag. 8, 961 (1929).

¹⁵ Int. Crit. Tables. III p. 216.

With Eqs. (2), (4) and (6), the various theoretical values of J''/J' for a given wave-length can be found. However, the ratio of the ionization currents produced in chamber D is not J''/J' because of the Compton change of wave-length

$$\delta\lambda = (h/mc) \text{ vers } \phi.$$

Due to this change of wave-length the proportion of the scattered rays of primary wave-length λ_1 which is absorbed in chamber D is different for the scattered rays from the proportion of the primary rays of the wave-length λ_1 absorbed in D in the absorption experiment. The absorbed scattered rays are proportional to $i_1 k_1' / p_1 k_1$ where k_1' is the value of k_1 for the scattered rays. The ionization produced is proportional to $i_1 p_1' k_1' / p_1 k_1$, where p_1' is the value of p_1 for the scattered rays. However, according to Compton,¹⁴ $p_1' = p_1$, so long as the Compton change of wave-length does not cross a critical absorption wave-length. Hence the ionization produced is proportional to $i_1 k_1' / k_1$. The values of i_1/k_1 and i_2/k_2 are shown in the columns respectively headed I_1 and I_2 in Table III.

If we have two wave-lengths, and if the J 's of Eq. (9) are to represent ionization currents in chamber D , we have

$$\frac{J''}{J'} = \frac{(i_1 k_1'' / k_1) s_1'' + (i_2 k_2'' / k_2) s_2'' \sec(\frac{1}{2}\phi'')}{(i_1 k_1' / k_1) s_1' + (i_2 k_2' / k_2) s_2' \sec(\frac{1}{2}\phi')}.$$

The values of J''/J' where $\phi' = 75^\circ$ and $\phi'' = 97^\circ 30'$ or 120° are shown for the various theoretical formula for s_ϕ in Table IV. The experimental values of J''/J' when methyl iodide is in the chamber D are also shown in Table IV.

TABLE IV. *Experimental and theoretical values of J''/J' . Methyl iodide in ionization chamber.*

		A	B	Mean			A	B	Mean		
75°	97.5°	1.079	1.107	1.093	1.098	1.170	1.152	1.059	1.106	1.103	1.174
75°	120°	1.627	1.690	1.659	1.738	1.898	1.725	1.663	1.694	1.740	1.905

Those values shown under A are for the paraffin slab whose mass per unit area is 0.365 gm/cm^2 and those under B for the slab whose mass per unit area is 0.595 gm/cm^2 .

During the progress of this research, a paper by DuMond¹⁵ on multiple scattering has appeared. In this paper, DuMond discusses the problem of double scattering from a sphere, and obtains a formula for the ratio of the intensity of doubly scattered rays to that of singly scattered rays. The formula contains a function of ϕ , the scattering angle, but this function is very nearly constant in the range $\phi = 75^\circ$ to 120° . We have been unable to find any certain direction in which J''/J' changes with the thickness of the

¹⁵ J. W. M. DuMond, Phys. Rev. **36**, 1685 (1930).

slab in our experiments, and this is, we believe, in agreement with DuMond's theoretical finding that the ratio of double to single scattering does not vary with the angle in the range considered. Instead, therefore, of extrapolating the values of J''/J' to zero thickness, we have merely taken the mean values as shown in Table IV.

In calculating the theoretical values, the range of scattering angles at a given setting of the ionization chamber has been neglected and the calculation been made on the assumption that the scattering angle is the angle at which the ionization chamber is set. This is allowed because the correction due to the range of the scattering angle is small since the range of $5^\circ 32'$ due to the width of the slits plus $30'$ due to the height of the slits only makes a difference in the third decimal place in the theoretical values of J''/J' in Tables IV and V. Further, in calculating the theoretical values it has been assumed that none of the scattered rays at the angles used are of the unmodified type. Compton¹⁷ writes Wentzel's formula¹⁸ for the intensity of the unmodified rays in the form

$$I_{unm} = I_e n^2 \left\{ \int u(r) \frac{\sin kr}{kr} dr \right\}^2 \quad (10)$$

where $k = (4\pi/\lambda) \sin(\phi/2)$ and $u(r)dr$ is the probability that an electron is at a distance r to $r+dr$ from the center of an atom, n is the number of electrons in an atom of the scatterer and I_e is the Thomson value of the scattering from a single electron. In the case of helium, Pauling¹⁹ gives the probability for each of the two electrons as

$$u(r) = 4r^2 \left(\frac{Z-s}{a} \right)^3 \exp \{ - (Z-s)r/a \} \quad (11)$$

where Z is the atomic number of helium, a is the radius of the normal orbit in the hydrogen atom on the Bohr theory and s is the screening constant. We have applied this formula for $u(r)$ to the case of the K electrons of carbon, putting $Z=6$, $s=0.39$ and $a=0.53\text{\AA}$ in Eq. (11) and $n=2$ in Eq. (10). Performing the integration in Eq. (10), we obtain

$$I_{unm} = 4I_e / (1 + .022x^2) \quad (12)$$

where $x = (4/\lambda) \sin(\phi/2)$. For $\lambda=0.26\text{\AA}$ and $\phi=75^\circ$, I_{unm} from each carbon atom in paraffin is $0.065 I_e$. The average chemical formula for paraffin is $\text{C}_{24}\text{H}_{50}$. The L electrons of C and the electrons of H do not scatter unmodified rays at $\phi=75^\circ$, so that the ratio of unmodified rays scattered by paraffin to the total scattering at $\phi=75^\circ$ is 0.7 percent. We are therefore justified in neglecting the unmodified rays in our calculated values of J''/J' .

In Table III it will be noted that λ_2 for the absorption curves when methyl iodide is just on the long wave-length side of 0.375\AA , the critical ab-

sorption wave-length for iodine. We accordingly felt rather doubtful of the reality of this wave-length. For this reason we replaced the methyl iodide with ethyl bromide. The temperature when ethyl bromide was used in the ionization chamber was 24.5°C. At this temperature the density of the bromine in saturated ethyl bromide is 0.00197 gm/cm³. The primary x-rays were filtered through copper as well as aluminum in an attempt to increase the homogeneity of the rays. The absorption measurements are shown by the black circles in Fig. 4. The absorption measurements were carried to a much greater thickness of aluminum than in the case where methyl iodide was in the chamber. This was done in order to obtain the wave-lengths as accurately as possible. The solid curve of the Fig. 4 is constructed with the use of the data shown in Table III. Again as in the case of methyl iodide we have two wave-lengths, but both are on the short wave-length side of the absorption edge from bromine. The experimental and theoretical values of J''/J' are shown in Table V.

TABLE V. *Experimental and theoretical values of J''/J' . Ethyl bromide in ionization chamber. Potential 95 kv.*

75°	120°	1.755	1.795	1.775	1.740	1.755	1.89	1.860

5. DISCUSSION

The agreement of the experimental values of J''/J' with the Dirac or Klein and Nishina values as shown in Table V is excellent. At the wave-lengths used the Dirac or Klein and Nishina Formula is a much better description of the experimental facts than the Compton or Thomson Formula. The agreement of the experimental values of J''/J' with the Dirac values as shown in Table IV is also good for the 90 kv x-rays. The agreement for the 125 kv x-rays, however, is not so good although the agreement of the mean values with the Dirac values is good. The corona discharge when the x-ray tube was excited with 125 kv was considerable and this seemed to introduce irregularities into the electrometer readings. This difference between the *A* and *B* values for $\phi''=97^\circ 30'$ is due to the irregularities.

In calculating the theoretical values of J''/J' , two wave-lengths have been used. In the case of ethyl bromide, the longer wave-length was 0.47Å. This wave-length is perhaps somewhat fictitious and we feel that the reality of the wave-length 0.26Å is greater because by far the larger part of the absorption curve in Fig. 4 is due to this wave-length. If it is supposed that only this wave-length is present in the primary rays, the Dirac values in Table V become 1.098 and 1.753 for $\phi''=97^\circ 30'$ and 120° respectively, while the Klein and Nishina values become 1.103 and 1.771. Also it might be objected that even the wave-length 0.26Å is an average wave-length. We have therefore calculated the Dirac values in the case of ethyl bromide for $\lambda=0.22$,

0.24, 0.28, 0.30Å in addition to 0.26Å. The values of J''/J' vary from 1.098 to 1.108 at $\phi''=97^\circ 30'$ and from 1.73 to 1.76 at $\phi''=120^\circ$. The Dirac theoretical values of J''/J' are therefore practically constant for a wave-length range of 0.08Å about 0.26Å. The Compton values are also practically constant over the same range. This is our justification for using the average wave-length 0.26Å in the calculation of the theoretical values.

If the effect of the Compton change of wave-length on the ionization produced in the chamber is neglected, the Dirac theoretical values of J''/J' for 0.26Å become 1.035 at $\phi''=97^\circ 30'$ and 1.540 at $\phi''=120^\circ$ in total disagreement with the experimental values. The ionization produced by the photoelectrons ejected from the brass wall at the end of the chamber and the aluminum window were neglected because with the length of chamber used this ionization is only a small fraction of the total ionization in the chamber. The aluminum window was 0.005 cm thick and the absorption in it was neglected.

We observed a rather curious effect during these experiments. The hardness of x-rays as determined by absorption in aluminum depends upon (a) the angle at which the rays leave the target of the x-ray tube (b) the nature of the gas in the ionization chamber, and (c) the temperature of the chamber if saturated vapor is used in the chamber. The length of the ionization chamber is such that the x-rays are incompletely absorbed. It is quite possible to apply a higher voltage to an x-ray tube and yet obtain less penetrating x-rays.

For the wave-lengths used in this research it is not possible to discriminate between the Dirac and the Klein and Nishina formulas. Recently, Chao²⁰ using γ -rays of wave-length 0.0052Å has shown that the Klein and Nishina Formula fits the experimental facts much better than the Dirac Formula. This research was assisted by a grant from the Science Research Fund of Washington University.

APPEARANCE OF EXTRA LINES IN X-RAY DIFFRACTION
PATTERNS OF MIXTURES AND ABSENCE OF SOME
LINES PECULIAR TO THE COMPONENTS OF
THE MIXTURES

BY ROY W. DRIER

DEPARTMENT OF METALLURGY
MICHIGAN COLLEGE OF MINING AND TECHNOLOGY
HOUGHTON, MICHIGAN

(Received February 2, 1931)

ABSTRACT

Abnormalities in x-ray spectra of mechanical mixtures of minerals are described. The spectra of some show the presence of extra lines, and in the spectra of others some lines peculiar to the components are missing. Some possible reasons are briefly considered.

THE x-ray, useful in the solution of many problems, has revealed the existence of others. Among these are the appearance in x-ray diffraction patterns of mechanical mixtures, of lines not peculiar to either of the components of the mixtures, and the disappearance, in the spectra of the mixtures, of some of the lines peculiar to the components.

It is not the purpose of this paper to offer any definite explanation of these phenomena of the disappearance of spectral lines and the appearance of new lines but rather to record them and to mention a few possible reasons for them.

The diffraction patterns are composed of spectral lines produced in Debye-Scherrer or Hull type cameras. These lines are indicative of interplanar spacings in the crystal structure.

These effects were first noticed by the writer while he was working with Dr. G. L. Clark, of the Department of Chemistry, of the University of Illinois. The mixture which drew attention to this phenomenon was one of rutile (TiO_2) and barite (BaSO_4).

The two minerals, rutile and barite, were rayed separately for their diffraction patterns. Mixtures of the two were made, and diffraction patterns of the mixtures were then obtained. These were simple mechanical mixtures, mixed on glazed mixing paper and placed in capillary tubes for raying. No heat or pressure entered into the process of sample preparation.

The apparatus used was a G. E. diffraction unit. It supplied 30,000 volts R.M.S. to a molybdenum target, water-cooled Coolidge tube operating at 20 m.a. The films were held in a cassette in the form of an arc 8 inches in radius. The samples (-200 mesh) were contained in small, capillary, Pyrex glass tubes about 2 inches long and approximately 0.03 inches in internal diameter. This tube is held in the center of the circle of which the film mentioned above is an arc. By means of a ZrO_2 filter placed in the cassette between the sample and the film, practically all but the $\text{MoK}\alpha$ radiation is filtered out, the film registering this monochromatic beam only.

A comparison of the spectra of the components and of the mixture revealed that some of the lines peculiar to the constituents were missing in the mixture pattern and that some of the mixture lines were not included in the spectra of the constituents.

Several series of mixtures were then made up and rayed, for the purpose of investigating this "extra line" phenomenon. The mixtures were Cu-Zn, Cu-Ag, Cu-NaCl, and Cu-Ni. Each series was composed of members whose proportions varied from 0% A-100% B to 100% A and 0% B. The Cu-Zn series had the following mixtures: 100% Cu-0% Zn, 95% Cu-5% Zn, 75% Cu-25% Zn, 50% Cu-50% Zn, 25% Cu-75% Zn, 5% Cu-95% Zn, and 100% Zn. This series was proportioned according to weight, but the rest of the mixtures were proportioned according to volume, which was approximated by eye. Although a more accurate method of proportioning and making the mixtures could have been followed, it was felt that each series would yield samples which would vary approximately as desired.

The Cu-Zn series was the most outstanding of the five. A few of the lines appearing in the Cu did not appear in the mixtures, and several of the lines of the zinc patterns were not a part of the composite spectrum. In each of the mixture-spectra there were found eight distinct lines which occurred in neither the Cu nor the Zn spectrum.

The extra lines in the Cu-Zn series agreed fairly well with the spectrum of alpha-brass, a fact which seems to indicate the occurrence of interfacial diffusion. In an attempt to reproduce this reaction, a sheet of zinc was ground to a knife edge. This knife edge was pressed into -100 mesh copper filings and held there for 24 hours. It was then removed; the copper filings were brushed off, and the knife edge was placed in an x-ray beam. The resulting spectrum contained only the lines which were in the spectrum of an untreated piece of the same zinc. If interfacial diffusion occurred in the powder mixture, it was probably due to a catalytic action, possibly of the x-rays themselves.

Spectra of pure Ag and pure Cu and of a 50-50 mixture showed no new spectral lines in the mixture, but did show that the (100) 4 copper line was missing in the mixture and that there was a slight gradual shift to the right (i.e., shortening) in the mixture as compared to the copper. Some slight traces of impurities were indicated in the spectra of the Ag and Cu.

The Cu-Al series seemed to be regular; there were neither extra lines nor any lines missing. In the mixtures which had a low aluminum content many of the Al lines were faint and some had disappeared, but such a disappearance is to be expected of reflections from an element of comparatively low atomic number. E. C. Bain¹ noticed the appearance of extra lines in mixtures of Cu and Au heated to the sintering point. His spectrogram of the mixture before heating indicated merely the composite spectrum of Au and Cu. The writer is inclined toward the opinion that when the mixture was heated to the sintering temperature some such sort of reaction as diffusion or solid solution took

¹ E. C. Bain, *Chem. Met. Eng.* 28, 2 (1923).

place which would account for the new lines. Davidson and Aborn,² in their research on the structure of ZnO and CuO catalysts, carried on at 360°C, noticed "extra lines." It might be that the temperature obtaining during the experimentation was near enough to the melting point of zinc to make possible the occurrence of a reaction between the ZnO and the CuO, or it might be that the oxides were reduced and formed conditions which permitted the reaction to take place. Davidson and Aborn favor this latter possibility, especially since the extra lines seemed to agree fairly well with the spectrum for gamma brass.

There is a possibility, too, that if reduction did occur, the tendency for zinc to become brittle between 200°C and 300°C, indicating a possible change in atomic arrangement, might account for their extra lines. In working with mixtures of ZnO and Cr₂O₃, G. R. Griffin,³ noticed in the mixture-spectra the disappearance of some lines peculiar to the components. Tamman,⁴ has predicted the appearance of "overstructure lines." Hull,⁵ while interpreting the spectra of a number of minerals, noticed the absence of some of the spectral lines which theoretically should have been present.

For these phenomena there are several possible causes. It is conceivable that the extra lines are due to a secondary reflection; this hypothesis, however, is not in accord with the fact that some of the extra lines are those of a solid solution or other phases of the system. The appearance of new lines might be explained by interfacial diffusion. But the disappearance of regular lines could not be so effected. A possible explanation of such disappearance is interference. Research on this problem is being continued in an attempt to determine the cause or causes of the phenomena.

THE DEPENDENCE OF X-RAY ABSORPTION SPECTRA
UPON CHEMICAL AND PHYSICAL STATE

BY J. D. HANAWALT*

UNIVERSITY OF MICHIGAN

(Received January 30, 1931)

ABSTRACT

The x-ray absorption spectra of As, Se, Br, Zn, Hg, Xe, and Kr, and of compounds of some of these elements have been photographed for both the solid and the vapor states at a dispersion of about 5 X.U. per mm. The effect of the chemical and physical state of the absorbing atom upon the secondary structure which lies to the short wave-length side of the main absorption edge was investigated. It was found that: (1). The monatomic vapors Zn, Hg, Xe, and Kr exhibit no secondary structure at distance from the main edge greater than the ionization potential of the atom. (2). Polyatomic vapors usually, though not necessarily, have a secondary structure similar to that which is exhibited by the same molecule in the solid state. (3). For a polyatomic molecule in the solid state there is often an additional structure observed which is absent when the molecule is in the vapor state. (4). There is an additional structure in the secondary absorption of solid NaBrO_3 which is not observed in a solution of NaBrO_3 . (5). Completed electron shells of atoms in the solid state do not necessarily mean the absence of secondary absorption edges as has been suggested. In order to account for this dependence of secondary absorption on molecular and physical state it is suggested that perhaps the secondary discontinuities correspond to the excitation energies of the structure electrons postulated by O. W. Richardson.

INTRODUCTION

A STUDY of the x-ray absorption spectrum of a substance shows that there are sharp discontinuities in the absorption at wave-lengths corresponding to the energies of the Bohr levels of the atom. These absorption discontinuities do not always have the same appearance for different elements. The absorption edge may be what is known as "simple," or there may be some absorption discontinuities of lesser magnitude associated with the principal absorption edge. Fig. 2 (a) and (b) illustrate respectively a simple edge and one with secondary absorption. This secondary absorption falls to the short wave-length side of the main edge and therefore means the absorption of quanta of greater energy than that which produces the main edge. In some cases the difference in energy between a secondary discontinuity and the main edge may be more than 300 volt electrons. Experiments show that the wave-length of the main edge and the type of the absorption are functions of the chemical state of the absorbing atom. Experiments also show that the chemical state of an atom affects the emission spectrum of the atom. These latter experiments are complicated by the fact that one can not be sure of the chemical state of atoms on the anode of an x-ray tube, so it seems that absorption experiments have an advantage in this respect. An excellent and

* National Research Fellow.

complete presentation of the researches on the influence of chemical combination on the x-ray absorption and the x-ray emission spectra of an atom has been given by A. E. Lindh.¹ However, because of the complexity of the results, no unified picture of the work can be as yet formed.

There are two general questions, probably more or less related regarding absorption spectra to be considered. What are the factors which govern the position of the main edge; and, what is the origin or interpretation of the secondary absorption structure? The suggestions regarding the first question, as given by Wentzel, Coster, Stelling, Aoyama, Kimura and Nishina, are summarized by A. E. Lindh.¹ The latest work is that of Pauling² who was able to calculate quantitatively the shifts in the position of the *K* absorption edge in the alkali chloride series and in the potassium halide series. The answer to the second question as given by Coster,³ Lindsay,⁴ Ray,⁵ and others, has been in terms of the simultaneous transitions of two or more electrons within the atom, due to the absorption of a single quantum. This suggestion does not give any idea as to why secondary absorption is a function of chemi-

Fig. 1. (a) Simple edge. (b) Edge with secondary absorption.

cal state, though Coster and Wolf⁶ have postulated that multiple jumps will be less probable in an atom which has completed electron shells. On the side of emission spectra, the suggestion of F. K. Richtmyer⁷ of simultaneous transitions of electrons to account for x-ray satellites seems to be the most acceptable at present in view of the recent experiments of Du Mond and Hoyt.^{8,9} This fact no doubt makes the same hypothesis more probable as an explanation of secondary absorption. The writer simply wishes to bring out here that with the present knowledge regarding secondary absorption one can not make much use of the experimental data, whereas, because of its pene-

trating power, it seems that the x-ray has the possibility of giving interesting information about the atom in the solid state. It was thought that a study of the x-ray absorption of vapors, where one is concerned with isolated atoms or molecules, would be of help to the problem.

APPARATUS

In order to study absorption in vapors one must have a cell which will transmit the radiation, which will stand the requisite temperature to secure sufficient vapor pressure, and which will not react with the hot vapors. One is practically limited to a study of those vapors which have their characteristic x-ray absorption in the region from about one to two and one-half angstroms, since at shorter wave-lengths the energy dispersion becomes too small, and at longer wave-lengths nothing can be found to use for a cell. Fig. 2 shows the arrangement which was used. *S* is the slit, *C* is the calcite crystal, and *P* is the photographic plate. The furnace *B* is for controlling the vapor pressure, and the furnace *A* is for superheating the vapor. The furnace box is

Fig. 2. Diagram of x-ray spectrograph.

made of transite. The vapor cell *V* is made of Pyrex or of quartz, and the concave windows *W* may be drawn as thin as 0.005 mm in Pyrex,¹⁰ and to 0.003 mm in quartz, and yet maintain a vacuum and stand temperatures to the melting points. In order to prevent any vapor condensation on the windows *W*, the openings in the ends of furnace *A* were covered with three sheets of Al foil or mica with air spaces between the sheets. *H* is a glass tube with gold-beater's skin windows. The air is flushed out with hydrogen simply to reduce the air path of the radiation. The dispersion of this spectrograph in the region worked varies from 4.9 to 5.3 X.U. per mm. The usual slit width was 0.05 mm, though for special cases it was narrowed to 0.025 mm or widened to 0.1 mm. The x-ray tube was an extra large size of the Siegbahn type. The current was usually about 30 m.a., and exposure times varied from 4 to 30 hours depending on the absorbing material.

PREPARATION OF MATERIALS

The substances which were investigated in this work were As, Se, Br, Zn, Hg, Xe, and Kr, and compounds of some of these elements. When it was possible, each substance was studied in both solid and vapor forms. In the solid form the absorption spectrum was secured for various thicknesses of screen, while in the vapor state all degrees of absorption could easily be se-

¹⁰ Slack, J.O.S.A. 18, 123 (1929).

cured by regulating the vapor density through the temperature. After thorough cleaning and baking of the cell *V*, the material was inserted, and the cell sealed-off under high vacuum conditions. The cell was about 40 cm long. With this length of path a few cm pressure of vapor was usually sufficient to produce the maximum contrast in the absorption spectrum. The vapor was always superheated so that there would be no condensation on the ends of the tube. When studying Zn, the vapor was superheated to 950 degrees C, though all of the other vapors could be studied at temperatures much lower than this. Attention must be paid to the fact that polyatomic molecules dissociate at certain temperatures, so that this temperature must not be exceeded. The fact that the x-radiation itself decomposes some molecules did not cause any difficulty in this work since, for example with AsH_3 , the As atoms froze on the walls of the cell and left only AsH_3 in the path of the radiation.

In studying solids, if it is possible, the simplest method is to soak cigarette paper in a solution of the material and let it dry. A metal like Zn may be rolled to a thin sheet. Thin sheets of metallic As were formed by passing AsH_3 through a Pyrex tube heated to 500 degrees C. The AsH_3 decomposes, depositing a silvery mirror of As which can be peeled off of the tube. Because of its surface tension, it is hard to get a thin sheet of Hg. A screen of finely divided Hg was formed by reducing mercurous nitrate by formic acid held in gelatine. This gives an emulsion containing very densely packed mercury globules of about 10μ diameter.¹¹ The compound NaBrO_3 can not be had in the vapor form so it was studied as a solid and in solution. Solutions varying from saturated to $1/3$ normal were put in cells from 0.7 to 2.0 mm thick. These cells had thin mica windows.

EXPERIMENTAL RESULTS

Due to the character of secondary absorption, there has been no uniformity among different workers in the methods of recording measurements. The absorption regions may vary in width from the slit width of a few volts to as much as 40 volts. The tables in this paper record the distances of both sides of every absorption band, or the distance of the center of the absorption bands from the principal edge. The secondary discontinuities near to the principal edge are always sharper than those farther from the edge. This diffuseness of those farther out, makes it impossible to state their position to closer than about 10 volts.

B. B. Ray¹² has introduced two definitions which it will be convenient to use for purposes of classification and of discussion. Any absorption discontinuities which exist at energy distances from the principal edge of less than the ionization potential of the atom will be called "fine structure" while the term "secondary absorption" will be used to designate absorption discontinuities which occur at greater distances than this from the main edge.

An inspection of Table I shows the following facts: The secondary absorption of As in the solid and vapor states is radically different. AsCl_3 in the solid

¹¹ M. Wolf, *Zeits. f. Physik* 53, 72 (1929).

¹² B. B. Ray, *Ind. Journ. Phys.* 3, 477 (1929).

form shows an additional structure near the main edge which does not occur for the vapor. The same statement applies to the spectra of As_2O_3 in solid and in vapor form. AsH_3 shows no secondary structure. In the vapor state, the principal edges agree within the experimental error, while in the solid state there are differences as great as 5.2 ± 1.5 volts.

The results of the study of Br_2 and its compounds are uncertain in a few cases because one can not get rid of the effect due to the AgBr in the photographic plate. All of the solids and the NaBrO_3 solution show an extensive secondary absorption structure. A comparison of the NaBrO_3 solid and the solution shows the same type of additional structure which appeared in the solid As compounds here occurring for the solid NaBrO_3 . There are shifts in the positions of the main edges of as much as 6.9 ± 2.3 volts.

The positions of the main edges of the Se compounds were not determined. Se_8 vapor exhibits one very close fine structure line but no secondary absorption. Se solid has a white line absorption at the main edge and perhaps an indication of a fine line like that shown by the vapor. SeO_2 solid and vapor both show a secondary absorption, and, as in the cases of the As and Br compounds, there is an additional structure in the absorption spectrum of the solid which does not appear in that of the vapor.

* Faint absorption.

The upper temperature is the superheated vapor temperature, the lower is the temperature at which the vapor would be saturated.

No compounds of Zn were studied. The metal itself shows a very extended secondary absorption which is absent in the absorption spectrum of Zn vapor at 950°C. There is a very faint fine structure line at 5.8 volts from the main edge for Zn vapor. The data given on the secondary absorption of Zn are the results of observations on a number of different plates obtained under different conditions. Plates were taken using slit widths of 0.025, 0.05, and 0.1 mm. The fine structure close to the edge is just detectable with the narrowest slit, but with this slit the radiation is so faint that it would take too long a time to secure the secondary absorption farther from the edge. The $WL\beta_1$ line falls close to the K edge of Zn, so that some plates were taken using a Pt filament with a Mo, and also a Pt target to eliminate any uncertainties due to the presence of emission lines.

The K edge of Kr proves to be a simple edge without even a white line at the edge. The wave-length of the K edge of Kr is measured using $\text{SrK}\alpha_1$ (873.37 X.U.) as a reference line.

The L edges of Xe show no secondary absorption, but at the L_{III} and L_{II} edges there is a white line absorption which is 3.9 volts in width. The positions of the L_{III} , L_{II} , and L_I edges of Xe were measured from the $\text{WL}\beta_1$ (1279.17 X.U.), $\text{WL}\beta_2$ (1242.03 X.U.), and $\text{WL}\gamma_5$ (1129.2 X.U.) lines, respectively.

The data on mercury show that there is no secondary absorption for the liquid or the vapor, but there is for the Hg compounds. However, the structure is very faint and the values given are only approximate. The L_{II} edges of HgCl_2 solid and vapor also show a very faint secondary structure which has the same energy separations from the main edge as has that associated with the L_{III} edges. No secondary structure was found for any L_I edges. Noting the positions of the main edges, it is seen that HgCl_2 solid has the shortest, and HgO solid the longest wave-length. These edges can be determined to about 4 volts.

SUMMARY AND DISCUSSION

A consideration of the experimental results permits a number of generalizations to be made.

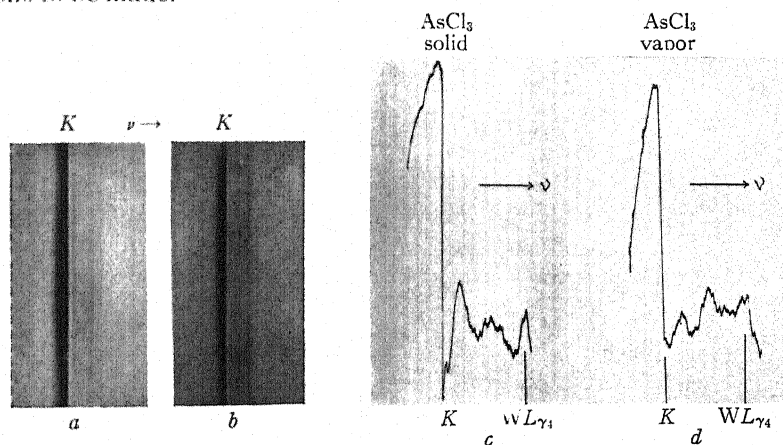

Fig. 3. AsCl_3 (a) solid; (b) vapor.

1. The secondary absorption of a polyatomic vapor usually has the same main characteristics as that of the solid, though the solid shows some additional structure, near the main edge, not found for the vapor. The examples of this are AsCl_3 , As_2O_3 , and SeO_2 . Fig. 3 shows the data for AsCl_3 . The microphotometer trace records clearly the dark line which splits the first white region, but it does not resolve the next dark region into the two close dark lines which can be seen on the original plate.*

* One may feel some assurance that statement No. 1. is a *bona fide* effect because of the fact that due to its perfect homogeneity the vapor makes as good, and probably a better absorbing screen for displaying secondary absorption than does the solid.

2. The Br secondary absorption shown by NaBrO_3 in the solid form has the same characteristics as that of NaBrO_3 in solution except that there is an additional structure near the main edge for the solid which is not observed for the solution. This same experiment has been performed by Meyer¹³ for both

Fig. 4. NaBrO_3 (a) solid; (b) vapor.

KBrO_3 and NaBrO_3 . He did not observe any additional structure in the absorption spectra for the solid state. Yost¹⁴ found no detectable difference in the K absorption of manganous and chromate ions in crystals and in aqueous solutions.

Fig. 5. As (a) solid; (b) vapor.

3. The secondary absorption of a polyatomic vapor may differ entirely from that of the solid. This effect is shown by As and illustrated in Fig. 5. As is tetraatomic in the vapor state.

¹³ H. Th. Meyer, *Wissenschaftliche Veröffentlichungen aus dem Siemens-Konzern* 7, 101 (1929).

¹⁴ D. M. Yost, *Phil. Mag.* 8, 845 (1929).

4. The secondary absorption of a compound may differ from that of the element. Every case investigated in this work corroborates this statement. Also, this effect is well known from previous work with the lighter elements, and has recently been shown by Lindh¹⁵ for Cu and Ni.

5. Secondary absorption is not observed for any monatomic vapor. Hg vapor, Zn vapor, Xe, and Kr are the examples of this; and one may also include Coster's and Van der Tuuk's¹⁶ case of argon. Xe and Kr were not studied in the solid form. Liquid Hg showed no secondary absorption, but Zn in the solid state exhibited the extensive structure shown in Fig. 6.

6. A monatomic vapor may show a fine structure a few volts from the main edge. Zn vapor has a faint absorption at 5.8 volts from the principal edge, though it is too faint to be seen in Fig. 6. Coster and Van der Tuuk found an absorption line for A at 1.7 volts from the main edge. They inter-

Fig. 6. Zn (a) solid; (b) vapor.

preted this as due to the transitions of the electron to different virtual orbits of the A atom, since the 1.7 volts coincides exactly with the resonance potential of K which is the next higher atom in the periodic table. The 5.8 volts for zinc does not coincide with the resonance potential of Ga, which is only 3.06 volts and would not be resolved. However, the ionization potential of Ga is 5.97 volts. This might mean that the electron stops either at the first virtual orbit, causing the main edge, or travels entirely out of the atom causing the fine structure line.

The L_{III} and L_{II} absorption edges of Xe showed a white line absorption at the main edges. The widths of these white lines were 3.9 volts. The short wavelengths edges were quite diffuse. Lepape and Dauvillier¹⁷ have studied Xe and found a white line absorption only at the L_{III} edge. The width of their

¹⁵ A. E. Lindh, *Zeits. f. Physik* **63**, 106 (1930).

¹⁶ Coster and Van der Tuuk, *Zeits. f. Physik* **37**, 367 (1926).

¹⁷ Lepape and Dauvillier, *Comp. Rend.* **177**, 34 (1923).

white line was about 13 volts which they related to the ionization potential of Xe. (11.5 volts). However, with the K electron absent, the outer field of Xe should compare with the next higher atom which is Cs, and which has an ionization potential of 3.88 volts. The reason for there being no white line absorption at the L_I edge may be that according to the selection rule $\Delta l = \pm 1$, transitions to the first virtual orbit could take place from the L_{III} and L_{II} orbits, but not from the L_I orbit. The absorption edges of Hg and of Kr were 'simple' without the white line at the edge. However, this may simply be because the energy dispersion in this wave-length region is from 70 to 90 volts per mm. while in the Xe L region it is 9.7 volts per mm.

7. Secondary absorption is not exhibited by all polyatomic vapors. Se_8 vapor and AsH_3 are two examples of this.

8. Completed shells of the atom in the solid state need not necessarily be associated with the absence of secondary absorption. The Br absorption in both AgBr (in the photographic plate) and NaBr shows a secondary structure. Meyer¹⁸ has reported that secondary absorption is absent for these compounds, and several people^{6,18} have remarked that secondary absorption will not be exhibited by atoms with completed shells such as Br^- .

The points at which the results of these experiments differ from those of other workers can be attributed to higher dispersion and better resolution. The resolution is such that the $WL\gamma_4$ line, which is measured in Siegbahn's laboratory as 1025.8 X.U., is here separated into two components 15 mm apart. This is 0.79 X.U. and gives 0.68 ν/R units or 9.25 volts for the separation of the O_{II} and O_{III} levels of W . The results of Meyer,¹⁸ for instance, that there is no structure in the K edge of Br in the photographic plate, and that the secondary absorption of NaBrO_3 solid and solution are identical, were gotten if the experiments were performed with an 18 cm radius Siegbahn spectrograph using a calcite 100 face (dispersion 16.6 X.U. per mm); or using a calcite 111 face (dispersion 7 X.U. per mm). This latter dispersion should be high enough to observe the additional structure but it is apparent from the pictures obtained that the 111 face does not allow the resolution which can be gotten with the 100 face.

It is not apparent as yet how successful the idea of multiple electron transitions will be in explaining the effects of physical and chemical state on secondary absorption. Several workers have quantitatively correlated the energies of the secondary discontinuities with the energies of certain chosen multiple electron jumps. In the table are shown the energies of *double* electron jumps simply calculated from the energy levels of the atom next higher in atomic number. There is an approximate agreement with at least one compound of each element. A more precise calculation such as that of Kievit and Lindsay¹⁹ was not attempted because the discontinuities here measured could not be located more accurately than about 10 volts unless the discontinuities were close to the main edge, where they are always sharper. It seems that if

¹⁸ R. Swinne, Phys. Zeits. 30, 523 (1929).

¹⁹ Kievit and Lindsay, Phys. Rev. 36, 648 (1930).

²⁰ G. Wentzel, Ann. d. Physik 66, 437 (1921); 73, 647 (1924).

secondary absorption is due to double electron transitions, then those discontinuities occurring more distant from the main edge represent transitions of electrons from deeper levels of the atom and so would be expected to be sharper, rather than more diffuse, than the discontinuities occurring close to the main edge and representing transitions of outer electrons.

The suggestion of transitions of electrons in multiply ionized atoms which has been made by Wentzel²¹ to account for x-ray satellites, and applied also to absorption spectra^{21, 22} does not seem suited to explain secondary absorption, because the number of quanta of radiation of sufficient energy for ionization which are produced by the x-ray tube is so small that the number of ionized atoms in the absorbing screen at any time is a negligible fraction of the total number present.

The data as it appears in this work would seem to favor the idea of relating the secondary absorption to some characteristic of the structure of the molecule or solid. One might suppose that the secondary edges correspond to the energies of excitation of the vibrational states of "structure electrons" such as postulated by O. W. Richardson²³ to account for the facts observed in experiments both on the secondary electron emission of substances and the soft-x-ray production of substances. The relation between the secondary absorption discontinuities and the kinks in the secondary electron curves can not be carried very far at present because the sensitivity is so much less for the x-ray secondary absorption determinations of energies. However, there are some points of similarity between the observations made in the study of x-ray absorption spectra, and in the study of secondary electron emission.

The kinks in the secondary electron curves correspond to the Bohr energy levels of the atom when the experiment is done roughly, but with increased sensitivity many more kinks are discovered which can not be related to the Bohr levels of the atom. The range in which these kinks occur is from zero to about 500 volts. Above this range one finds only kinks which agree with Bohr levels. These facts are exactly paralleled by the study of x-ray absorption spectra. Also, the present experiments indicate a close relation between the occurrence of secondary absorption and the structure of the substance. Turning to the study of secondary electron emission, it is found that the number and positions of the kinks which are not related to Bohr levels are functions of the structure of the substances which the primary electron beam bombards. For example, the kinks obtained using a polycrystalline substance seem to be the sum of those from the faces of a single crystal of the substance studied separately. (This is presumably not a diffraction phenomenon.) There are enough of these kinks so that Richardson was able to see that they could all be included in tables like sets of bands, and this fact led to the idea of relating them to the excitation energies of the vibration levels of some oscillating system.

An obvious experiment to check the validity of such an idea to account for

²¹ E. C. Stover, *Phil. Mag.* **2**, 97 (1926).

²² H. R. Robinson, *Phil. Mag.* **4**, 763 (1927).

²³ O. W. Richardson, *Roy. Soc. Proc. A* **128**, 63 (1930).

secondary absorption would be to study the absorption spectra of both elements of a chemical compound and see in how far the secondary absorption is a function of the individual elements and in how far a function of the compound. Satisfactory data for such a check do not exist at present.

In order to be certain that the absence of secondary absorption for zinc vapor at high temperature is not simply a temperature effect, experiments are now being carried out on the effect of high temperature on the secondary absorption exhibited by solids.

The writer wishes to express his warm appreciation for the excellent and ample facilities for research which have been available at the Department of Physics of the University of Michigan. He is particularly indebted to Professor G. A. Lindsay for much helpful advice, and to Mr. G. Kessler for his part in the difficult task of making the thin quartz windows.

INFRARED ABSORPTION BANDS IN HYDROGEN SULPHIDE

BY HAROLD H. NIELSEN AND ERNEST F. BARKER
DEPARTMENT OF PHYSICS, UNIVERSITY OF MICHIGAN

(Received January 30, 1931)

ABSTRACT

Absorption spectrum of H_2S in the region from 1.0μ to 10.0μ .—The absorption spectrum of hydrogen sulphide in the infrared has been investigated with a prism spectrometer from 1.0μ to 10.0μ . Two regions of absorption, one at 2.6μ and another 3.7μ were located, both of which revealed fine structure when examined under high dispersion.

Structure of the 2.6μ absorption band of H_2S .—The band at 2.6μ was found to consist of P , Q , and R branches, the P and R branches being made up of somewhat irregularly spaced lines and the Q branch broadened unsymmetrically, sloping off more steeply toward lower frequencies. The separation between the most prominent lines in the P and R branches was found to be about 10 cm^{-1} . A slight convergence was observed toward higher frequencies.

Structure of the 3.7μ absorption band of H_2S .—The 3.7μ band was found to consist of but one branch, made up of several prominent lines with weaker satellites on either side. The average spacing between these is about 9.0 cm^{-1} , and no convergence was discernable.

Qualitative quantum mechanical discussion of structure of absorption bands of H_2S .—Only a qualitative discussion of the structure of the observed bands is given, based on the classical quantum mechanical solution of an asymmetric rotator due to Witmer. The band at 2.6μ is accounted for by a vibration of the electric moment along the least axis of inertia while the band at 3.7μ is shown to arise from a vibration along the intermediate axis. It is pointed out that the rigorous quantum mechanical solutions of asymmetric rotators confirm the conclusions drawn herein and in addition satisfactorily explain the broadening of the Q branch.

RECENT quantum mechanical studies of asymmetric rotators¹ have emphasized the importance of investigating the vibration rotation spectra of molecules belonging to this class. The water-vapor absorption bands measured by W. W. Sleator² and again by Sleator and Phelps³ are characteristic of this kind, and they have suggested that a study of the infrared spectrum of hydrogen sulphide might prove fruitful.

W. W. Coblentz⁴ has mapped the spectrum of hydrogen sulphide in the region from 3μ to 12μ with a prism spectrometer. More recently A. H. Rollefson⁵ has published two bands in hydrogen sulphide at 4.2μ and 8.0μ . In the present work an absorption cell forty centimeters long with mica windows was used, and the spectrum carefully remapped from 1.0μ to 10.0μ with a Wadsworth type prism spectrometer. It was, however, impossible to dupli-

cate any of the bands previously reported, but two other absorption maxima were located, lying at 2.6μ and 3.7μ . The prism curve of the absorption spectrum of hydrogen sulphide as determined in this investigation is shown in Fig. 1 A. The maximum near 4μ reported by Coblentz and Rollefson was found in the first trial, but upon careful purification of the gas it disappeared and almost certainly is to be ascribed to carbon dioxide as an impurity. Likewise in another series of observations when a cell with rock salt windows was used, the band reported by Rollefson at 8.0μ was found. In all other trials, mica windows were used and although this spectral region was carefully searched, the 8μ band could not be found. It appears that this band can not be due to the hydrogen sulphide molecule, for on all occasions before searching for it, the presence of the absorption maxima at 2.6μ and 3.7μ was first confirmed. It is suggested that the 8.0μ band may be characteristic of some substance formed by the interaction of hydrogen sulphide with the rock salt windows.

Fig. 1. Absorption bands in hydrogen sulphide. A, Prism curve with low dispersion. B, Fine structure in the band at 2.6μ . C, Fine structure in the band at 3.7μ .

A prism grating spectrometer designed by C. F. Meyer was available for further investigation of the hydrogen sulphide spectrum under high dispersion. The apparatus was equipped with a vacuum thermopile constructed by Meyer and was used in conjunction with a Moll thermal relay and a Leeds and Northrup high sensitivity galvanometer. This gave a sensitivity sufficiently high to make the use of slit widths of 16 angstrom units feasible. The grating used in both regions was one with a spacing of 7200 lines per inch (2834 lines per centimeter) ruled on a copper-nickel surface. The calibration of this grating was obtained from a table prepared by A. A. Levin for this spectrometer, based upon the positions of the -3 and -4 lines of hydrogen chloride determined by Colby, Meyer and Bronk.⁶

Two lengths of absorption cell were used, the H_2S being at atmospheric

⁶ Colby, Meyer and Bronk, *Astrophys. J.* 57, 7 (1923).

pressure in each. For the band at 2.6μ , a length of ten centimeters was found most advantageous. This cell was double, one side being filled with dried air to compensate for the water-vapor absorption in the atmosphere. At 3.7μ a cell twenty five centimeters long was used. Compensating windows were not necessary here since the diminution of the energy due to the mica could satisfactorily be taken into account by making a preliminary run with the cell empty, and no atmospheric absorption occurs in this region.

The hydrogen sulphide gas was obtained in ordinary lecture bottles from the Matheson Company, their analysis showing a purity of 99.7 percent. In order to remove any carbon dioxide, carbon disulphide and hydrogen chloride,

the gas was passed through three successive wash bottles each of which contained a solution of potassium hydrosulphide (KHS). After drying over phosphorus pentoxide, the gas was gathered by freezing with liquid air and finally purified by partial distillation. This was done immediately before each run.

The two absorption maxima which had been located prismatically, reveal fine structure when examined under high dispersion. They are distinctly different in type, but are both characterized by an irregularity of structure suggestive of water vapor bands. When only the most intense lines are considered however, the patterns resemble the bands due to certain symmetrical molecules.

The 2.6 μ region. The 2.6 μ band shows distinct *P*, *Q* and *R* branches, the *P* and *R* branches being made up of irregularly spaced lines. The average spacing for those of greatest intensity is about 10 cm⁻¹. Moreover, proceeding from the center outward it seems possible to identify the various lines in the *P* branch with corresponding lines in the *R* branch. A slight convergence is noticeable toward higher frequencies, and the *Q* branch is broadened unsymmetrically, sloping off more steeply toward lower frequencies. Curve B shows those details of this band which repeated themselves in the many sets of data taken. Original circle settings have been replaced for convenience by a scale of frequencies, and in Table I the frequencies and approximate relative intensities of the lines are given.

TABLE II. Wave numbers and intensities of lines in the band at 3.7 μ .

1.0	2687.8		.8	2746.7	

The 3.7 μ region. The 3.7 μ band is of the type which shows an envelope with but one maximum. It also has been resolved, at least partially, revealing a number of prominent lines, characterized in general by accompanying satellites of lesser intensity on either side. No apparent convergence is discernible and the most prominent lines are separated by an average spacing of about 9.0 cm⁻¹. Details repeating themselves in all sets of data are shown in curve C where as before a frequency scale replaces the original circle settings. Table II gives the frequencies and relative intensities of the lines measured in this region.

INTERPRETATION OF THE OBSERVED BANDS

It is hoped in a later communication to give a complete description of this spectrum in terms of the rigorous quantum mechanics of an asymmetrical

rotator model. At present, it seems better, however, to consider qualitatively only the general characteristics of the two observed bands.

A solution for the asymmetrical rotator by a perturbation method is given by E. E. Witmer⁷ in the classical quantum mechanics where the perturbation function involves the third moment of inertia. Taking A , B , and C as the three principal moments of inertia where $A < B < C$, the energy levels are shown to be of two kinds, A -levels arising when the molecule rotates principally about the least axis of inertia, and C -levels, arising when the molecule rotates principally about the largest axis of inertia; their combined number being $J+1$. The energy values of A -levels are those of a symmetric rotator rotating about the A -axis plus a certain perturbation component to the energy involving C . The C -levels are similarly determined by the energy expression of a symmetric top rotating about the C -axis plus another perturbation component involving A .

Hund⁸ and Dennison⁹ have shown that isosceles triatomic molecules have three fundamental modes of vibration, two of which are along the bisector of the apex angle, and a third perpendicular to this. If the three absorption bands corresponding to these three vibrations can be observed, the dimensions of the triangle (i.e., the apex angle and the lengths of the sides) may be calculated, from which the three moments of inertia may in turn be determined. In hydrogen sulphide only two bands have been observed, however; hence this means of determining the shape and moments of inertia is not available. The indeterminacy of the shape of the molecule introduces the further limitation that one can not know whether the bisector of the apex angle will be the least or the intermediate axis of inertia, since this depends upon the magnitude of the angle. Consequently the appearance of the third fundamental, were it observable, cannot be predicted, for if the bisector of the apex angle were the least axis of inertia, there would be two identical bands of one kind, while if it is the intermediate axis of inertia there would be two identical bands of the other type.

In hydrogen sulphide the electric moment vibrates in the plane of the three atoms, i.e., along either the A -axis or the B -axis. When the electric moment changes along A , and the rotation is principally about the same axis, quantum transitions occur among the A -levels governed by the rules (retaining the nomenclature of the symmetric rotator) $\Delta J = \pm 1, 0; \Delta K = 0$. When, however, the rotation is principally about C , quantum transitions occur among the C -levels and are determined by the rules, $\Delta J = \pm 1, 0; \Delta K = \pm 1$. This gives rise to a band having P , Q and R branches, the P and R branches originating from the transitions $\Delta J = \pm 1, 0; \Delta K = \pm 1$; and $\Delta J = \pm 1, \Delta K = 0$; and the Q branches from $\Delta J = 0, \Delta K = 0$. The band observed at 2.6μ having distinct, P , Q and R branches, is consequently due to a vibration of the electric moment along the least axis of inertia; i.e., the A -axis.

Vibrations of the electric moment along the B axis are perpendicular to

⁷ Witmer, Proc. Nat. Acad. 12, 602 (1926).

⁸ Hund, Zeits. f. Physik 31, 81 (1925).

⁹ Dennison, Phil. Mag. 1, 195 (1926).

rotations about both the A and C -axis, hence quantum transitions among both A and C -levels must be governed by the selection rules $\Delta J = \pm 1, 0$; $\Delta K = \pm 1$ alone. It may easily be seen that the resulting band is of the type observed at 3.7μ with no Q -branch. The regularity in spacing and intensity of the lines of bands of symmetric rotators is due to the fact that many transitions are over the same frequency range giving rise to lines which are precisely superposed. In the case of asymmetric rotators the positions of successive energy levels are altered by the asymmetry, but with no definite order; hence no regularity of line structure is here to be expected since only rarely do two or more lines fall at the same place.

The general characteristics are borne out also in the rigorous quantum mechanical solutions of the asymmetric rotator given by Kramers and Ittman and by Wang. One of the main differences is the splitting up of the $J+1$ levels of the old theory into $2J+1$ levels on the basis of the new. The magnitude of this doubling as given by Wang is:

$$\Delta\nu = \left\{ \frac{1}{2} \frac{\left(\frac{1}{C} - \frac{1}{B} \right)}{\frac{1}{A} - \frac{1}{2} \left(\frac{1}{C} + \frac{1}{B} \right)} \right\}^K \left\{ \frac{h \left[\frac{1}{A} - \frac{1}{2} \left(\frac{1}{C} + \frac{1}{B} \right) (J+K)! \right]}{2^{3K} \pi^2 (J-K)! (K-1)!^2} \right\}$$

This is seen to be small when K is small and the rotation is almost entirely about either A or C , but becomes large for those levels which mark the transition from rotation principally about one axis to rotation principally about the other. It is this doubling of the levels that accounts for the broadening of the Q branch. In the symmetric rotator, the Q branch arises from transitions from a rotational level in one vibrational state to the corresponding rotational level in another vibrational state. In the asymmetric case each rotational level save one is a doublet, and transitions now occur from the one doublet component of such rotational levels in one vibrational state to the other doublet component of the corresponding rotational level in another vibrational state. The Q branch thus arising is not a sharp maximum, but consists of many lines near the center of the band.

The kind cooperation and support given to this work by Professor H. M. Randall, and Professor D. M. Dennison's many helpful suggestions in the interpretation of these bands are gratefully acknowledged.

NOTE ON THE INTERPRETATION OF CERTAIN ${}^2\Delta$, ${}^2\Pi$ BANDS OF SiH

BY ROBERT S. MULLIKEN

RYERSON PHYSICAL LABORATORY, UNIVERSITY OF CHICAGO

(Received February 4, 1931)

ABSTRACT

It is shown that Jackson's ${}^2\Delta$, ${}^2\Pi$ SiH bands have a *regular* ${}^2\Pi$ state and thus are closely analogous to the $\lambda 4300$ bands of CH. The orbit-spin coupling coefficient A is determined for the ${}^2\Pi$ state of SiH and shown to agree closely with A of the 2P state of the Si atom, from which the ${}^2\Pi$ molecular state is supposed to be derived. This is a new example of a relation which seems to be universal. Another new example of the same relation, found in BeH, is also cited.—The coefficients A and B of the ${}^2\Delta$ state and B of the ${}^2\Pi$ state of SiH are also discussed.

C. V. JACKSON has obtained some SiH bands near $\lambda 4100$ and has shown by a skilful analysis that they have a structure corresponding to a ${}^2\Delta$, ${}^2\Pi$ transition.¹ Because of the analogy of Si to C, there is a very strong presumption that these bands are analogous to the ${}^2\Delta$, ${}^2\Pi$ bands of CH near $\lambda 4300$. In the case of CH the ${}^2\Delta$ doublet is very narrow and inverted ($A/B \sim -0.07$, $B = 14.57$), while the ${}^2\Pi$ is regular ($A/B = +2.0$, $B = 14.2$). According to Jackson, the ${}^2\Delta$ state of SiH is narrow and *regular*, but the ${}^2\Pi$ *inverted*, with $A/B \sim -10$, $B = 7.4$. From a consideration of electron configurations, however, it is clear that if the ${}^2\Pi$ state of SiH is inverted it cannot be at all analogous to that of CH, since in such simple molecules² an inverted Π state implies a group of three equivalent π electrons, whereas a regular Π state implies only a single π electron outside of closed shells. In the case of the ${}^2\Delta$ state, however, the existence of a reversed sign of A in SiH, while rather unexpected, has no such important implications. For the ${}^2\Delta$ state of CH is attributed to an electron configuration $\cdots \sigma\pi^2$, in which the small observed doubling can be ascribed to the small interaction of the spin of the σ electron with the orbital angular momenta of the two π electrons.³ In similar cases in atomic spectra, we know that doublets of this kind may be either regular or inverted.

A study of Jackson's analysis shows that, while the fact that the ${}^2\Delta$ is regular is incontrovertible, the only evidence that the ${}^2\Pi$ is inverted comes from an application of Van Vleck's theoretical work³ on Λ -type doubling. [The question whether a given ${}^2\Pi$ level is regular or inverted can in general also be decided by determining the lowest J value in each of the two sets of levels supposed to be ${}^2\Pi_{1/2}$ and ${}^2\Pi_{1/2}$, but this method could not be used in the present instance because of the complexity of the band and the weakness of the lines having low J values.] Van Vleck's theory demands that in case *a* the Λ -type

¹ C. V. Jackson, Proc. Roy. Soc. 126A, 373 (1930).

² R. S. Mulliken, Phys. Rev. 33, 730 (1929).

³ J. H. Van Vleck, Phys. Rev. 33, 496-7 (1929).

doublets shall be much wider in the ${}^2\Pi_{1/2}$ than in the ${}^2\Pi_{1/2}$ levels, and if we assume case *a*, this criterion applied to the experimental data indicates an inverted ${}^2\Pi$. This was the basis of Jackson's conclusions.

But, as is mentioned in another forthcoming paper,⁴ we have in the ${}^2\Pi$ of SiH a state which is case *a* for the lowest *J* values but goes over to case *b* with increasing *J*. In such a case the ${}^2\Pi_{1/2}$ Λ -type doublets, although they should at first be wider than those for ${}^2\Pi_{1/2}$, should soon get narrower again and their widths should pass through zero, while the ${}^2\Pi_{1/2}$ doublets should begin to widen rapidly under the influence of the approach to case *b*.³ This would give on the whole wider doublets for ${}^2\Pi_{1/2}$ than for ${}^2\Pi_{1/2}$, and would require that we reverse Jackson's conclusions and interpret the ${}^2\Pi$ state as regular. In order to prove that this interpretation is correct we should show that the Λ -type doublets change sign with increasing *J* in what is here considered to be the ${}^2\Pi_{1/2}$ state (Jackson's ${}^2\Pi_{1/2}$ state). Now according to Jackson, the levels which we call ${}^2\Pi_{1/2}$ show measurable doubling only beginning with *K* = 14, while in the ${}^2\Pi_{1/2}$ levels doubling becomes appreciable at *K* = 8. But Jackson remarks that lines going to the levels *K* = 5 and 6 of ${}^2\Pi_{1/2}$ also show a doubling, which he classifies as a perturbation. If, however, we suppose that the Λ -type doubling in the ${}^2\Pi_{1/2}$ state first increases to a maximum, which is just large enough to be measurable, at *K* = 5 or 6, then decreases again, passes through zero at about *K* = 11 or 12, and again increases with opposite sign until at *K* = 14 it is again large enough to be detected experimentally, all the observed relations are explained, and we have surely a regular ${}^2\Pi$ state. Table I, based on Jackson's Table VIII, gives the values of the Λ -type doublet separations.

TABLE I. Λ -type doublet widths (cm^{-1}) in ${}^2\Pi$ state of SiH.*

<i>K</i>	${}^2\Pi_{1/2}$	${}^2\Pi_{1/2}$	<i>K</i>	${}^2\Pi_{1/2}$	${}^2\Pi_{1/2}$	<i>K</i>	${}^2\Pi_{1/2}$	${}^2\Pi_{1/2}$
4	—	—	9	—	0.66	14	0.33	1.61
5	-0.30	—	10	—	0.80	15	0.60	1.91
6	-0.27	—	11	—	0.99	16	0.84	2.12
7	—	—	12	—	1.0	17	0.99	2.42
8	—	0.38	13	—	1.35	18	1.32	—

* Most of these values are weighted averages of values obtained from *P*, *Q*, and *R* branches as given by Jackson in his Table VIII. The negative signs for the low numbered *K* values of ${}^2\Pi_{1/2}$ and the positive signs for all other values are of only relative significance here, and furthermore are based only on the fact that according to Van Vleck's theory, the sign of the doubling should be the same in case *b* (high *K* values) for ${}^2\Pi_{1/2}$ as for ${}^2\Pi_{1/2}$. Empirically there is no way of deciding, from data on Δ , Π bands, whether the T_a or the T_b levels of the Π state are higher. (In the case of a Π , Σ transition this *can* be decided empirically).

Thus we have a regular ${}^2\Delta$ and a regular ${}^2\Pi$ state in SiH, and there is every reason to believe that these are analogous to the similar states of CH. It is of interest to determine the magnitudes of the coefficients *A* of the coupling between Λ and *S* for the two states of SiH. The value of *A/B* for the ${}^2\Pi$ state can be estimated most accurately by fitting Hill and Van Vleck's formula⁵ for the general intermediate case between cases *a* and *b* to the data on

⁴ R. S. Mulliken and A. Christy, forthcoming Phys. Rev.

⁵ E. L. Hill and J. H. Vleck, Phys. Rev. **32**, 250 (1928).

the term *differences* between ${}^2\Pi_{1/2}$ and ${}^2\Pi_{1/2}$ states of the same K values (cf. Jackson's Table IX). This and a further use of Jackson's data on ΔF 's in order to determine B more accurately, give $A/B = +19.5$ and $B = 7.35$.⁶ [$A/B = -15.5$ would do equally well if we did not know from Van Vleck's theory of Λ -type doubling that $A > 0$.] In a similar way one obtains for the ${}^2\Delta$ state the values $A/B = +0.6$ and $B = 7.3$ [$A/B = +3.4$ would equally well explain the observed spectrum, but since we expect a very small A for a $\sigma\pi^2$ ${}^2\Delta$ state, and since $A/B \sim -0.07$ is very small in ${}^2\Delta$ of CH, the value $A/B = +0.6$ is the more probable].

We thus have $A = +4$ for the ${}^2\Delta$ state and $A = +143$ for the ${}^2\Pi$ state, which may be compared with the values $A = -1$ and $A = +28$ for the corresponding states of CH. In the case of CH there is an interesting relation between A in the ${}^2\Pi$ state of the molecule and A in the 3P state of the carbon atom from which the ${}^2\Pi$ of CH is supposed to be derived by the addition of a hydrogen atom.² For a $\dots p^2 {}^3P$ atomic state, we know that for normal coupling the over-all width of the triplet, i.e., ${}^3P_2 - {}^3P_0$, is $1\frac{1}{2}A$. For the normal state of carbon, ${}^3P_2 - {}^3P_0 = 42 \text{ cm}^{-1}$, giving $A = +28$ in exact agreement with A as obtained from the ${}^2\Pi$ state of CH. [Similar, although usually less exact, agreements are found in many other hydrides. Usually the A from the molecule is somewhat *less* than that from the atom.²] A similar comparison is of interest for the normal 3P of the silicon atom and the ${}^2\Pi$ of SiH. For the atom, ${}^3P_2 - {}^3P_0 = 223$, giving $A = +149$, in excellent agreement with the value $A = +143$ from SiH. The significance of such agreements has been discussed in a previous paper.²

In connection with the comparison of A values of atoms and their hydrides, a recent result of Watson and Parker⁷ is of interest. These authors find $A = +1.97$ for the presumably $1s\sigma^2 2s\sigma^2 2p\pi$, ${}^2\Pi$ state of BeH, which agrees well with the value $A = +2.08$ from the triplet separation (${}^3P_2 - {}^3P_0$, $\Delta\nu = 3.12$) of the $1s^2 2s 2p$, 3P state of the Be atom.

⁶ No attempt has been made to obtain very accurate values of A and B , but it is believed that the A value of the ${}^2\Pi$ state is fairly accurate, the calculations having been made by means of the Hill and Van Vleck formula in such a way as to make the best use of the experimental data.

COLLISIONS OF THE SECOND KIND AND THEIR EFFECT ON
THE FIELD IN THE POSITIVE COLUMN OF A GLOW
DISCHARGE IN MIXTURES OF THE RARE GASESBY L. B. HEADRICK AND O. S. DUFFENDACK
UNIVERSITY OF MICHIGAN

(Received January 24, 1931)

ABSTRACT

A study was made of the collision processes in the uniform positive column of a glow discharge in mixtures composed of two of the rare gases, helium, neon and argon and a mixture of each of these gases with mercury vapor, by means of measurements of the electric field and by spectroscopic observations. The discharge tube was of cylindrical form, 4.4 cm in diameter, with plane parallel electrodes. The electrode distance could be varied from zero to 32 cm by means of an external electromagnet. The phenomena were studied with currents from 20 to 40 m.a. and pressures from 5 to 30 mm of mercury. The mixtures were circulated through the discharge tube and a purifying system during the entire time that observations were being made. It was very important to maintain extreme purity of the gases. The results show that the electrical and spectral characteristics of the uniform positive column in mixtures of monatomic gases can be explained principally in terms of collisions of the second kind between the ions or metastable atoms of one gas and the neutral atoms of the other. The effect of limitation of electron velocities is insufficient to explain the results, and its effect is shown to be negligible as compared with collisions of the second kind when the concentration of one gas is very small. The necessary condition for a large effect to be produced in the electrical and spectral characteristics of the positive column by a small percentage of one gas added to another is that a close resonance exists between the metastable states of the main gas and the ionization potential or excited states of the added gas atom or ion. By the introduction of as little as 0.4 percent neon or argon into helium, a marked increase in the electric field is produced, and the spectrum emitted is changed almost completely from the arc spectrum of helium to that of neon or argon respectively. The addition of mercury vapor at room temperature to neon caused a decrease of 45 percent in the field while the addition of mercury to either argon or helium produced a small increase. In the cases where the excitation and ionization potentials of the added gas were above the metastable states of the main gas, no reactions between the two gases could occur to affect the concentration of metastable atoms. In these cases practically no change in either the spectral or electrical characteristics were observed upon adding a small amount of one gas to another. However, in larger proportions the change produced in the field was proportional to the amounts of the two gases and the difference between the field in each of the pure gases. This result is accounted for mainly by the difference in the energy of the ionization processes in the two gases by electron impact.

INTRODUCTION

THE phenomena occurring when electricity passes through a gas are many and complicated. The various phenomena have been the subject of many investigations and a great deal is known about the electrical and spectral characteristics of the different types of electrical discharges. Until the development of the Bohr theory of the atom, the beginning of the classification of spectroscopic data, and the measurements of critical potentials by means of

electrons of controlled velocity, very little was known about the mechanism of the elementary processes involved in the discharge of electricity through gases. With the information obtained from the classification of spectroscopic data, the spectroscopic study coupled with measurements of the electrical characteristics of a discharge gives a very powerful means of studying the elementary processes taking place. This method has been used by the writers to study the collision phenomena occurring in the positive column of a glow discharge in mixtures of the rare gases.

Klein and Rosseland¹ suggested that since a collision between an electron and a molecule may result in the excitation of the molecule, due to its absorption of the kinetic energy of the moving electron, the reverse of this process should also take place; that is, the change of excitation energy of a molecule to kinetic energy of an electron at a collision between an excited atom and a slowly moving electron. This type of collision is called a collision of the *second kind*. The former process is called a collision of the *first kind*. Franck² has shown that the theory of Klein and Rosseland may be extended to include impacts of the second kind between excited atoms and neutral atoms.

Nearly all gases, unless very carefully purified, contain small amounts of other gases as impurities. It has been observed from spectroscopic studies that, in certain regions of a discharge and for certain gases as impurities, the spectra of the impurities were often stronger than that of the main gas. These observations led to spectroscopic investigations of discharges in mixtures of gases.

Duffendack^{3,4,5,6} and a number of his pupils have made spectroscopic studies on the excitation in a low voltage arc in mixtures of the rare gases with nitrogen, carbon monoxide, and various metal vapors in a tungsten furnace. The limits and maxima of excitation observed were explained on the basis of collisions of the second kind between the excited atoms or rare gas ions and the neutral gas or metal molecules.

Sawyer,⁷ Takahashi,⁸ Naudé,⁹ Kruger,¹⁰ Frerichs¹¹ and others have used the hollow cathode discharge with the rare gases to excite the spectra of various metals and have explained the observed maxima and limits of excitation on the basis of collisions of the second kind.

Penning^{12,13} has shown that certain phenomena regarding the sparking potentials of mixtures of the rare gases and also other gases can be explained by means of collisions of the second kind.

In the present investigation the study of the effect of collisions of the second kind on discharge characteristics has been extended to the positive column of a glow discharge. Mixtures of the three rare gases, helium, neon and argon and mixtures of each of these with mercury vapor were used. The study of collision phenomena and the processes of production of ions was made by observing simultaneously the changes in excitation and in the electric field in the positive column with the change in the proportion of the two gases in a mixture.

THEORY OF THE UNIFORM POSITIVE COLUMN

The phenomena occurring in the positive column are independent of the material and form of the electrodes and depend only on the properties of the gas, the current density, and the tube diameter. For pure monatomic gases the positive column is uniform under almost all conditions. In diatomic gases or in mixtures, for certain limits of current and pressure, the positive column is striated. The electric field in the uniform positive column is uniform. In the striated positive column a slight sinusoidal variation is superimposed upon the uniform field. This variation has a wave-length equal to the distance between striations. The field reaches a maximum value at the cathode end of the luminous region of each striation. The theory of the uniform positive column will be discussed in detail since practically all of the work in this investigation was done with a uniform column. While most of the data on this part of the discharge are qualitative, some approximate empirical relations have been worked out for a considerable range of the variables. For a tube of cylindrical form, the field is directly proportional to the pressure and inversely proportional to the radius of the discharge tube. At a small current density, for which the positive column does not completely fill the tube, the field increases with an increase in current. The field reaches a maximum value when the column just fills the tube and then decreases slowly until the current density reaches a high value, corresponding to nearly one hundred percent ionization of the gas, after which the field increases quite sharply and rapidly with further increase in current. This condition of practically complete ionization has never been attained in large discharge tubes. It has been studied by Langmuir¹⁴ in capillary tubes with a current density of the order of 40 amp/cm².

Schottky¹⁵ has made a study of diffusion currents to the tube walls in the positive column and has developed a theory on the basis of the results obtained. The assumptions made for a cylindrical discharge tube are the following:

- (1) The field in the positive column is the source of the energy necessary to maintain a certain degree of ionization which is required for a given discharge condition.
- (2) Ions are lost by diffusion to the walls where recombination occurs.
- (3) The current density and concentration of positive ions and electrons is constant throughout the length of the column.
- (4) The

radial component of the positive ion current is equal to the radial component of the electron current. (5) The concentration of positive ions and electrons is zero at the walls and reaches a maximum at the tube axis. (6) The dimensions of the tube are large compared to the mean free path of the molecules. (7) Sufficient collisions occur to give both the positive ions and electrons a Maxwellian distribution of velocity.

The equation obtained from these assumptions without the use of Poisson's equation is given below.

$$G = \frac{2.4}{R} \left(\frac{V_i}{H} (B^+ + B^-) \frac{K^+ \cdot K^-}{(K^+ + K^-)^2} \right)^{1/2}$$

Where G is electric field in volts per cm; R is tube radius in cm; V_i is ionization potential of the gas in volts; H is an efficiency factor of ionization; B^+ is energy of random motion of positive ions in volts; B^- is energy of random motion of negative ions in volts; K^+ is mobility of positive ions; and K^- is mobility of negative ions.

This expression for the dependence of the field on the tube radius checks the empirical relation. The field will however not be equal to zero for R increased indefinitely but will reach a minimum value. The above form of the equations results from the assumption that ions are lost only by diffusion to the tube walls and therefore does not hold for large values of R where recombination in the body of the gas becomes important. This theory does not give the dependence of the field on current density or on pressure.

Morse¹⁶ has developed an equation for the electric field in the positive column, giving its dependence on both the tube radius and the pressure, but not on the current density. He assumes that the relations for mobility and average number of ions produced by an electron under given conditions are known and uses the results of Schottky to determine the diffusion currents to the tube walls. The calculations are based on three general differential equations which represent the conditions for a stable discharge in a tube of unit cross section. The following result is obtained.

$$E = 5.76eV_r \frac{Gp}{r}$$

Where E is field in the positive column in volts/cm; G is a constant inversely proportional to the mobilities of positive ions and electrons; p is gas pressure in mm of mercury; r is tube radius in cm; and V_r is ionization potential of the gas, or if metastable states are formed, the first critical potential.

The value of the field given by this equation satisfied the empirical relation for its dependence on both the tube radius and the pressure, but still leaves the dependence on current density to be explained qualitatively. The field increases with the current for small current densities where an increase in current increases the diffusion to the tube walls, but the field decreases slowly for large current densities where the increase in current decreases the

percent of diffusion to the tube walls. In order to obtain an expression for the field as a function of the current it would be necessary to determine the diffusion current to the tube walls as a function of the current density in the tube.

APPARATUS

A detailed diagram of the entire vacuum system is shown in Fig. 1. *R* represents the gas storage reservoirs, *P* the gas purifying tubes, *D* diffusion pumps, *G* the McLeod gauge and *T* a Toepler pump. Fig. 2 shows a drawing of the discharge tube and a diagram of the electrical circuit used.

PURIFICATION OF THE GASES

Since the results of this investigation depended largely on the purity of the gases used, each gas was very carefully purified before being admitted to the discharge tube. The helium, free from neon, was obtained from the Ohio Chemical Company in a steel bomb under high pressure and was purified by circulating it with a Toepler pump through a charcoal trap immersed in liquid air. The pure gas was stored at a little less than atmospheric pressure in a liter glass reservoir which had been well baked and evacuated.

The neon, of spectroscopic purity, was obtained from Linde Air Products Co., Buffalo, N. Y., in liter glass bulbs. It was further purified in the same manner as described above for helium and stored in a liter glass reservoir. In most cases both of these gases were purified again just before being admitted to the tube by circulating slowly through charcoal in liquid air for about one hour. However, no difference could be found by spectroscopic means or by changes in the electrical characteristics of the discharge when the gases were admitted to the tube directly from the storage reservoirs.
